<tr>
<td>LOLER</td>
<td>Lifting Operations and Lifting Equipment Regulations 1998, as amended</td>
</tr>
<tr>
<td>L.E.L</td>
<td>Lower Explosive Limit, the lowest concentration of a specified gas in an air mixture that can explode if an ignition source is introduced.</td>
</tr>
</tbody>
</table>
L.T.E.L  Long Term Exposure Limit. The maximum allowable concentration of a specified contaminant within a specified exposure time. Typically specified for a reference period of 8 hours (see TWA and WELs).

In workplace exposure limits, concentrations of airborne particles (fume, dust etc.) are usually expressed in mg.m-3.

Mine Entry  See also ‘Adit’ and ‘Shaft’.

NVQ  National Vocational Qualification

Outcrop  The area over which a coal seam (or other rock type) occurs at bedrock level – whether exposed at ground surface, or buried beneath drift

Operator  A person appointed by the owner in writing to exercise for the time being the function of organising or supervising borehole operations at the site, where that function involves the exercise of overall control of the borehole site

Oxidation  To convert into an oxide; combine with oxygen

Pelistor  Gas sensor used to detect flammable gases

Permeable Ground  Rock or superficial deposits that will allow gas and/or water to pass through it with relative ease

Piling  Construction of deep foundations by driving a preformed pile (usually concrete or steel) into the ground or by casting concrete in a pre-bored shaft which may be cased or uncased

Piling Rig  Machine used for the installation of piles by drilling boreholes or driving or vibrating preformed piles

ppm  Parts per million

PUWER  Provision and Use of Work Equipment Regulations 1998, as amended

Pyrite or Iron Pyrite  An iron sulphide with the formula FeS2. Nicknamed “fool's gold” due to its resemblance to gold. Often found in association with coal seams

Rockhead  Interface between soil (superficial deposits) and the underlying solid rock

Regulations  Legal duties made under the Health & Safety at Work etc Act 1974 and any other enabling Act. Rules made by a
government or other authority in order to control the way something is done or the way people behave. Breach of the regulations is a crime throughout the UK.

Guidance on managing the risk of hazardous gases when drilling or piling near coal

1. Introduction

Serious incidents, which have occurred during geotechnical drilling operations to investigate and treat former coal mine workings, have highlighted the need for guidance to ensure the safety of operatives and the public whilst undertaking such work.

Of particular concern are incidents where carbon monoxide has been measured or inferred as entering houses contemporaneously with adjacent drilling operations, in one instance affecting the health of the residents and in another the loss of two lives. The source of the carbon monoxide in both cases was not clear, but possibilities are that the gas was either in the workings due to existing or previous spontaneous combustion or that the drilling operations themselves, which were air flush drilling into a spontaneous combustion prone seam, produced the gas.

Subsequent research carried out by the Coal Authority led to a group, comprising Health and Safety Executive, British Drilling Association, Association of Geotechnical and Geoenvironmental Specialists and the Coal Authority, being formed to produce guidance, in conjunction with the industry, on how coal mine workings and unworked coal can be drilled, treated and piled through, without creating or displacing hazardous gases.

Entering former coal mine workings, coal mine entries and unworked coal can present many hazards for both site operatives and properties adjacent and in close proximity to the site. Operations to investigate, treat or disturb such features should only be considered by suitably competent persons. Moreover physical entry to such environments can only be undertaken by persons qualified to do so under The Mines Regulations 2014.

Where proposed works will intersect, enter or disturb the Coal Authority's property it is a prerequisite that prior consent is obtained. In the case of an accident occurring, if it is established that a contractor has knowingly undertaken work which was advised against by a competent authority, or that he has knowingly circumvented authorised schemes designed to ensure safety, this may be seen as an aggravating factor in any potential prosecution of the company.

This document gives guidance on the general procedures to be adopted when drilling or piling into former coal mine workings (including shafts and adits) and unworked coal. Following the guidance is not compulsory, unless specifically stated, and you are free to take other action, use alternative strategies and arrangements to ensure compliance with the law.

However, if you do follow the guidance you will normally be doing enough to comply with the law and demonstrate good practice. Health and Safety inspectors seek to secure compliance with the law and may refer to this guidance.

2. Scope

This document is designed and published in order to provide guidance with respect to hazardous gases for the safe drilling and piling through coal measures up to a maximum depth of 300m. These gases include the most common such as methane, hydrogen sulphide, carbon dioxide and carbon monoxide, but also less common such as hydrogen. It also includes oxygen.
deficient air.

This guidance will only apply in the onshore coalfield areas of Great Britain where the proposed activity will or is likely to intersect areas of unworked coal seams and former coal mine workings (including shafts and adits), henceforward referred to as just unworked coal and former coal workings, (which are in most instances the property of the Coal Authority).

Coalfield areas are identified by the Coal Authority Interactive Viewer which can be viewed at http://mapapps2.bgs.ac.uk/coalauthority/home.html and a coal mining report or ground stability report can also be obtained from https://www2.groundstability.com/. Furthermore the Coal Authority has defined specific ‘Coal Mining Development Referral Areas’. These are areas, based upon Coal Authority records, where the potential for instability and other safety risks associated with former coal mining activities are likely to be greatest. These areas are known as the high risk development area can be viewed at;

All drilling applications are included within the scope. Principally these are ground investigation, piling, drilling and grouting, geothermal, water well and processes which are geotechnical in nature. Driving precast piles is also included.

The scope of this document is limited to and includes all matters concerning health and safety in relation to hazardous gases associated with unworked coal and coal workings. These include identifying the hazards, evaluating the risks and taking protective measures both on and in close proximity to sites. The responsibilities and duties of Clients, Designers and Contractors are covered in this document.

Not included in the scope of this document are hazardous gases in landfills, hazardous gases in contaminated land, and naturally occurring gases as a result of non-coal geology. These are covered by BDA (British Drilling Association), ESA (Environmental Services Association) and other authoritative publications. However the guidance within this document may be useful in other areas.

The document does not cover the activities involved in hydraulic fracturing (also called “fracking”) or exploration drilling for oil and gas.

3. Disclaimer

The information contained in this guidance has been compiled by the British Drilling Association Ltd, the Coal Authority, the Health and Safety Executive, the Federation of Piling Specialists and the Association of Geotechnical and Geoenvironmental Specialists and reviewed by those listed under acknowledgements above and is supplied to the recipient on the following terms:-

The authors and compilers of this guidance are not responsible for the results of any actions taken on the basis of the information contained in this guidance, or for any errors or omissions from this guidance.

The authors and/or compilers of this guidance are not engaged in rendering professional services, except when acting on a personal consultancy basis.

The authors and/or compilers of this guidance shall not be liable to any recipients of this
guidance in respect of any damage, loss, proceedings or expenses incurred in consequence of this guidance. No liability is accepted in respect of any act or omission by the recipient in reliance on the information contained in this guidance. All recipients of this guidance are advised to seek expert advice, where required, from a relevant competent professional/organisation.

This guide is only intended for use in the stated context and should not be used otherwise. The guidance is compiled from the authorship team's knowledge of current good professional practice and standards. Any limitations are identified where possible but the guidance may require amendment should additional information become available.

In this document reference is made to various National Regulations, European, International and British Standards and other appropriate reference documents. Some of the major aspects of these have been summarised. This is done only to assist users of this guidance by drawing their attention to these regulations and standards.

It is the responsibility of those who use this guidance to make themselves thoroughly conversant with all the appropriate legislation and standards and not to rely on any reference or summary contained in this document that may be incomplete or incomprehensive. It is not intended that this document should replace any Acts, Codes of Practice, Regulations or other documents having legal or contractual standing.

Of necessity this document addresses the broad principles that should be adopted. Advice in respect of specific equipment or operations should be obtained from the appropriate body or technical reference source.

The recognition of the various and individual responsibilities are fundamental to the application of this guidance and the principle of ensuring the significant risks and hazards are addressed by: identifying the hazards, evaluating the risks from the identified hazards, implementing suitable and sufficient control measures and recording the significant findings, should always be applied.

4. Legal duties/competence requirements for those undertaking drilling or piling work

General legal duties are defined for those undertaking applicable construction works e.g. drilling sites defined under the Boreholes Sites and Operations Regulations 1995 and the Construction (Design and Management) Regulations 2015. This section deals with those specific areas that relate to the drilling and construction process.

Any work covered by this guidance should be done only when the employer has satisfied themselves that they have the organisational competence and capability and/or those persons performing the tasks have the individual capability and competence. Below is an outline of minimum attributes necessary to undertake work involving the drilling or piling activities that may be affected by hazardous gases.

Appointing the right organisations and individuals to complete a particular project is fundamental to its success, including health and safety performance.

Anyone responsible for appointing designers (including principal designers) or contractors (including principal contractors) to work on a project must ensure that those appointed have the skills, knowledge, experience and training to carry out the work in a way that secures health
and safety. If those appointed are an organisation, they must also have the appropriate organisational capability.

Those making the appointments must establish that those they appoint have these qualities before appointing them. Similarly, any designers or contractors seeking appointment as individuals must ensure they have the necessary skills, knowledge, experience and training.

4.1 The Boreholes Sites and Operations Regulations 1995

The Boreholes Sites and Operations Regulations place a number of important health and safety related duties on the operator, whether he be the owner or an appointed person. Owners, who are employers, have duties under the Health and Safety at Work etc. Act 1974 to ensure, so far as reasonably practicable, the health, safety and welfare of their employees. They also have a duty to conduct their undertakings in such a way as to ensure, so far as reasonably practicable, that persons not in their employment who may be affected by their undertakings are not exposed to risks to their health or safety.

In addition the Management of Health and Safety at Work Regulations 1999 places a duty on employers, in entrusting tasks to their employees, to take into account their capabilities and competence as regards health and safety.

When appointing an operator, the owner is therefore required to ensure that the demands of the appointment do not exceed the operator’s ability to carry them out. Owners should take into account the competence of the operator and the capacity to discharge duties and exercise authority on the site. Individual persons or the staff of a body of persons appointed as the operator should have adequate practical and theoretical knowledge and relevant experience of the type of borehole site and borehole operations which are to be carried out there.

An operator’s competence may need to be reviewed if and when circumstances change or events require it. Operators may be appointed for several borehole sites providing the combined duties are reasonably within their capacity to manage the sites effectively.

At sites where numerous fairly shallow boreholes are to be drilled to a standard pattern, for example in the case of exploration for shallow coal reserves, the operator appointed for the site may be in control of several simultaneous drilling operations.

It is recommended that an individual person should not be expected to exercise overall control of more than one deep drilling operation at any time. An individual person may be appointed as the operator for a drilling operation while at the same time being the appointed operator for a number of sites where drilling is not being carried out. An individual person may be appointed as the operator for a number of production borehole sites.

If the operator is an individual, during short periods of absence, for example during holidays or periods of sick leave, a suitable substitute should be appointed.

The Regulations recognise the need for operators of borehole sites to have available all the information necessary for them to discharge their duties under these Regulations. It puts a duty on owners to furnish appointed operators with all such information in their possession.

In addition to seeking improvements to the safety and protection of health of persons who work at borehole sites, these Regulations are also aimed at protecting the safety of persons
who do not work at borehole sites but who may be put at risk by the drilling of boreholes.

Owners, operators and other persons entitled to drill boreholes, who may be employers, are required to comply with their general duties under HASAWA and under these Regulations for the safety and health of persons who do not work at their borehole sites. They should take all reasonably practicable measures to ensure that they have identified how their boreholes may create hazards to persons other than their employees.

These include in particular, residential property owners, visitors at tourist mines and persons working at other borehole sites. Boreholes may also create hazards to potholers, persons working in deep construction works or underground storage facilities and persons on the surface in the case of boreholes drilled from high ground towards the surface of lower lying land or boreholes which may allow underground fluids to escape and be released at the surface.

Where owners appoint persons other than themselves to be the operators of borehole sites, they are required to ensure that they supply the operators with all the information in their possession which is relevant to the safety and health of persons on the site and persons who may be remote from it but who may be affected by it.

There is a duty on appointed operators to exercise overall control of the borehole site and to co-ordinate the measures taken by themselves and every other employer and self-employed person at the site to comply with the requirements and prohibitions imposed upon them by or under the relevant statutory provisions.

It is not necessary for individual operators or persons acting on behalf of a body of persons appointed as an operator to be present at a site at all times during borehole operations. Such persons should make arrangements to be contacted at any time in the event of an emergency or when their direction is required.

Operators have a duty to exercise overall control of the borehole site. They should make suitable arrangements for the effective control of the site. These should provide for competent supervision of operations, inspection of the site and the issue of necessary rules or instructions. These should take the form of written ‘operator’s rules’ or ‘operator’s instructions’ or when appropriate may be direct spoken instructions. Operators should ensure that suitable arrangements are made for all rules and instructions to be received, understood and complied with by those for whom they are intended.

They should ensure that during drilling operations and operations involved with the repair, maintenance or modification of a well, the site is constantly supervised by a competent person capable of recognising an ingress of well fluids under pressure and taking the actions required to maintain the safety of the well and thereafter safely restore it to normal operation. In the case of borehole operations associated with exploration or production of oil, gas and coal bed methane or drilling for deep coal reserves in poorly documented land, that person should possess relevant evidence of competence in well control.

Operators have a duty to co-ordinate their work and their safety measures with those of other employers and self-employed persons working at the site.
4.2 The Construction (Design and Management) Regulations 2015

4.2.1 Client

The CDM regulations 2015 define a client as anyone for whom a construction project is carried out. This definition includes both non-domestic (or ‘commercial’) clients and ‘domestic’ clients (i.e. clients for whom a construction project is carried out which is not done in connection with a business). The Regulations apply in full to commercial clients.

**The client has a major influence over the way a project is procured and managed.** Regardless of the size of the project, the client has contractual control, appoints principal designers, designers, principal contractors and contractors, and determines the money, time and other resources available.

4.2.1.1 Domestic client

A domestic client is someone who has construction work done on their own home, or the home of a family member, which is not done in connection with a business. Local authorities, housing associations, charities, landlords and other businesses may own domestic properties, but they are not a domestic client for the purposes of the CDM regulations 2015. If the work is in connection with a business attached to domestic premises, such as a shop, the client is not a domestic client.

**For domestic clients, the effect of the regulations is to pass the client duties on to other duty holders. This includes the principal designer and principal contractor duties falling to the designer and contractor in control of the pre-construction and construction phases, where the domestic client does not make these appointments.**

4.2.1.2 Commercial client

The guidance applies to commercial clients, and any reference to ‘clients’ elsewhere in this guidance should be read as referring to commercial clients only, unless specific reference to domestic clients is made.

Commercial clients are organisations or individuals for whom a construction project is carried out in connection with a business, whether the business operates for profit or not. This includes clients based overseas who commission construction projects in Great Britain.

In any project there may be more than one client. However, all clients should agree that only one of them should be responsible for carrying out the requirements of CDM regulations 2015.

The client is required to make suitable arrangements for managing the project so that health, safety and welfare is secured.

To be suitable, the arrangements should focus on the needs of the particular project and be proportionate to the size of the project and risks involved in the work.

Clients should take ownership of these arrangements and ensure they communicate them clearly to other duty holders. The client must maintain and review their arrangements to ensure they remain relevant throughout the life of the project.

If a client needs help in making these arrangements, the principal designer should be in a position to help with this. Clients could also draw on the advice of a competent person if they are required to appoint such a person under the Management of Health and Safety at Work...
Regulations 1999. More information on the obligations of the client is contained within the relevant section of the CDM Regulations 2015.

The Client must also:

- make suitable arrangements for managing a project, including the allocation of sufficient time and other resources. Ensure that these arrangements are maintained and reviewed throughout the project. Provide PCI as soon as is practicable to every designer and contractor appointed, or being considered for appointment, to the project
- before the construction phase begins, a construction phase plan is drawn up by the contractor if there is only one contractor, or by the principal contractor; and the principal designer prepares a health and safety file for the project
- take reasonable steps to ensure the Principal Designer and Principal Contractor comply with their duties under the CDM Regulations 2015

4.2.2 Principal Designer

Principal designers are designers appointed by the client in projects involving more than one contractor. A principal designer is the designer with control over the pre-construction phase of the project. This is the very earliest stage of a project from concept design through to planning the delivery of the construction work.

They can be an organisation or an individual with sufficient knowledge, experience and ability to carry out the role that has: the technical knowledge of the construction industry relevant to the project, for example an intimate knowledge of the issues and hazards involved within the drilling and/or piling industry. For more information on the duties of the Principal designer, please see the relevant section of the CDM regulations 2015.

Principal Designer's legal duties are to:

- plan, manage, monitor and coordinate the pre-construction phase
- identifying, eliminating or controlling foreseeable risks during pre-construction, construction or for those
- maintaining, cleaning or using the structure as a workplace once it is built
- ensuring coordination and cooperation with the project team throughout the pre-construction phase
- providing pre-construction information that is within the Client's possession and/or easily obtainable that has an appropriate level of detail and is proportionate to the nature of risks involved with the project
- liaise with the Principal Contractor to ensure the construction phase plan and health and safety file are completed

4.2.3 Designer

Designers are those, who as part of a business, prepare or modify designs for a building, product or system relating to construction work. This means any person (including a Client, Contractor or other person who in the course or furtherance of a business prepares or modifies a design; or arranges for, or instructs, any person under their control to do so, relating to a structure, or to a product or mechanical or electrical system intended for a particular structure, and a person is deemed to prepare a design where a design is prepared by a person under
their control including temporary works. This definition includes contract engineers who have responsibility for analysis of the site, including the location of the coal workings and the calculations for the work. A designer has a strong influence during the concept and feasibility stage of a project. When preparing or modifying designs, a designer must take account of the general principles of prevention, and the pre-construction information provided to them, with the aim, as far as reasonably practicable, of eliminating foreseeable risks. Where this is not possible they must take reasonably practicable steps to reduce the risks or control them through the design process, and provide information about the remaining risks to other duty holders. For example, if the drilling process presents a risk of gas migration and the process can be designed out, so far as is reasonably practicable, then this is a legal duty. Although it is understood that residual risks may well remain, decisions such as these have an important influence on the overall health and safety performance of the project.

The Designer in providing advice and plans for drilling and piling works into coal measures should be able to demonstrate their familiarity and competence in the following areas;

- HASAWA and the accompanying relevant regulations
- CDM requirements
- contractual matters
- Coal Authority Permitting regime
- desk study principles and practice
- coal measures geology and hydrogeology
- historical coal mining
- risks from hazardous gases
- migration of gases on and off site
- influence of atmospheric conditions
- monitoring for hazardous gases on and off site
- drilling and/or piling processes
- emergency procedure for coal seam fires, blow outs and evacuation

4.2.4 Principal contractor

Principal contractors are contractors appointed by the client to coordinate the construction phase of a project where it involves more than one contractor.

A Principal Contractor is the organisation or person that coordinates the work of the construction phase of a project involving more than one contractor, so it is carried out in a way that secures health and safety. They are appointed by the Client and must possess the skills, knowledge, experience and training, and (if an organisation) the organisational capability to carry out their role effectively given the scale and complexity of the project and the nature of the health and safety risks involved. For more information see the relevant section of the regulations.

In liaison with the Client and Principal Designer, Principal Contractors have an important role
in managing the risks of the construction work and providing strong leadership to ensure standards are understood and followed. To ensure this they should be able to demonstrate its competence to undertake and manage the risks arising from the work by providing evidence of:

- experience of similar work (References)
- a health and safety policy and organisation for health and safety
- arrangements for health and safety
- management within the organisation which should be relevant to the nature and scale of the work and how they will discharge their duties
- access to competent advice - corporate and construction-related
- demonstration of appropriate health and safety qualifications for drilling/piling and management, for example SMSTS or equivalent
- using only competent, assessed and authorised personnel
- having appropriate insurance cover employers liability, public liability etc.

Using only suitable plant with:

- rig certification (LOLER)
- compliance with PUWER (Dangerous rotating parts)

Principal Contractors must also comply with CDM by:

- having a Construction Phase (Health and Safety) Plan and suitable and sufficient risk assessments/method statements etc.
- plan, manage, monitor and coordinate the construction phase
- provide suitable site inductions (proportionate to the nature of the visit)
- prevent unauthorised access to the site
- provide suitable and sufficient welfare facilities depending on the size and nature of the work involved, for example for drilling/piling work this may include the provision of showers
- liaise with the Principal Designer and other contractors
4.2.5 Contractor

Anyone who directly employs or engages construction workers or manages construction is a contractor. Contractors include sub-contractors, any individual, sole trader, self-employed worker, or business that carries out, manages or controls construction work as part of their business. This also includes companies that use their own workforce to do construction work on their own premises. The duties on contractors apply whether the workers under their control are employees, self-employed or agency workers.

Where contractors are involved in design work, including for temporary works, they also have duties as designers. Contractors and the workers under their control are those most at risk of injury and ill health. They can influence the way work is carried out to secure their own health and safety and that of others affected.

Contractors have an important role in planning, managing and monitoring the work (in liaison with the principal contractor, where appropriate) to ensure risks are properly controlled. The key to this is the proper coordination of the work, underpinned by good communication and cooperation with others involved. Contractors must also comply with CDM by:

- making clients aware of their duties
- planning, managing and monitoring construction work
- appointing and employing workers
- providing supervision
- providing information and instructions
- preventing unauthorised access to the site
- providing welfare facilities if there is no Principal Contractor or ensuring welfare facilities have been provided which are suitable and sufficient given the nature and size of the project.

The drilling or piling contractor shall be able to demonstrate its competence to undertake and manage the risk arising from the work. This may be shown by:

- experience of similar work (References).
- using only competent, assessed and authorised personnel
- having appropriate insurance cover
- using only suitable plant with:
  - rig certification (LOLER)
  - compliance with PUWER (Dangerous rotating parts)
- a Health & Safety Policy for their organisation
- having a Construction Phase (Health and Safety) Plan when they are the only contractor and a Principal Contractor has not been appointed
- or additional documentation demonstrating expertise and experience
4.2.6 Drilling and piling operatives

Drilling and piling operatives shall be able to demonstrate their competence.

For drilling this should be all of the following:

- knows standards of health and safety required for site operations; can identify all foreseeable risks arising from their work activity and know what actions to take to control these risks; can apply existing knowledge to new circumstances
- consistently works to agreed standards of health and safety; quickly identifies defects and unacceptable risks; demonstrates good attitude and example at work; capable of working safely with minimal supervision
- plays a full role in site consultation; demonstrates ability to report unsafe conditions to supervisor; demonstrates motivation to learn
- attends site induction; attends mandatory in-house training; works safely to agreed standard under supervision; demonstrates safe behaviour and wears appropriate PPE at all times
- NVQ/SVQ certificate in Land Drilling (or proof of an equivalent level of experience and continuous development)
- a current and valid Audit card as issued by the British Drilling Association or an equivalent body in a State of the European Union
- CSCS Land Drilling card
- or have proof of an equivalent level of training and experience

The certificates and cards for Lead Drillers shall be applicable to the work and specific boring / drilling operation on which they are engaged.

For piling this should be:

- NVQ/SVQ certificate in Piling Operations (or proof of an equivalent level of experience and continuous development)

4.2.7 Plant operatives

Plant operatives shall be able to demonstrate their competence.

For plant operatives this should be all of the following:

- knows standards of health and safety required for site operations; can identify all foreseeable risks arising from their work activity and know what actions to take to control these risks; can apply existing knowledge to new circumstances
- consistently works to agreed standards of health and safety; quickly identifies defects and unacceptable risks; demonstrates good attitude and example at work; capable of working safely with minimal supervision
- plays a full role in site consultation; demonstrates ability to report unsafe conditions to supervisor; demonstrates motivation to learn
- attends site induction; attends mandatory in-house training; works safely to agreed standard under supervision; demonstrates safe behaviour and wears appropriate PPE at all times

Operatives using plant covered by Construction Plant Competence Scheme (CPCS) e.g. piling rigs, excavators, dumpers etc. employed on the contract should hold an appropriate card (or proof of equivalent training and experience of operating this category of machine).

4.2.8 Site supervisors
Site supervisors shall be able to demonstrate their competence.

- as for plant operatives and in addition this should be all of the following: knows how to lead in identifying remedial actions to mitigate risk in all foreseeable circumstances; understands implications of his or her own decisions on others; knows when to ask for specialist help
- NVQ/SVQ certificate or equivalent proof of experience and continuous development of knowledge and skills
- able to identify causes of problems and to deploy resources to solve problems on own initiative; demonstrates leadership skills, appropriate communication strategies; can read plans, think through problems and is flexible to adapt to changing circumstances
- 3-5 years' experience of this operation; trained and qualified to a level where they can describe risks of the range of work activities he is responsible for, is capable of identifying remote risks, and anticipating problems of change Appropriate CSCS card
- safe site supervision training, forexample: SSSTS or equivalent (essential)Or have proof of an equivalent level of training and experience

4.2.9 Site engineers
Site engineers shall be able to demonstrate their competence

This should be all of the following:

- evidence showing how you ensure co-operation and co-ordination of design work within the design team and with other designers/contractors; ensure that hazards are eliminated and any remaining risks controlled
- task knowledge appropriate for the tasks to be undertaken. May be technical or managerial
- health and safety knowledge sufficient to perform the task safely, by identifying hazard and evaluating the risk in order to protect self and others, and to appreciate general background
- experience and ability sufficient to perform the task, (including where appropriate an appreciation of constructability), to recognise personal limitations, task-related faults and errors and to identify appropriate actions
- evidence of significant work on similar projects with comparable hazards, complexity and procurement route
- professionally qualified to Chartered level or aiming to be, membership of a relevant construction institution, for example CIBSE; ICE; IEE; IMechE; IStructE; RIBA; CIAT; CIOB
- validated CPD in their field of work
• appropriate degree
• appropriate CSCS card
• safe site supervision training when acting in supervisory role, for example: NEBOSH Construction, SMSTS (desirable), SSSTS or equivalent (essential)
• or have proof of an equivalent level of training and experience

4.2.10 Site managers

Site managers shall be able to demonstrate their competence.

• as for site supervisors and in addition this should be all of the following :Appropriate CSCS card (or proof of equivalent training/ experience)
• site manager’s safety training when acting in a managerial role, for example: details of any specific training such as, but not limited to, the Construction Skills CITB 'Site Management Safety Training Scheme' certificate or equivalent. NEBOSH Construction (desirable), SMSTS or equivalent (essential)
• or have proof of an equivalent level of training, experience and familiarisation of the processes to be undertaken on site
5. Coal Mine Gases – Properties and Problems

5.1 Coal Mine Gases and their Principal Hazards

5.1.1 Atmospheric Air
Atmospheric air is often a component of gas emitted from mines. Most often mine gas is a mixture of atmospheric air and various pollutants, the pollutants in some cases completely displacing the air. Typically, air contains approximately 20.9% oxygen under normal atmospheric pressure. Oxygen is the dominant reactive gas in the atmosphere. The remaining comprises 79.0% nitrogen and 0.03% carbon dioxide by volume. The remainder includes argon and other trace gases.

5.1.2 Oxygen (O₂)
Hazardous conditions can arise from excess levels of oxygen, but such conditions are extremely unlikely to be encountered. On the contrary, hazardous conditions due to reduced levels of oxygen, usually as a result of oxidation of carbonaceous material, are likely to be encountered. Monitoring the oxygen content of the air is often the best means of ensuring safety. There are substantial risks if the concentration of oxygen in the atmosphere varies from normal. Operations should not be carried out where workers are consistently exposed to concentrations of oxygen below 19% v/v (percentage by volume). With reference to specific statutory requirements, any difference in oxygen content from normal should be investigated, the risks assessed and appropriate measures taken in the light of the risk.

Once oxygen levels approach 17% v/v breathing can become laboured and judgement impaired. Once oxygen concentrations approach 10% v/v there is a high probability of unconsciousness and death.

Low oxygen levels are most often found in conjunction with elevated levels of carbon dioxide (see below), although high concentrations of methane can also produce oxygen deficiency.

Sometimes coal mine atmospheres contain excess levels of nitrogen, which are due to oxygen being removed, usually by conversion into carbon dioxide which is then dissolved in water.

5.1.3 Methane (CH₄)
Methane (CH₄) is a colourless, odourless, flammable gas. Methane is present in mine workings due to desorption from the coal seams. Methane was produced during the conversion of organic matter to coal due to heat and pressure and some of the gas produced remains within the structure of coal. In general, the methane content of coals increases with depth. As a consequence, where only shallow seams have been mined or deeper seams have become flooded by rising mine waters, high methane concentrations are unlikely to be present. Conversely, where deep mined seams are connected either directly to the surface or through shallow workings, methane may be a significant constituent in mine gas. Groundwater can also become saturated with dissolved methane and act as a transport mechanism for the gas, which is then released at a remote location (due to pressure release or discharge to an unconfined water body).

The principal dangers arising from methane are fire and explosion. However, methane is also a known asphyxiant and this should be considered as part of risk assessment when...
determining suitable control measures. Methane is explosive at concentrations of between about 5% and 15% v/v (volume fraction) in air (50,000-150,000 ppm). Sometimes gas concentrations are quoted in terms of percentages of the Lower Explosive Limit (%LEL), where 100% LEL is 5% v/v. So, for example, 1% methane by volume is equal to 20% LEL. Although concentrations higher than 15% v/v (the Upper Explosive Limit or UEL) cannot be directly ignited they can dilute into the explosive range or represent a risk of ignition as they will burn at the interface of the gas and air.

Even small quantities of gas can produce significant damage and risk to people, especially if the gas volume is confined at the time of ignition. A particular aspect of gas ignitions is the fact that the size of the flame is much larger than the volume of the gas before ignition, due to the temperature of the flame. This means that the flame can impact on a much wider area than might be expected and may mean that an ignited flame might be hard to avoid. Ignitions within confined spaces can produce significant overpressures causing harm both to operators and structures. For these reasons it is especially important that monitoring is undertaken where methane might be encountered. If detected moving away from the source is also an important safety precaution.

Methane is ignited relatively easily by either naked lights or sparks from electrical equipment such as switches. Great care needs to be exercised in not allowing methane to come into contact with electrical equipment, or taking electrical equipment into atmospheres potentially containing methane. Any equipment which may come into contact with methane must be suitably ATEX compliant. This also applies to any equipment used to monitor for the presence of methane and other mine gases.

Methane has a density of about 0.7 kg/m³, compared to the density of air of about 1.2 kg/m³. Being lighter than air, mixtures of methane and air, especially at high methane concentrations, will tend to rise in air. Methane mixtures may also form layers when rising gas encounters horizontal barriers, such as ceilings, and especially where the gas is emitted close to such a horizontal barrier.

Methane is not toxic, but can act as an asphyxiant by displacing oxygen from the air. For a pure mixture of air and methane, every 10% of methane will produce a 2% reduction in oxygen.

5.1.4 Carbon Dioxide (CO₂)

Carbon dioxide (CO₂) is a colourless, odourless gas. It is highly toxic and it is an asphyxiant and can cause adverse health effects in concentrations greater than 0.5% v/v. Carbon dioxide in mines originates predominantly as a result of oxidation processes. These processes are generally as a result of oxidation of carbonaceous material, but biological processes could also be involved. In oxidation processes a unit volume of oxygen will produce an equal volume of carbon dioxide. Consequently, an increase in the concentration of carbon dioxide will be at the expense of an equal reduction in the concentration of oxygen. In many cases the sum of the concentrations of oxygen and the concentration of carbon dioxide will be close to 21% v/v - the atmospheric concentration of oxygen. However, solution of carbon dioxide in water can result in atmospheres which are predominantly nitrogen. In the mining industry, a mine air mixture rich in carbon dioxide and poor in oxygen is also known as blackdamp or stythe.

Carbon dioxide has a density close to 2 kg/m³, which is significantly higher than air. As a result, blackdamp emissions have a tendency to layer at ground level, especially if the mine gas is cold,
which enhances the density difference. Blackdamp is therefore particularly dangerous in cases such as cellars, trenches, cuttings and any other confined low lying ground. The gas can also flow downhill and collect in low lying ground at a distance from the point of emission.

Carbon dioxide is toxic, but the principal danger arising from emissions is asphyxiation due to the associated reductions in oxygen. The 8 hour long term exposure limit (LTEx) is 0.5% v/v or 5000ppm and the 15 minute short term exposure limit (STEx) is 1.5% v/v 15000ppm (See 6.2). For more information see BS8576.

5.1.5 Carbon Monoxide (CO)

Carbon monoxide (CO) is a colourless and odourless gas that is toxic, flammable and explosive. It is denser than air. Symptoms of mild exposure include: headaches and flu like effects. Carbon monoxide is produced as a result of incomplete combustion of fuel. In domestic situations the main danger arises from problems with heating appliances and leaking flues. In mines the gas is generally associated with spontaneous combustion of the coal seams (see Section 6.2). Indeed, the presence of carbon monoxide has long been used as an indicator of the probable presence of an in-seam heating or combustion.

Carbon monoxide is normally found in low levels, at a few ppm, in abandoned mine workings which does not represent a risk to health. However, the Coal Authority has found carbon monoxide at one location, at a level of about 200ppm where historically there had been spontaneous combustion. This suggests that carbon monoxide could remain for substantial periods underground. In contrast, carbon monoxide has a lifetime of about four months in the general atmosphere.

Carbon monoxide is toxic at very low levels. The LTEx for CO is 30ppm and the STEx is 200ppm. For further details see the Table in 6.2, but severe effects will result from spending short times in concentrations as low as 0.1% v/v (1000ppm).

The LEL in air for carbon monoxide is 12.5%. The UEL in air is 74.2%.

The density of carbon monoxide is 1.25 kg/m³, but because it is generally found in low concentrations, it does not have any effect on the physical behaviour of the gas, such as layering.

5.1.6 Hydrogen Sulphide (H₂S)

The principal characteristic of hydrogen sulphide is its smell, which may be perceived at levels as low as 0.003 ppm. The short term exposure limit STEx for H₂S is 10ppm and the long term exposure limit LTEx is 5ppm. The LEL in air for hydrogen sulphide is 4.5%. The UEL in air is 45.5%.

Hydrogen Sulphide in mines is produced either as a by-product of degradation of organic material or due to the action of acidic mine water on sulphide materials, such as pyrites. Hydrogen sulphide is highly soluble in water and dangerous conditions can arise from gas release due to disturbance of standing pools containing saturated solutions of the gas. It is heavier than air and although flammable, at between 4.3% – 46% v/v, its principal danger is its toxicity.

Although very pungent at first, it quickly deadens the sense of smell, so potential victims may be unaware of its presence until it is too late. The gas is toxic and is likely to result in
unconsciousness at concentrations over 250 ppm and death at over 1000 ppm.

5.1.7 Hydrogen (H₂)

Hydrogen is not normally encountered within abandoned workings although it has sometimes been found where there have been signs of spontaneous combustion. Hydrogen can also be formed by concrete when certain metals are part of the admixture when, for example, incinerator bottom ash is used. Hydrogen may be produced from the dissociation of water (H₂ and O₂) if used in an attempt to put out a spontaneous combustion fire, resulting in an explosion.

The principal danger of Hydrogen is that it is explosive in the range 4% to 75% v/v in air.

5.1.8 Other gases

Although methane is the principal hydrocarbon gas found in mine workings, there will also be lower levels of other alkanes, especially ethane (C₂H₆). Because the concentration of ethane is usually about two orders of magnitude less than that of methane (in typical mine gas – natural gas can have much higher concentrations), it does not represent a significant increase in risk. However, it affects infrared methane detectors disproportionately and so, where present, it can give erroneously high readings.

**Radon** occurs naturally at varying concentrations in large parts of the United Kingdom. It is commonly present in mine gas and can also be released from groundwater when it is extracted from the ground. It can also arise from deposited wastes such as those from the nuclear industry, phosphorus slags, and coal ash.

In operating mines the build up of radon is prevented by ventilation of the mine which dilutes and removes the gas from the mine. In closed workings, there is a potential to build up levels of radon although radon's half-life is only 3.8 days. There is limited information on the general levels encountered within old workings and it will depend on the types and composition of rocks exposed by mining. However, some measurements from metal mines suggest that radon levels can be measured in the tens of thousands of becquerels per metre cubed (Bq/m³).

The principal risk from radon is lung cancer, usually as a result of prolonged exposure to elevated levels of the gas in homes or workplaces, caused by emissions from radioactive decay in the underlying rocks. The risk is a combination of the level of radioactivity with the exposure time.

The Health Protection Agency recommends that radon levels should be reduced in homes where the average is more than 200 Bq/m³ over a 12 month period. The target level of 100Bq/m³ is the ideal outcome for remediation works in existing buildings and protective measures in new buildings. In a drilling context, prolonged exposure is unlikely, due to the limited times when drillers are likely to encounter undiluted airflows from mining voids and therefore the risk will be low. For example, continuous acceptable exposure (100 Bq/m³) in a building for one year would be about 50 million Bq.minutes/m³, whereas 10 minutes exposure to say 50,000 Bq/m³ would be 500,000 Bq.minutes/m³ or 100 times less. Where these instances do occur it is likely that other mine gases, created in stagnant mine atmospheres, will also be present and detectable.
## 5.1.9 Characteristics and effects of toxic mine gases

**LTEL** - Long Term Exposure Limit (8-hour TWA reference period)  
**STEL** - Short Term Exposure Limit (15 minute)

From EH40 Occupation Exposure limits, HSE
5.2 Spontaneous combustion ('Spon Com')

Spontaneous combustion of coal is the process where coal catches fire without an external heat source. Spontaneous combustion usually occurs in coal as a result of air flowing over it. Coal will oxidise in the presence of air releasing carbon dioxide and, importantly, heat. Where the flow of air is insufficient to carry away the generated heat the coal will warm and increase the rate of oxidation. In this way the coal's temperature can increase until it auto-ignites. However, where the airflow is very low there will be insufficient oxygen for oxidation and the process will be stopped. The process of spontaneous combustion therefore requires sufficient air to allow oxidation/combustion, but not so much as to cool the coal.

Spontaneous combustion of coal is most often associated with former coal workings. In operating mines it is usually found in collapsed ground, which contains coal, or in fractured coal around roadways. In these situations it is the replenishment of potentially oxidising gas conditions by ventilation air in the workings which allows continued heating. It is also found where coal outcrops at the surface especially where it has been disturbed by mining operations which allows air to come into close contact with the coal.

As the temperature of the coal increases, gases other than carbon dioxide are produced. These include hydrogen, higher hydrocarbons and carbon monoxide. Carbon monoxide is produced in conditions of incomplete combustion caused by a limited supply of oxygen. These gases are produced, albeit at lower concentrations, at temperatures well below those at which the coal actually catches fire.

There appears to be very little in the literature regarding spontaneous combustion of coal in air flush boreholes. Nevertheless, details of known examples of this happening, along with anecdotal evidence, suggest that there have been potentially many other cases where such events have not been reported.

The production of spontaneous combustion, or heating, of coal by air flush drilling is probably a combination of two factors. These are the production of heat by the mechanical action of the drill on the coal and the oxidation of the coal due to the injected air. The presence of broken coal and fines may also increase the rate of oxidation as it is a surface process and comminution of coal leads to an increase in its surface area.

Whatever the cause, ignition of a coal seam can have dangerous consequences. Where associated with underground workings there is a danger of the fire spreading through the workings and threatening the safety of any properties lying above them. There is also the potential to spread hazardous gases, including carbon monoxide, through the workings to locations where they might escape at the surface, especially up dip.

A list of seams which have had incidents of spontaneous combustion in the past is available on the Coal Authority website at:

However, this list is by no means comprehensive and some of these incidents have occurred within deep mines where the condition of the coal may be materially different to its condition when near the surface. It should not be assumed that because a seam is not on the list it is not capable of spontaneous combustion.
5.3 Atmospheric pressure

Atmospheric pressure is usually the most important factor controlling the movement of gases within abandoned mine workings. Where water levels are rising within an area of workings gas will be displaced and potential pressurisation can occur. Nevertheless, even in these circumstances changes in atmospheric pressure can still have an effect on the movement of gas and the concentrations of gas in the workings.

If the atmospheric pressure falls below that in an abandoned mine and there are connections between the mine and the surface then there will be a flow from the mine to the surface, until the pressure becomes equal. If the connection to the surface is good, which is most common for shallow workings, then the pressure in the mine is usually close to atmospheric pressure and the rate of emission from the mine is related to the rate of fall in atmospheric pressure. The time of greatest risk of surface emissions of mine gas is therefore when deep depressions are moving across the country where pressure fall rates of 4mb/hr are possible.

Rising atmospheric pressure, by the same argument, will tend to push air into the workings. In this case, the air will either dilute the pollutants or completely displace them in a zone close to the point of ingress. On falling pressure, gas from deeper in the mine will displace any fresh air drawn into the mine, but may still contain atmospheric air as part of its composition.

If the connection to the surface is poor, which is the usual case with deeper workings, the rate of flow will be related to the difference between atmospheric pressure and the pressure in the mine. Such differences can be substantial, especially where pressurisation due to rising mine water is present.

5.4 Migration and pathways

5.4.1 Migration

Gas and vapours migrate by pressure driven flow and/or diffusive flow through the soil pore spaces. Migration can also be driven by the buoyancy of gases. Migration of a vapour source in groundwater (i.e. the dissolved contamination) can be a significant pathway for vapours to reach off-site receptors on many sites. The bulk gases (methane and carbon dioxide) can also migrate in groundwater. The concept of migration of gases due to pressure differences and the existence of connections between workings and the surface were raised in the previous section. Pressure differences may be produced by:

- rising water levels
- atmospheric pressure
- differences in gas density
- injection of fluids and gases

The first two have been discussed already. The movement of gas due to differences in density is sometimes referred to as natural ventilation. Where there are two points of access to a mine void and the density of the gas in the void is higher than that of the atmosphere then, due to gravity, the denser air will flow from the lower connection and draw fresh air into the higher connection. If, alternatively, the density of the gas in the void is lighter than that of the atmosphere, then, by gravity, the atmospheric air will displace the lighter air by entering by the lower connection and forcing the lighter mine gas out of the higher connection.
The density of the gas will be a function of its temperature and composition. The density of a gas will decrease as its temperature increases, which means that warmer air tends to rise. The density of a gas mixture is made up of that of its constituents, so if it contains gases of a lower molecular weight its density will tend to be lower. For example, mine atmospheres with high levels of carbon dioxide are likely to be more dense than the surrounding atmosphere. Nevertheless the effect of temperature can be important. Because the mine atmosphere is less prone to temperature change, but the outside temperature can change substantially, especially overnight, the flow of gas from the mine can vary over a 24 hour period or even reverse.

If migration pathways are present, gas will migrate either vertically or horizontally through the ground to an exit point. Depending on the specific site conditions, migration can be driven by diffusion or pressure.

The most likely case where fluids are injected into workings is during drilling or piling operations where air or water flush drilling are utilised. The extent to which injection of fluids, such as air and water, into workings will influence the movement of the mine atmosphere will be a function of the flow of the fluids, the void volume and the resistance to the flow.

Where there is a very large open interconnected void the induced pressures are likely to be small and this has been borne out by experiment. However, if the connected void is small it is possible that it could become pressurised. In the case of air flush, the maximum pressure will be the back pressure exerted by the resistance of the air returning up the annulus between the drill string and the side of the drilled hole. In the case of water flush, higher pressures could be exerted if void volumes were very small and the volume of water injected was to fill a significant portion of it.

In comparison the low pressure and relatively low flow methods employed in open or closed bore piling techniques do not lend themselves to ground pressurisation.

Beyond pressurising the workings the injection of air or other materials will also displace gas within the workings, potentially moving dangerous gases into places they did not previously occupy. In general, air flush, as it uses much larger volumes, has a greater potential to displace mine gases over larger distances. Conversely there have been sites where no migration has been observed as close as 10m to sources that are surrounded by impermeable clay (for example, London clay). For more information see BS8576:2013.

Methane from mine workings usually migrates to the ground via fissures in the overlying rock or via shafts and adits. Emissions of methane (fire damp) or carbon dioxide (black damp) from the ground are a common problem in areas where coal measures outcrop near the ground surface or adits and shafts connect with abandoned deep underground workings.

Measurements to date have shown that normal air flush drilling is capable of having an effect on the gases in voided mine workings at distances up to 60m although flows were low (see Appendix I- Case Study 4).

5.4.2 Pathways

Pathways between mine workings and the surface can be of a number of forms although they are all weaknesses within the intervening ground which present a lower resistance to movement of gases. The mine workings themselves also represent a pathway through which gas can move considerable distances.
At shallow depth, emissions are dependent on the presence of seepage pathways to the surface and external forces such as variations in barometric pressure. An understanding of these factors is necessary when assessing the hazards and risks to surface development. For more information see BS8576:2013.

Examples of pathways are:

- mine entries (shafts and adits)
- shallow mine workings
- previous boreholes
- water wells
- service ducts and trenches
- faults / break lines
- permeable strata

The most obvious form of pathway is a shaft or an adit constructed to access the workings. Although such mine entrances are usually filled to some degree, they may still represent a weak point through the strata due to containing permeable fill. Gas is also able to move along the interface between the strata and the lining of the mine entry. For more information see BS8576:2013.

Collapses of ground over coal workings are also a potential route for gas migration. In some cases the movement of the developing void to the surface may not be complete, but the weakening of the strata may be sufficient to allow movement of gas. In general, fracturing of the strata, either mining induced or natural, such as faults, are potential lines of weakness which can provide pathways.

Where it is unknown whether pathways exist, the risk assessment must consider that pathways might be present. As such a layer of clay in the superficial deposits cannot be classed as impermeable if it is not known whether pathways exist.

Where mine gas gets close to the surface it has the potential to run through ground which might have a higher permeability than the natural ground surrounding or underlying it. Examples are made ground and service runs.

Colliery spoil as placed is frequently high in sulphides. Upon exposure to air and moisture these have the potential to generate significant sulphate and low pH conditions which are aggressive to concrete. Over time the corrosion of piles formed using concrete may, in addition to detrimentally affecting load bearing characteristics, lead to the formation of a new pathway. It is therefore important to design the concrete to resist such attack.

5.5 Monitoring and Testing

Refer also to Section 10.5

5.5.1 General

If carrying out works or investigations in areas which may be affected by mine gas, then suitable safeguards must be in place to ensure a safe working environment. The risk assessment for the drilling operations should identify any significant risks from gas and should make sure that
a suitable drilling method is being used along with adequate testing and monitoring procedures and that the appropriate equipment is in place before commencement of operations.

Monitors are readily available which will detect the gases described in Section 6.1 and alarm if trigger gas levels are exceeded. The most likely gases to be encountered are methane and carbon dioxide (usually associated with low oxygen). An ability to measure carbon monoxide can also be of great benefit in identifying potential spontaneous combustion. **This guide recommends that monitors / alarms should routinely sample for carbon dioxide, carbon monoxide, methane and oxygen.** The presence of hydrogen sulphide is very rare and is apparent by its smell even at very low levels.

All gas monitors being used need to be calibrated and tested with copies of supporting certificates available on site. Provision needs to be made to ensure that monitors are operational at all times whilst in use on site. It is important that personnel doing the work are appropriately skilled, knowledgeable, experienced and trained.

When using gas monitors, it is important to remember that monitors measure gas properties and not the gases directly. For further information see BS8576:2013.

Due to the nature of the gas detection cells, some gases can affect cells other than those for which they were designed. This cross sensitivity effect can cause monitors to provide false readings. Some examples of this are:

- **infrared methane cells will also record ethane, and other hydrocarbons, at an enhanced level.** This means that small levels of ethane mixed in with methane will show methane levels potentially well in excess of actual levels.

- **electrochemical cells used to detect gases such as oxygen, carbon monoxide, hydrogen and hydrogen sulphide often show cross sensitivity to the other gases.** Known examples include both hydrogen and an unsaturated hydrocarbon (e.g. ethyne/acyetylene) registering as carbon monoxide and resulting in a misdiagnosis of the particular problems encountered.

- **pelistors, sometimes used to detect methane, are also cross sensitive to other flammable gases, so that hydrogen will register as methane.**

**When unusual readings are being detected during operations and cross sensitivity is suspected another instrument using a different type of cell may help, but laboratory analysis of a gas sample will be required to provide certainty.**

5.5.2 On site monitoring

Gas monitors may be carried by individuals or a single monitor placed in a suitable position, where appropriate. The key guideline for siting monitors and alarms is that they must be located close to those who might be affected. For example, on a drilling rig the monitors should be sited close to the drill string and the operators, to ensure that the atmosphere being tested is the same as that to which the workers are exposed.
A monitoring regime needs to be designed to address the works being undertaken. The following are suggested criteria:

a) When drilling in confined spaces where pathways exist or potentially exist into underground workings (e.g. mine entries and boreholes), continuous monitoring in the working area close to the source is recommended. Personal monitors should also be considered for those operatives working within the confined space. Additionally, further tests should be carried out to check for layering of cold gas or blackdamp at ground level or methane in the roof of an enclosed area or at any open boreholes within the confined space. Exit routes from the confined space should be well defined, clear of obstruction and identified to those working in the confined space. Evacuation should take place in these circumstances, in the first instance, at gas concentrations at the trigger level rather than the action level due to the enhanced risk in these situations.

b) When drilling boreholes into shafts or mine workings, for the purposes of investigation, grouting etc, the following points should be considered:-

- Continuous monitoring at the drilling rig location (with appropriate alarm) at no more than 1.0m height near the drill string.

- If steel casings are being inserted and welded, then prior to each section of casing being attached, the contractor needs to monitor for gas within the mouth of the casing. The main risk is an explosion of flammable gas caused by contact with a flame. It is suggested monitoring 0.5m down the casing to obtain a meaningful reading. It is also suggested that any other adjacent boreholes should be monitored for flammable gas to indicate whether there is any in the immediate vicinity before drilling commences.

c) Boreholes which are left open temporarily for operational reasons (see d below) and which are in contact with workings, represent a potential route for gas and so should be checked periodically for potentially hazardous conditions. The interval for inspections should be based on the findings of the initial and ongoing risk assessment. It should be remembered that gas composition can change with time due to atmospheric pressure effects.

d) When a series of holes are being drilled such as when mine workings are being grouted or on a piling scheme prior to cast then pathways (boreholes) can be left open for short periods until the grout is injected or the concrete is poured. However the time between drilling and sealing should be kept to a minimum and where these two operations cannot be achieved concurrently temporary caps or bungs should be inserted into the hole. Where this has not occurred, low pressure events have caused temporary releases of gas.

e) Air flush drilling is the technique most likely to displace gases which may emit from adjacent pre drilled holes, or other pathways to the surface.

Monitoring of specific perimeter holes is unlikely to protect properties adjacent to the site. Whilst these holes may intersect mineworkings, other unconnected mineworkings and pathways may exist elsewhere.

All parties involved in the works need to be aware of atmospheric conditions and realise that under falling or low atmospheric pressure, gas more readily emits from the ground (usually
during adverse weather conditions).

The following table suggests trigger levels of gases, measured within the general working area, at which the drilling supervisor should be informed and he/she should make an assessment of the situation and determine suitable actions to take. The table also includes suggested action levels where drilling should cease and all personnel withdrawn from the affected working area. If withdrawal takes place there should be no return to the affected area until a competent person has investigated and assessed that it is safe to do so. Action should be taken to ascertain the cause of the threat and put mitigating measures in place. Mitigating measures should have already been considered as part of the emergency plan.

A suitable and sufficient risk assessment should be prepared taking into account the guidance and tables of alarm settings and responses contained within BS8576 – guidance on investigations for ground gas.

The carbon monoxide Action level has been suggested as a higher action level of 100ppm rather than the 200ppm STEL assigned by the HSE to take some account of the cumulative effects of the gas and ensure a more robust monitoring regime is in place. The trigger level for hydrogen sulphide has been suggested as 1ppm which, although only 20% v/v of the LTEL, would represent a very strong unpleasant smell. The table below should be considered as part of a procedure/emergency plan.

5.5.3 Off-site monitoring

There will necessarily be less control over off site locations, because they will be in land owned by others. A gas risk assessment should be carried out, based on a source – pathway – receptor model (see section 9.2), to determine whether there is a medium to high risk of gas migrating off site which might cause harm. If so the working method should be reviewed to determine whether the risk can be reduced. If not, then the contractor should arrange for monitors to be installed in adjacent, off site, occupied buildings which are assessed as being at risk.

Off-site monitoring will normally be in the form of alarms to provide immediate warning to those potentially affected. All those provided with alarms should be provided with clear instructions on what to do in the event of an alarm sounding. The precise actions will vary with the type of risk, but the instructions should set out:

- What they should do to make themselves safe in the first instance
- Who they should contact for further assistance. During operations this should be the site supervisor, but there should also be an out of hours contact in case of problems after work
has stopped on site. The out of hours contact should be able to arrange for someone to quickly attend the site to investigate the problem.

Alarms could be backed up with monitoring by staff visiting properties at intervals during the day and/or by continuously monitoring and logging results using a suitable instrument to provide a full picture of conditions during the full period of working including out of hours.

Depending on the particular risks, suitable alarms will be flammable gas alarms, carbon monoxide alarms and carbon dioxide alarms. The first two are available through retail outlets, but carbon dioxide alarms are usually more expensive and need to be obtained through specialist suppliers. In all cases the alarms should be calibrated where appropriate and within their approved lifetime.

In all instances and particularly where the risk assessment has identified a high risk of gas then competent specialist advice should be sought by those planning on undertaking the work.

6. The Influence of Flush and Injected Materials

6.1 Introduction

Any material that is injected into mineworkings will have the effect of displacing any gas that is already present within the workings. The amount of gas displaced will depend upon the volume of the displacing agent being injected.

The selection of a particular drilling fluid is normally based on the geology and structure of the site to be drilled, required fluid functions for the selected drilling method, fluid efficiency and productivity. Part of the selection process shall also include whether it will have harmful effects on persons, property or the environment – either directly or indirectly. Before final selection of a particular drilling fluid, the project risk assessment shall consider whether hazardous gases are likely to be present; could be created, or could be mobilised to cause harm by any of the preferred drilling fluids. A selected drilling fluid shall eliminate or minimise the risk of harm.

The flushing mediums most generally used are air, air mist and water. Beyond the potential oxidation of the coal causing spontaneous combustion, using air flush also has the capability of displacing large volumes of gas, as large pressures are required to flush out the spoil from the drill hole.

Conversely, water will have a cooling action and displace much smaller volumes of hazardous gases. It does have the disadvantages that a water supply needs to be available and also in weak strata it can cause erosion of the borehole. Although rare, the use of water has also been known to precipitate mine working collapses in nearby ground due to the washing out of supporting material.

Whilst the highest degree of displacement during drilling will come from the injection of compressed air, including air mist, the effect of inserting large volumes of non-compressible materials, such as grout, should also be considered.

6.2 Drilling fluid

Drilling Fluid is a fluid circulated through the in-hole drilling assembly. Its basic constituent may be air, water or mud or a combination of these. Main functions include carrying the cuttings from the drill bit to surface; cooling and cleaning the drill bit; suspending the cuttings; reducing
friction between the drill rods and the sides of the borehole; stabilising the borehole, and preventing fluid loss to the formation. The drilling fluid may also have the function of transmitting power to a bottom hole drilling tool e.g. DTH hammer, mud motor etc.

Many types of drilling fluid are used but they generally fall into a few broad classifications and variations.

6.2.1 Air flush

Compressed air is often chosen as the drilling fluid for rotary and rotary percussive drilling methods. It is supplied generally by mobile compressors, either owned or hired in by the drilling contractor. Some rigs have compressors mounted on board e.g. quarry and large waterwell rigs. It is efficient in cleaning the hole due to its self-expanding property but has a low specific gravity of close to zero.

To effectively flush the borehole the compressor must supply a sufficient volume of compressed air at an adequate pressure. The compressor capacity that is necessary is a function of the uphole velocity required to lift the cuttings to surface. An optimum uphole velocity is approximately 1200 metres / minute but will vary depending upon cutting size and density. If the drill bit produces large, high density cuttings then either the uphole capacity has to increase i.e. larger compressor required or the cuttings will be reground by the bit to a smaller size for uplifting.

Uphole velocity is calculated with reference to cutting size and density; annular space between rod outside diameter and hole diameter, and compressor free air discharge (FAD).

Note: Discharge volumes of compressed air i.e. compressor volume rating are always given as FAD which means that the air will occupy equivalent volume when the air pressure drops to that of standard atmospheric air.

Air Flush - hazardous gas risk assessment - Factors to be considered are:

- Fire needs an ignition source. Will the drill bit generate heat and / or sparks to cause ignition of coal? Air is not particularly effective as a substantial coolant
- Will the introduction of compressed air (which contains oxygen) fuel a fire e.g. coals already smouldering or liable to spontaneous combustion thus having the potential for creating hazardous gases?
- Air heats up when compressed. Compressors cool the air before discharge and normally have a discharge temperature gauge. Is the air delivered to the drill bit of sufficiently low temperature to cool the bit i.e. is the compressor working correctly?
- High volumes of compressed air will expand into voids e.g. old workings, broken ground etc. and may displace / drive existing hazardous gases in those voids. Where and how far will those gases be displaced to in relation to the source-pathway-receptor model?
- Is the compressor of a greater capacity than required to achieve sufficient uphole velocity? If so more air than necessary may be being introduced into the formation. This may be achieving greater drilling productivity at the expense of driving hazardous gases further away from the borehole
- Does the Coal Authority normally allow the use of this drilling flush for the type of project and the strata that is to be drilled?( See Appendix E)
6.2.2 Air Mist Flush

This is a variant of air flush. The principal constituent of the drilling fluid is still compressed air but water is added to increase the fluid viscosity, provide more cooling, assist in dust suppression, and provide a little more lubrication. A water injection pump injects small amounts of water into the compressed air delivery hose thus raising the specific gravity of the drilling fluid to about 0.2.

Because the air mist drilling fluid has higher viscosity than air it is more capable of “lifting” cuttings than compressed air. Cuttings of similar size and weight will not require the same uphole velocity as that required for air flush given that everything else is equal. Compressor capacity to generate the lower uphole velocity will therefore be less. One reason that air mist is selected for coring, for example, is that because of the decrease in velocity at the bit face there is less erosion of the core.

Air Mist Flush - hazardous gas risk assessment - Factors to be considered are:

Those in 6.2.1 as for Air Flush plus the following:

• what safeguards are to be employed if the water injection pump fails or the water supply is cut off?

6.2.3 Foam Flush

This is a variant of air flush in that the principal constituent is compressed air. However it can be considered to be a significant improvement in safety terms in that a significantly smaller capacity compressor is employed. Foam flush has the benefit of reducing the uphole velocity to as little as 15 metres / minute due to its great cutting carrying capacity.

Air is combined with a foam fluid. The latter comprises a small quantity of water and foaming agent which is prior mixed and then injected into the compressed air delivery hose by an injection pump. The ratio of foam fluid to air is about 1:150, and foam fluid usually consists of about 1% by volume of foaming agent mixed with water. The foaming agent may incorporate high molecular weight polymers which increase the foam bubble strength. The consistency of the foam flush is much like shaving foam when it emerges from the top of the borehole. It has an interlocking bubble structure of encapsulated air that provides its high lifting capacity. Some skill is necessary to adjust the consistency – too little foam fluid injection will result in the bubble structure not being formed and thereby loss of cutting carrying capacity.

One major disadvantage is the volume of foam that emerges at surface. This takes time to settle and drop its cuttings unless sprayed with water. Handling of the foam / cuttings waste is a major exercise which may explain why it is not more generally used especially in high production open holing.

Foam Flush - hazardous gas risk assessment - factors to be considered are:

• In general, foam flush may comprise the risks associated with air flush or air mist flushing with regard to hazardous gases there is the possibility that incorrect operation will effectively convert the flushing into air mist or air flush. This may happen if the mixing of the foam fluid is done incorrectly e.g. foam fluid is omitted or insufficient. It could also occur if the injection pump fails. Incorrect operation will usually be detected fairly quickly as no foam will emerge at the surface
• Environmental considerations and COSHH assessments

6.2.4 Water flush

Water by itself is often used in drilling. Being far more viscous than air it can lift cuttings at an optimum uphole velocity of 30 metres / minute, some 40 times less than air. A water flush pump is employed with capacity suitable to obtain this velocity for the specific drilling application. The capacity will vary between 45 litres / minute up to approximately 220 litres / minute. The water flush pump will also be able to generally provide up to 50 bar pressure.

While water is readily available in developed locations and relatively cheap, it does have the disadvantage of being expensive to provide in locations at relatively short distances from the water network. Unlike air flush and air mist it also has greater problems of control, containment and waste management on emergence from the borehole. It can be re-circulated in that the borehole returns are taken to cutting settling pits or tanks and the water (less cuttings) is then pumped back into the drill rods. In all cases this is the preferred flush medium where receptors are present within the risk area.

Water flush - hazardous gas risk assessment - factors to be considered are:

• water flush is a major coolant and therefore the drilling bit will remain relatively cold during drilling. It will also have the effect of damping any sparks.
• water flush will not contribute to the creation of hazardous gases as air is not being introduced into the unworked coal or coal workings.
• water flush is non compressible and will therefore only displace a volume, equivalent to its own, of gases that may be present within any voids or broken ground.
• water flush may not be suitable where major voids are anticipated, potentially resulting in the complete loss of flush fluids from the hole.
• use of water flush in situations where underground combustion is known to be occurring, will need careful additional consideration and planning to manage the potential generation of high pressure steam and other hazardous gases at the contact point.

6.2.5 Mud flush

Mud flush for the purpose of this guidance is the combination of adding any substance, other than foaming agent, to water to improve the latter’s capabilities during the drilling process. The substances may be naturally occurring e.g. bentonite, and / or naturally occurring polymers e.g. starches, guar gum etc., and / or synthetic polymers. There may be other chemicals e.g. potassium formate introduced into mud flush to achieve various effects. This guidance does not consider oil-based mud or synthetic-based mud, both of which are employed mainly in off-shore oil and gas operations.

Mud flush involves the mixing of substances with water and should be performed in accordance with the manufacturer’s / supplier’s recommendations. This will often include mixing plant. The mud drill fluid is then supplied to a mud pump which pumps the fluid into the drill rods (or borehole annulus on occasions). Mud flush is mainly selected because it has a high density which permits a low uphole velocity, and obviates the need for casing because it prevents hole collapse; prevents fluid loss to the formation, and is economical in use with re-circulation.
Mud flush - hazardous gas risk assessment - factors to be considered are:

- mud flush is a major coolant and therefore the drilling bit will remain relatively cold during drilling. It will also have the effect of damping any sparks
- mud flush will not contribute to the creation of hazardous gases as air is not being introduced into the unworked coal or coal workings
- mud flush is non compressible and will therefore only displace a volume, equivalent to its own, of gases that may be present within any voids or broken ground
- environmental considerations and COSHH assessments associated with the mud ingredients and possible loss of containment on return to the surface.
- mud flush may not be suitable where major voids are anticipated, potentially resulting in the complete loss of flush fluids from the hole.

6.2.6 Summary - drilling fluid influence

In conclusion, the selection of any drilling fluid with regard to hazardous gases is of prime importance. The “lighter” drilling fluid of air flush has the greatest potential to provide conditions for the ignition and / or support of an underground fire creating hazardous gases and / or the displacement / mobilisation of existing underground hazardous gases. Air mist shares the same potential and if not well controlled is considered to be a major source of risk. Foam flush contains a very slight risk if not controlled but is unlikely to create a hazard. Water and mud flush will have a negligible effect and can therefore be classed as having minimal risk.

6.3 Grout and other void filling materials

Most bulk infilling of mine working voids and broken ground is undertaken with grout. However, expanding foams are becoming more prevalent for smaller voids. Most grouts are essentially non-compressible and will therefore displace and move volumes of gases that are equal to the amount of fluid injected. Where grout is being used as bulk filler the volumes injected can be quite considerable.

With grout introduced through a gravity feed it is possible that any displaced gas will eventually migrate back to the surface through weaknesses or boreholes and as the process of infilling is gradual the effects are likely to be negligible. However if gases become trapped by the grout they could become pressurised and force a route to the surface. Grouting is usually carried out from the ‘down dip’ side of the site in an up dip direction which will displace any gases in an ‘up dip’ direction. Properties on the ‘up dip’ side of the site could therefore face an increased risk at this time and this should be accounted for in the risk assessment. The creation of a grouted perimeter curtain around the site could limit the ‘off site’ movement of any gas and allow for controlled ‘on site’ venting of any displaced gas.

Pressure grouting could also have the effect of pressurising and mobilising any gases within the voids, driving them to the surface, should a suitable pathway exist. Grout injected into the workings via a tremie with an open annulus between it and the casing could provide a preferential pathway back up the injection hole for any displaced gases.

Foaming agents are designed to expand as they are injected and will initially displace gases in a similar way to pressure grouting. However its use within former coal mine workings is generally limited to surface based collapses at the moment.

It should be noted that curtain material may be placed within mine workings as a barrier prior to the injection of grout, to prevent uncontrolled migration. It is unlikely that the placing of these materials will have any substantial displacing effect on the mine atmosphere.

The potential hazards involved with the injection of any bulk filling material should always be considered as part of the risk assessment.

6.4 Piling

It would be good practice for any mine working stabilisation work, using grout injection, to take place in advance of any piling technique. Piling can be split into three global groups, open bore,
closed bore and driven methods. Where the method involves the introduction of uncured concrete to the bore it should be remembered that this operation is carried out at relatively low pressures when compared with grouting; analogous to gravity feed methods. Secondly the concrete consistency used is relatively low in comparison. It should be noted that piling methods will only have the potential to act as a pathway when they come into contact with existing closed or open pathways. Should the technique remain within a zone unaffected by pathways, for example where a significant thickness of impermeable strata exists between the piling works and any mine workings, then no potential for ingress of gas exists.

6.4.1 Open bore piling

Sometimes known as bored or segmental flight auger, the boring and concreting are two distinct parts of the operation, As such in the time between boring or augering of the void and concrete placement there may be a period where the pile is left open and the possibility of a temporary pathway dependant upon conditions, especially if temporary or permanent casing is used. Where pile holes are in contact with unworked coal or mine workings they should be temporarily plugged and monitored for gas. These pile holes should be sealed at the earliest practicable opportunity, pending permanent sealing when the concrete is introduced,

Factors to be considered are:

- Will the introduction of atmospheric oxygen during the open bore phase cause a spon com risk?
- Are gases likely to vent through the open bore?
- Once concrete has been introduced additional pathways maybe closed

6.4.2 Closed bore piling

Continuous Flight Auger and auger displacement piling form part of this category. The operation differs from the above in that once at the required depth, concrete is introduced to the base of the bore under pressure and the tool only withdrawn when sufficient head of concrete has developed around the tool which effectively protects the pile from the ingress of gases. This operation continues until the pile is fully cast to final level. It is not anticipated that a significant pathway exists during this operation provided that sufficient head of concrete is present to outweigh any gas influx.

Factors to be considered are:

- Closed bore piling will not contribute to the creation of hazardous gases as air is not being introduced into the unworked coal or coal workings
- The method will only displace a volume equivalent to its own of gases that may be present within any voids or broken ground

6.4.3 Driven piling

This method usually takes the form of using a piling hammer to install preformed elements of either concrete or steel. In the same way casing can allow a pathway to develop so a driven steel tube has an increased potential for gas migration. Precast concrete units do not have this disadvantage. Where the pile driving is protracted due to the slow progress of the pile there is potential for a limited pathway to arise due to the small lateral movement of the pile, known as pile whip.
Factors to be considered are:

- Will prolonged pile driving lead to pile whip increasing the potential for a pathway to develop?
- Will prolonged driving of steel tubular sections result in heating of the element sufficiently to aid combustion particularly where sandstones are present?
- Will the introduction of the hollow tube allow contact between the mine gases and the atmosphere fuelling a fire e.g. coals already smouldering or liable to spontaneous combustion?
- The method will only displace a volume, equivalent to its own, of gases that may be present within any voids or broken ground
- Are the gases likely to vent through the hollow section?

7. Coal Authority Permit

7.1 Introduction

During privatisation of the coal industry in 1994 the Coal Industry Act transferred ownership of unworked coal and coal workings, including shafts and adits, (previously vested in the NCB & British Coal) to the Coal Authority. In the interests of public safety and to ensure the proper exchange of relevant information, the Coal Authority, as owners, requires that any activity which intersects, disturbs or enters any of its property interests requires its prior written authorisation.

This authorisation can take the form of a Licence, an Agreement, or a Permit, depending upon the nature of the activity to be carried out. The Coal Authority began issuing Permits in 1999 to regularise construction related activities which intersect its property.

The following activities may require a Permit and are dealt with by the Authority's Licensing and Permitting team:

- site investigation boreholes
- treatment of abandoned coal mine workings
- searching for, Investigation, treatment and sealing of coal mine entries (shafts and adits)
- piling through intact coal seams or coal mine working
- geothermal boreholes (within 300m of the surface and excluding operations involving the pumping of minewater)
- water wells (water supply boreholes)
- ground anchors penetrating intact coal or coal mine workings
- trial pits and other activities which intrude into intact coal or coal mine workings

Incidental digging of coal and commercial coal mining are dealt with by Agreements and Licenses respectively. Boreholes for Mine Water Heat Recovery, which pump and the re-inject minewater once commissioned, require Coal Authority Access Agreements. The drilling and short-term pump test evaluation phase can be regularised by obtaining a Coal Authority Permit.
7.2 Permit application process

Applicants requiring a Coal Authority permit are required to complete an application form, which sets out who is involved, the proposed activity and how any associated risks will be managed including completing a suitable and sufficient risk assessment. The process requires the holder’s agreement to the Coal Authority’s Permitting terms and conditions document which effectively makes the applicant responsible for any adverse consequences which occur as a result of their undertaking the permitted works, either by way of their actions or omissions for a period of 12 years. As an agreement is being entered into it is expected that the permit holder should have some interest in the surface property, for example, be either the landowner or developer.

Applicants can apply using the Coal Authority on-line form at:

https://www.gov.uk/get-a-permit-to-deal-with-a-coal-mine-on-your-property

Submissions should include the appropriate application fee, a plan showing the location, the proposed permit boundary, the extent of works and any supporting information. Alternatively, a downloadable Application Form is available which can be emailed to permissions@coal.gov.uk with the necessary plan and information. All relevant links can be found on the Coal Authority’s website using the link above.

An application is not deemed complete and will not be processed until all necessary information is provided and the appropriate fee paid.

7.3 Requirements

The Management Health and Safety at Work Regulations 1999 require a suitable and sufficient assessment to be prepared considering the risks to health and safety that their employees will be exposed to at work. This includes looking at appropriate sources of information, such as relevant legislation, appropriate guidance and seeking advice from competence sources.

The HSE consider that it is a reasonably practicable step for companies planning to undertake work in the vicinity of mineworkings to have undertaken a desk study prior to undertaking the proposed works. This study should consider the mining circumstances of the site and the immediate surrounding area, based upon, but not restricted to, the information contained within an appropriate Coal Mining Report.

Operations which invoke the Boreholes Sites and Operations Regulations 1995 should be aware that these regulations define a mining area as land which lies within 1 km in any direction of the workings of any mine whether currently being worked or disused, or land in relation to which a licence to mine minerals has been granted.

Applicants should reduce risks to public safety arising from their proposed works by considering their location in relation to potential receptors, the method of work, the site-specific mining circumstances, the hazards of the site and its surroundings, the sequencing of the work and any additional risk mitigation measures that might be necessary.

When submitting an application, the applicant is expected to review the coal mining information available and carry out a risk assessment of the proposed works using the Source-Pathway-Receptor model around which the required responses are designed. Any proposals deemed by the Coal Authority to be high or medium risk will be referred back to the applicant for further
Under no circumstance should any intrusive activities take place which knowingly enter or disturb the authority's property without first obtaining a permit.

Undertaking works without permission constitutes trespass with the potential for court action and could adversely affect the sale of property and its value. Furthermore, home warranty and household insurances could be adversely affected and Planning Permission may be prejudiced. In the case of an accident or environmental incident occurring, if it is established that a contractor has knowingly undertaken work which was advised against by a competent authority, or has knowingly circumvented authorised schemes designed to ensure safety and protect the environment, this may be seen as an aggravating factor in any potential prosecution of the company.

Upon completion of the proposed works, applicants are required to submit the factual details of the works carried out, in the form of a completion or validation report, to the Coal Authority's Permitting Team. Where interpretation and recommendations are being provided to inform a remedial strategy and/or support a discharge of a Planning Condition in respect of mining legacy this information should also be reported the Permitting process requires this In order that nationally important information referred to in its Mining Reports is appropriately updated, where required.. Site works are considered to be ongoing until full completion reporting is received by the Coal Authority. This should be submitted within 3 months from completion of works or as agreed with the Coal Authority where a single permit covers a phased development scheme, within reasonable time limits.

8. Desk Study

8.1 Elements to be considered

A desk study should be carried out before any drilling or piling operations take place and should form part of the pre-construction information (PCI) under the CDM regulations 2015. Beyond the normal requirements to establish the location of services, identify any environmental issues etc, the drilling location needs to be assessed for potential risks from unworked coal and coal workings, and potential hazards identified, especially mine gas.

The desk study needs to identify, amongst other things:

- the depth and position of any known or possible unrecorded mine workings
- whether the seams are prone to spontaneous combustion. A list of seams that are known to have had spontaneous combustion incidents in the past is available on the Coal Authority's website at: https://www.gov.uk/government/publications/coal-seams-with-a-history-of-spontaneous-combustion
- whether there is a history of mining related gas problems in the area
- the nature of the strata above the workings or coal seams including layers of clay and any made or permeable ground
- zones of geological disturbance
- the presence and location of any mine entries
- the location of any existing properties, services, assets or other receptors close to
• other underground features e.g. ground water levels and mine water levels including their trends
• are the mine workings dry, flooded or partially flooded with water?

Further information on what is required from a desk study is available through the AGS publication ‘A Client's Guide to Desk Studies’: https://www.ags.org.uk/item/clients-guide-to-desk-studies/

The information gathered from the desk study should be used to formulate a conceptual site model (CSM) to gain a holistic view of both the surface and the underground environment. The conceptual site model should be updated as new information becomes available.

8.2 Sources of coal mining information

The Coal Authority holds an archive of approximately 118,000 old mining plans and a register of approximately 172,000 former mine entries. This information is disseminated to the public via its mining reports service. The information provided by these reports is a fundamental building block for the start of any desk top or other feasibility studies and any risk assessments necessary when planning proposed works.

Furthermore, the Coal Authority has defined specific ‘Development High Risk Areas’. These are areas, based upon Coal Authority records, where the potential for land instability and other safety risks associated with former coal mining activities are likely to be greatest. They include, for example, areas of known or suspected shallow coal mining, recorded mine entries, past surface mining hazards and areas affected by mine gas. Further information is available using our interactive viewer at:

http://mapapps2.bgs.ac.uk/coalauthority/home.html

The Coal Authority’s abandoned mine plans and other mining records can also be viewed, by prior appointment, at its Mansfield offices. Further information is available at;

It should be noted however that a significant proportion of shallow mineworkings have no plan record of their existence. There was no obligation on mine owners to make plans and deposit them with the Mines Records Office until 1872 by which time many millions of tonnes of coal had been mined. Furthermore many of the early mine plans are of variable accuracy and standards and their interpretation can require considerable expertise.

As a general rule it should be assumed that if coal of a workable thickness exists then there is a good chance that it may have been mined at some time in the past.

As part of the process of obtaining the Coal Authority's permission to enter or disturb its coal and mining interests, known mining hazards, which may influence the site, will be brought to the attention of the applicant.

Other important sources of information include:

• Coal Authority online Interactive Viewer
• coal industry technical publications
• Ordnance Survey plans
• geological plans
• British Geological Survey (Data, records, memoirs and archives)
• local authority plans / records
• aerial photo’s, National Archives, Ordnance Survey, Bodleian Library
• Network Rail / British Waterways/ Highways Agencies
• private / local company archives and records: mining reports / ground investigations / geotechnical consultants / mining engineers and surveyors
• landowners records
• public libraries and archives
• local history and archaeological groups/societies
• Public Records Office, National Archives
• mining museums and societies /speleological societies
• internet search
• local mining and historical publications
• Deputy Gaveller (Forest of Dean)

9. Risk Assessment

9.1 Introduction
Risk assessment is the systematic assessment of specified risks, based on their probability of occurrence (often referred to as likelihood), combined with the severity of consequence (often referred to as impact). The probability of an event occurring is not to be confused with a statement of risk in this context.

It would be anticipated that any drilling or piling project desk study would include an element of risk assessment to identify significant risks associated with the proposed works, including, but not limited to those associated with mine gas.

9.2 On site risks
There are three principal locations in which hazardous gas may result associated with drilling and piling works. These are:

• emissions through the top of the borehole or around the pile close to the rig during or immediately after those operations
• emissions from previously drilled boreholes or existing pathways, natural or man-made, linking either the unworked coal seam or coal mine-workings and the surface or a receptor
• spontaneous combustion of a coal seams or remnant coal resulting in the creation of carbon monoxide as a product of that combustion – See section 5.2
9.2.1 Emissions at the Rig

Whilst drilling or using open bore or some driven piling techniques, the greatest risk comes from entering a void or permeable ground containing a volume of gas at pressure. In this case there could be an outburst of gas into the working area. The possibility of this is difficult to exclude unless it is known there are open connections which exist into the workings which are being drilled into. The risk is likely to be higher in areas where mine water levels are known to be rising. The risk is also likely to increase with depth as the likelihood of a connection to the surface is likely to decrease with depth and in the first borehole to penetrate any workings, void or natural migration barrier to the surface. Clearly working within a confined area will greatly increase exposure to the risk and suitable mitigation measures would be required to provide protection in these circumstances.

Where blackdamp is contacted, this can give rise to the risk of asphyxiation. In low oxygen atmospheres unconsciousness can occur very rapidly and it is important that people are removed from such an atmosphere as soon as possible. This is particularly the case where the working area is a confined space, such as within a building. In these circumstances a dangerous atmosphere would remain in place for a long time rather than being dispersed as it would be in an outside environment. Care should be taken to ensure that routes of egress are clear and short. In certain circumstances where the risks merit it, breathing sets may be appropriate. The risks in these types of situations should be controlled by a Permit to Work procedure.

The risk from flammable gas, of which methane is the most likely to be contacted, is an ignition or explosion. For more information on managing the risk of flammable gas see BS 8576: 2013, guidance on investigations for ground gas.
Where high concentrations are found above the Upper Explosive Limit of 15% v/v it should not be assumed that the gas is safe. The gas will still burn at the interface and can be diluted into the explosive mixture due to mixture with air. The effects of such an event can be very sudden and it is therefore very important that people move to a point of safety at the first sign of flammable gas. It should also be borne in mind that the volume of the flame produced by an ignition is many times that of the volume of flammable gas that produced it. Again the risks are increased where working within a confined area as egress may be more difficult and the effects of an ignition in a confined area more damaging. Beyond the risk of the direct effect of an ignition on those within range there is the potential to cause secondary burning of the operatives clothing or other equipment and property. There has been a recorded instance where a rig and operative was set on fire when a smoker ignited methane near an open hole which had just been drilled. Where flammable gases are possible no naked lights, smoking, or storage of flammable liquids should be permitted within a minimum of 15m of the borehole (see also section 10.4).

Suitable blowout control equipment shall be provided for use during borehole operations where there is a significant risk of encountering pressurised fluids (as discussed above).

Well control equipment should be suitable for the type of operation being carried out in terms of size, connection type, pressure, temperature and the chemical properties of the formation fluids which may be encountered. It should be designed, constructed, installed, commissioned, used and maintained in accordance with appropriate recognised standards.

Blowout prevention equipment should be capable of isolating all possible routes from the well to the surface. It should cater for contingencies when drillpipe, casing, lining or other strings of equipment pass from the surface into the well. Suitable provision should be made to prevent uncontrolled flow of the well through or around that equipment. The blowout prevention equipment should be readily available for immediate use in an emergency.

9.2.2 Emissions from previously drilled boreholes and other pathways

Previously drilled open boreholes are a potential contact to dangerous atmospheres below ground. While drilling using air flush the mine atmosphere is likely to be displaced and diluted in the vicinity of the hole once air is introduced into the workings. Nevertheless, after a period of time gas can migrate to the surface through these holes due to naturally induced pressures or through convection of the gas in the holes. Alternatively, if the holes contact workings, drilling of another hole in the vicinity can displace gas up the holes through injection of water or more especially air. For this reason it is important to monitor any open holes during drilling operations that could pose a risk to the Public or operatives. It should not be assumed that holes are safe because they have been safe at some time previously. Again this is particularly the case in a confined environment if there are open holes within a building for example. Where holes need to be left open, temporary caps or seals should be considered to reduce the risk. Where boreholes are to remain in use a sampling point for gas should be incorporated in the borehole cap.

Where other possible pathways are likely to exist on site, between the mine workings being drilled and the surface e.g. mine shafts, the risk of gases being displaced via these pathways should be considered and monitoring undertaken as required. However it is likely that in many cases the location of such pathways will be unknown or uncertain and in such cases monitoring may not be practicable.
9.2.3 Spontaneous combustion

Some materials and substances, including most types of coal, will start to oxidise when exposed to air. When there is sufficient oxygen to cause the substance to oxidise and give out heat, but insufficient flow to carry away the heat quickly enough, the temperature will start to rise leading to further increases in the rate of oxidation, rate of heat output, and the rate of temperature rise. This can lead to the spontaneous burning (or combustion). Before any drilling operations commence which may contact an unworked or remnant coal, efforts should be made to establish whether a particular seam is known to be prone to spontaneous combustion. The Coal Authority website contains a list of those known in the mining industry and those which recent laboratory tests have been shown to represent a medium to high risk. See section 5.2 for more details.

9.3 Off-site risks

Potential receptors, both on- and off-site, should be identified and their sensitivity assessed. Off-site risks arise principally from the movement of dangerous mine gases onto adjacent land and into properties. Such gases can move through the atmosphere, but this is only likely to represent a problem where there are very large flows of gas. The more relevant risk is produced by the movement of gas through coal workings and other pathways and its subsequent displacement into adjacent properties.

The risk of off-site gas emission as a result of drilling operations arises primarily as a result of displacing the mine atmosphere by use of the flushing medium used in drilling.

Although carbon monoxide has been identified as a real and significant hazard, other mine gases could migrate in a similar fashion and provide the risk of methane, carbon dioxide or low oxygen atmospheres entering property. It should not be assumed that the use of air as a flushing medium will clear away other gas and therefore provide a clean environment. Tests have shown that even over short distances injecting air into a borehole moves existing mine atmospheres rather than replacing them.
The aim of the risk assessment is to identify whether there is an increased risk of gas entering adjacent properties due to operations: If there is a source, a potential pathway and a potential receptor then the necessary preconditions are in place. The risk assessment should define the ground gas sources, the sensitive receptors (persons using the building, and the building structure and fabric) and the pathways between the sources and receptors. In these circumstances gas could potentially migrate naturally. However, the risk assessment should identify any increased risk due to the presence of additional motive force created by drilling operations. In the case of piling it is unlikely that this will have significant influence due to the relatively low flow and high stiffness of the grout or concrete.

A motive force can be produced by injection of fluids such as air, water and grout into permeable ground and mine workings. The injection of these fluids has the potential to displace volumes of gas and increase pressure to allow the flow of gas through pathways.

Areas of ground which are at highest risk of mine gas are those which lie:

- on or in close proximity to a mine entry
- on or close to shallow mine works
- deeper areas of made ground, or landfill, infilled railway cuttings
- shallow made ground
- shallow infill ponds
- peat layers or layers of other organic material
- alluvium, chalk or other natural soils
- on fractured or broken ground connected to mine workings
• on a collapse which results in connection to mine workings or ground which is prone to such a collapse
• on opencast backfill
• on made ground and permeable strata directly above mine workings

Lower risks will be associated with an absence of these factors. Also if it is known that potential pathways, such as mine workings, are totally flooded it would have a large mitigating effect on the risk. However in reality it is very difficult to definitively prove that mine workings are totally flooded and that no pockets of dry roadways exist without detailed knowledge of the workings and a thorough understanding of the hydrogeology in the area. It should be noted that ground water levels will not, in many cases, correspond with the water levels in the mine workings. Other pathways may include:

• shafts, adits or other openings to mine workings
• fractured rock
• soil or rock above mine workings if it is sufficiently permeable to allow gas to migrate to surface
• migration via stone columns or around some types of piles
• pathway only exists if soil above peat is sufficiently permeable to allow gas to migrate to the surface
• open or poorly sealed boreholes

The risk assessment should estimate the likelihood of:

• whether there is a risk of mine gases being present in any unworked coal or coal workings contacted during operations
• whether carbon monoxide might be created
• the existence of pathways from source to surface which might allow the passage of gas.
• gas entering properties if it were to reach the surface

It should be based on a source – pathway – receptor model and needs to identify if the necessary conditions are in place and whether the proposed operation might enable the gas to enter properties at concentrations which will cause harm. All potential pathways should be identified, which includes natural geological pathways, services, underground structures and mine workings. Pathways that are not credible should be discounted.

Where it is not possible to define whether there is a likelihood of any of the above conditions then it must be assumed that there is a potential for them to exist and suitable mitigating control measures must be implemented
10. Practical measures

10.1 Introduction

If it is anticipated that a drilling operation will encounter unworked coal or former coal mine workings, including shafts and adits, particular risks to site personnel and members of the public must be considered. Precautions to protect those working on the site and any others who may be affected by the works will need to be evaluated before work commences.

Dangers from inhalation of hazardous gases, collapsing ground, ignition of coal seams and migration of gases both within and beyond the site need particular consideration. Practical measures to alleviate or control risk should be taken by the specific duty holders under CDM e.g. the Client, Principal Designer, Designer, Principal Contractor and Contractor.

These measures are intended to focus attention on planning and management of the drilling or piling works from design concept onwards. The aim is to ensure the safety of operatives, the Public and property from hazardous gases.

10.2 Pre-Tender Stage

This is the stage prior to inviting drilling or piling contractors to bid for the work. The Client (see section 4.2.1) or their appointed agent has a duty, under the CDM Regulations 2015, to provide pre-construction information (PCI) to be supplied with any invitation to tender for drilling or piling works. The PCI is information already in the client's possession (such as an existing health and safety file, coal mining information, gas information etc.) or which is reasonable to obtain through sensible enquiry. The information must be relevant to the project, have an appropriate level of detail and be proportionate to the nature of the risks. In particular details of anticipated ground conditions, underground structures or watercourses that may affect the safe use of drilling machines and site personnel should be listed. This also includes safety hazards which have the potential to affect adjacent land or occupants of adjacent properties. Other hazards such as buried services should also be identified.

It is recommended that a desk study is carried out. The desk study should be used to develop the preliminary conceptual site model that guides the approach to assessing risk on a site and the requirements to determine;

- underlying geology of the site
- whether coal seams are present
- whether the coal seams are known to be susceptible to spontaneous combustion
- presence of shafts or workings
- dip and strike of the strata
- potential gas migration pathways
- potential gases that may be encountered or produced
- proximity of properties and occupancy potential beyond the site boundaries
- site classification (green, yellow or ted according to BDA/SISG guidelines)

From the desk study (see Section 8) the principal safety hazards will be identified and forwarded in the pre-construction information pack for potential contractors to consider. Please note that
information on the coal seams underlying the site should be compared to the named seams on the Coal Authority web site under spontaneous combustion as per Section 5.2.

It is the Client's responsibility to apply for a Coal Authority permit and this is best done at either the pre or post tender stage. Only those who have a long term interest in the drilling or piling works should apply for permission as the applicant must take responsibility for the works and indemnify the Coal Authority for a period of 12 years.

In the urban environment the risk assessment will usually dictate that water flush drilling techniques are required for exploratory or remedial drilling. However it is recommended that Clients obtain the Principal Designer's advice and/or the Designer's advice on drilling methods before applying for permission.

The Coal Authority will only grant a permit when it is satisfied that the applicant has applied suitable safeguards to mitigate the potential hazards from unworked coal and coal workings and it is not uncommon for proposed methodologies to require alteration before a permit can be issued.

It is important that sufficient time is allocated for a permit to be granted and for the agreed methodology to be incorporated into the pre-construction information to be provided to the Principal Contractor and/or Contractors at tender stage. If the bidding contractors are unaware of the agreed methodology then bids submitted may vary and may not be directly comparable. This could result in a bid being incorrectly awarded which could in turn carry financial and contractual issues.

Refer to Section 7 for further details on procedures for permit applications to The Coal Authority.

The Contractor should ensure that permission has been obtained before commencing site works.

All drilling or piling works which require a Coal Authority permit should be formally contracted between the Client, the Principal Contractor and the Contractor. Such contracts should be in writing and clearly identify the responsibilities of each party with regard to hazardous gases either on-site or off-site. There should be clear agreement within the contract(s) as to the course of action and by whom in the event of hazardous gases posing a risk to site operatives, the Public or property.

10.3 Planning of Works Prior to Site Operations

This is the stage after contract award when the Contractor will plan for the works using the pre-construction information supplied at tender stage.

The successful Contractor will review the supplied information to determine the coal hazards that could be present, as part of their construction phase plan, risk assessment and method statement preparation. The Contractor will provide the Client with its construction phase plan, risk assessments and method statements.

The client must ensure that a construction phase plan for the project is prepared before the construction phase begins. The construction phase plan outlines the health and safety arrangements, site rules and specific measures concerning any work involving the particular risks identified. The risk assessment shall include a review of both the on-site and off-site
conditions and those who may be affected by the site works.

If there is a risk of gas entering properties, controls need to be put in place. Controls available include:

- the method of drilling – consider whether techniques that do not use a flush medium are suitable
- the flushing medium – water flush will displace smaller volumes of gas
- monitoring holes will not prevent gas migration, but monitoring might indicate whether dangerous gases are present

Where the risk of mobilising and displacing mine gases cannot be eliminated, mitigation measures must be put in place. The principal mitigation method is to install gas alarms in properties which are potentially at risk. Monitoring of gas levels may also be considered to identify any gas ingress below alarm threshold levels. Where there is a significant risk of harm or where the occupants are vulnerable, evacuation should be considered as an alternative.

Measures to be planned for could include but not be limited to;

- appropriate Personal Protective Equipment (PPE) for site workers
- appropriate Respiratory Protective Equipment (RPE) for site workers
- gas monitoring equipment and procedures (see Section 5.5)
- gas alarms
- suitable and sufficient material on site to seal boreholes in an emergency
- evacuation procedures
- fire control measures e.g. no naked lights, smoking, flammable liquid storage
- shutdown procedures
- blow out preventer
- first aid
- training

The Contractor should use the drilling flush method stipulated in the application for the Coal Authority's permission. If the Contractor considers from the risk assessment that a different drilling flush could be used safely, an application for an amendment to the Coal Authority permission shall be made and agreed prior to changing the flush method.

If off site gas monitoring is identified by the risk assessment then monitoring and early warning systems should be implemented where practicable and permitted. In all circumstances where monitoring equipment or alarms have been installed the Contractor shall ensure that the occupant has been briefed on their operation and has understood the requirement for them.

If an occupier refuses to allow gas monitors then the Contractor must reassess the risks and if required adopt other suitable mitigation measures. If the risks cannot be effectively mitigated and significant danger to the public remains then work must not proceed.

It should be noted that monitoring of specific perimeter holes is unlikely to protect properties
adjacent to the site. Whilst these holes may intersect mineworkings, other unconnected mineworkings and pathways may exist elsewhere.

10.4 Management of On-Site Works

This is the stage when the Contractor should ensure that the planned safe systems of work are strictly followed during site operations and that a copy of the Coal Authority permit is present on site which includes relevant site specific conditions. The Contractor should not commence work until emergency contingency plans are in place both on and off site as required.

Where flammable gases are possible no naked lights, smoking, or storage of flammable liquids should be permitted within a minimum of 15m of the borehole. This zone can be extended should the risk assessment or prevailing conditions dictate. Consideration should be given to the direction of the wind. Suitable warning notices should be posted warning of the restrictions and dangers.

If the safe system of work includes gas monitoring equipment then the equipment should be available on site and used by trained personnel to monitor the works. Refer to Section 5.5 for details. Gas monitoring must be undertaken at the top of the borehole prior to starting the rig or other plant to ensure the absence of flammable gases.

Where the borehole position has to be fenced off then escape routes must be set up and kept clear while drilling or piling operations are continuing.

Emergency control measures should be ready to be implemented if required.

10.5 Monitoring

Refer also to Section 5.5

This is the stage when the Contractor should ensure that the planned gas monitoring is strictly followed during site operations and from the start of drilling operations into permeable strata.

Prior to any gas monitoring the Contractor should ensure that the monitor is calibrated with inspection certificates available for inspection and that the appropriate drill crew are trained to operate the gas monitoring equipment. It is recommended that a reading is taken in fresh air to check that the sensors are reading correctly. When drilling into any unworked coal or coal workings this guide recommends that monitors / alarms should routinely sample for carbon dioxide, carbon monoxide, methane and oxygen. Carbon dioxide readings can be inferred from low oxygen readings which usually have a direct correspondence, but this is not always the case and slight changes in displayed oxygen concentrations are not uncommon in monitors. The presence of hydrogen sulphide is very rare and is apparent by its smell even at very low levels. Hydrogen is also very rare within mineworkings and can be monitored indirectly by a combustible gas meter if this gas is suspected. Should a flammable gas be recorded by this means and there is little or no methane then hydrogen may be present. Laboratory tests would be required to confirm the identity of the combustible gas.

If hazardous gases are expected to be encountered and the boreholes are close to the site boundary or adjacent properties then monitoring boreholes around the perimeter may be beneficial, in addition to the monitoring of the properties, when using air or air/mist and these should be monitored when coals or workings (broken ground) are encountered in the “production” borehole.
If hazardous gases are detected at either the top of the borehole or at any of the monitoring points then awareness of a potential gas problem will be heightened. If gases are detected in the general working area, in concentrations above the trigger levels (see Section 5.5.2.1), or if any of the gas alarms are activated then the drilling supervisor should be informed and he should make an assessment of the situation and determine suitable actions to take. Where the concentrations detected in the general working area exceed suggested action levels, drilling should cease and all personnel be withdrawn from the affected area. If withdrawal takes place there should be no return to the affected area until a competent person has investigated and assessed that it is safe to do so.

Where gas monitors/alarms are fitted inside buildings, on or off site, these should, where practicable, be inspected by the Contractor's site management at the time of any hazardous gas levels being detected on or off site. Those inspecting the gas monitors/alarms should carry personal gas monitors and test the atmosphere before entering any building, basement or room. If gas monitors within buildings cannot be inspected at this time e.g. locked residential housing, then this should be noted and provision made to alert occupants, before they enter these properties, to immediately check for elevated gas readings.

Hazardous gases are sometimes encountered under pressure when drilling and piling and it may be necessary to allow a hole to vent for a while until the pressure in the mineworkings drops and the emanating gas reaches safe levels. In circumstances where high levels continue a decision may have to be made to seal the borehole.

Gas monitoring equipment installed inside buildings should have suitable alarms to warn the occupants to take action and this may include the provision of special alarms for occupants with hearing difficulties. All such equipment must be calibrated and maintained, in good working order.

10.6 Rig operations

This is the stage when the contractor should start work after implementing all identified safe systems. Before commencing work all site personnel should have a site induction. The induction should include, but not be limited to, the hazardous gas information and instructions contained in the Construction Phase Plan. If required by the Construction Phase Plan, persons off site who may be affected by the works should be informed of precautions prior to operations commencing. Where warning alarms and monitoring is required then it should be in position and operable prior to operations commencing. All drilling crew should have basic hazardous gas training and should be aware of the recommended trigger levels. All on site personnel should have appropriate PPE and RPE (as identified by the risk assessment).

When drilling into coal seams where the depth of coal is definitively known the Contractor may choose to employ a different flush prior to encountering the coal, former workings or overlying broken ground and permeable deposits (e.g. air flush through superficial deposits and water flush through rock). The switch to the agreed flushing medium, as specified during the obtaining of the Coal Authority permit, must be made in a timely manner to ensure a suitable standoff distance is maintained between any potentially hazardous areas and the drill bit.

10.7 Spontaneous combustion

If a seam is likely to be contacted which could be prone to spontaneous combustion then air based flush should not be the primary method used to drill the holes. In practice this will usually
be water flush. Depending on the other drilling risks, there may be occasions when air flush drilling cannot be avoided, but in such circumstances there must be strict monitoring of the holes (along with any other precautions which the risk assessment determines) to determine if any signs of combustion are apparent. If any such signs are noted then the holes must be sealed and to this end grout and suitable equipment must be available on site to enable this to take place without delay.

Where conditions of a possible heating are detected management should be informed immediately. If still drilling, the drill flush should be switched off, and where it is safe to do so CO should be continuously monitored, the drill string should be removed and the rig moved off the borehole position. Open holes and any coal workings encountered should be grouted without delay to seal the fire from the air/oxygen. Consideration should be given to the inclusion of down hole temperature sensors to monitor the situation and ensure that the heating has been confined.

**DO NOT INSTINCTIVELY INJECT WATER INTO A COAL SEAM WHICH IS ON FIRE.** Water added to burning coals can dissociate, releasing oxygen and hydrogen leading to an uncontrolled and unpredictable explosion. No further drilling should be undertaken other than for controlling the fire/heating and this should only be undertaken following a specialist risk assessment.

The Site Manager/Engineer should arrange for a site meeting to inform all interested parties of the situation and co-ordinate an action plan to control the heating and assess the implications on properties adjacent the site, including hazardous gas migration, especially up dip from the incident. The Site Manager/Engineer should also ensure that the Fire Brigade has been notified and informed that water is unlikely to be an appropriate medium for extinguishing a coal seam fire.

Long term, monitoring will also be required to ascertain whether the heating has been controlled, which could involve the drilling of monitoring holes nearby.

**The Site Manager/Engineer must inform the Coal Authority of any incident at the earliest practicable opportunity.**

10.8 Borehole backfilling

Where multiple or singular workings/voids are expected to be encountered a robust method of backfilling must be identified and put into place to allow the entire borehole to be backfilled prior to mobilising to site. In the event (an) unexpected multiple or singular workings/voids are encountered during drilling the following backfilling procedures, listed in order of priority should be adhered to:

a. grout each working/void [with full consideration given to expected/anticipated nature of geology and condition of working/void; (dip, presence of mine water)] in such a manner as to allow tremie grouting and backfilling of the complete borehole column from full depth of the borehole to surface

b. each working/void should be plugged using an inflatable or similar robust device/method to form a good seal/plug to allow the borehole to be tremie grouted to the next working/void above/ground surface

c. plugged at the top of the shallowest working [to minimise the potential for gas migration into porous/fractured/permeable strata lying above/up dip of the
working/void] and tremie grouted to surface where plugging each working/void is not achievable

For the avoidance of doubt:

- step (a) must be attempted first with attempts detailed on drillers journals and site records. A record of grout used should indicate whether backfilling has been successful through comparison with theoretical volume of grout Vs actual quantity of grout used.
- step (b) should only be attempted where step (a) has been demonstrated to have been attempted and unsuccessful. The success of any seal/plug installed will be indicated by comparison with theoretical volume of grout Vs actual quantity of grout used.
- step (c) should only be used where steps (a) and (b) have been demonstrated to have been attempted and unsuccessful. As in steps (a) and (b) above, the success of any seal/plug installed will be indicated by comparison with theoretical volume of grout Vs actual quantity of grout used.

Any borehole that has encountered a working/void should not simply be plugged at rockhead. Any workings/voids encountered should not be left open/unsealed appropriately. As a minimum, any borehole should only be plugged at the top of the shallowest working where it has not possible to backfill the entire borehole column as indicated in steps (a) and (b) above. Evidence of attempting steps (a) and (b) above should be recorded and included in drillers journals and any reports issued.

10.9 Off-site considerations

The Contractor must consider the risks from hazardous gases being present in and around coal seams and former mineworkings and also from the operation spontaneously combusting (heating) the coal. This will also produce hazardous gases, which, dependent upon the flush being used, can move gases over considerable distances and possibly off site.

Due to this potential for hazardous gases to be forced out beyond the site boundaries the Principal Designer (where appointed), Designer, Principal Contractor (where appointed) and Contractor must also consider the risks to those beyond the site boundaries before work commences.

Different types of occupiers will have different risks. Those in commercial properties may be less at risk than residential occupants. Commercial building occupiers may accept hazardous gas monitoring and be suitably trained to respond to any alarms. Doors and windows may be opened providing some ventilation. Residential property occupiers may not be willing to have hazardous gas monitoring installed in their homes and may have their doors and windows closed for long periods during the day. Alarms installed in residential properties may have to alert sleeping occupants or those with hearing and mobility issues.

Given the unacceptably high risks to members of the Public, the prevention of the production of hazardous gases and the forcing of hazardous gases off site into adjacent occupied residential buildings should be prevented.

The distance gases can be forced along coal seams or workings is not able to be calculated with any reasonable degree of certainty. On very limited tests, at one site, indications were that under certain specific conditions the flow from the air flush drilling was not detected in test
holes much beyond 50m. It has to be emphasised that the results were specific to the ground conditions at the particular site and cannot be considered representative of other sites (see Case Study 4).

Air flush drilling has the greatest potential for causing gas migration, with the greatest impacts likely through fractured coals rather than open worked seams. There is also the potential for the flush to follow the fractures in seams which can outcrop beneath property, excavations, sewer systems, culverts or other sub-surface structures, presenting risks to personnel who may be working or living in the structures. Other structures that could be at risk from hazardous gases, particularly flammable ones, are lighting columns.

The examples given are not exhaustive and a risk assessment of the risks to any structures adjacent to the site needs to be undertaken and appropriate mitigation controls considered.

10.10 Emergencies

An emergency plan must be in place which should take into account the risks of spontaneous combustion, and hazardous gases emanating off site where property exists.

The Emergency Plan must be suitable for dealing with the risks identified in the site construction phase plan and associated risk assessments and be able to be implemented immediately.

The Site Manager/Engineer or Drilling/Piling Supervisor should have access to a list of emergency contact names and telephone numbers from where they can obtain advice and report abnormal situations.

Consideration must be given to the evacuation of properties at risk and the possible requirement to house residents in temporary accommodation.

If methane or coals ignite, the Drilling/Piling Supervisor should immediately notify their Manager.

Injured personnel should be treated by their First Aider. A BDA Audited Lead Driller is qualified in first aid; however, if they are injured or the injured person has suffered significant injuries the Ambulance Service should be called immediately.

In the event of an underground heating, the Site Manager/Engineer or Drilling/Piling Supervisor shall contact the Fire Brigade stipulating that water is unlikely to be an appropriate medium for extinguishing a coal seam fire.

If any flames at the surface are perceived to be moderate to low then attempts to extinguish the flame using carbon dioxide or powder fire extinguishers may be attempted, but it should be recognised that the source of the flames may be many metres down the hole and as such this may have little effect on the fire.

Where the borehole site needs to be evacuated other site personnel should be informed of the incident and the need to clear the borehole site. Where necessary, especially if boreholes are to be left to vent overnight, the borehole site should be fenced, with suitable warning signs posted, to prevent unauthorised personnel accessing the area where they would be at risk.

The Site Manager/Engineer must inform the Coal Authority of any incident at the earliest practicable opportunity, using the Coal Authority’s emergency call-out number 01623 646333.
10.11 Reporting and recording

The method and date of boring, water strikes, flush and prevailing strata found during boring operations will be recorded by the Drilling/Piling Supervisor in their company's record sheet. The subsequent method of backfilling should also be recorded in the borehole logs (see Section 10.8).

The Drilling/Piling Supervisor or Site Engineer will monitor the gases from the hole and record the results. Additionally the atmospheric pressure and flow of gases at the borehole head should be noted.

The following gases are to be recorded; methane, carbon dioxide, oxygen and carbon monoxide. Where there is reason to suspect other gases these should also be determined e.g. hydrogen sulphide, ethane, propane and hydrogen. If a flammable gas monitor is used and detects gases and there is little or no methane found by the other method then hydrogen may be present. Minor gases generally require a sample to be submitted to an Analytical Laboratory for chromatographic analysis.

Significant incidents such as emissions of hazardous gases into property or spontaneous combustion should be reported to the Coal Authority at the earliest practicable opportunity, using the Coal Authority's emergency call-out number 01623 646333. Furthermore such incidents along with gas monitoring results should be included within the validation/completion report which is required to be sent to the Coal Authority under the terms and conditions of a Permit. Site works are considered by the Coal Authority to be ongoing until a completion report is received.
Appendices

Appendix A - Case Studies

Case 1

Following reports of subsidence below a large pharmaceutical works in the north east of England the Coal Authority was called upon to investigate and subsequently carry out remedial stabilisation grouting under the occupied control building of the plant. As the building was clearly unstable it was decided that water flush drilling could not be used as this could worsen the underground conditions resulting in further damage to the structure. The works were undertaken as part of a CDM project and during the design stage and at pre start meetings the potential for mine gases within unrecorded workings had been considered along with possible unrecorded gas migration pathways. As well as monitoring for gases adjacent to the drill string the risk control measures called for the installation of a series of gas monitoring meters at strategic places within the control building along with emergency evacuation procedures should the alarms have sounded. Furthermore lone working procedures were established for certain areas of the building involving personal gas alarms and 2 way radios.

The work involved drilling down to 25 metres into unrecorded shallow coal mine workings which were thought to contain voids of up to 5m. A series of holes had been established around the perimeter of the building when carbon dioxide was recorded at 2% v/v blowing out of one of the last holes to be drilled. At this stage the drill string was pulled out and the gas was allowed to vent into the atmosphere discharging the pressurised void of gas (approximately 5 hours duration). None of the monitors in the buildings recorded any carbon dioxide and it decided that there was no reason to evacuate the buildings.

Carbon dioxide emissions at these levels could have had very serious consequences, especially within a confined space, however the risk assessment and control measures employed ensured that the works were undertaken safely and no one was injured.

Case 2

At 3 am a father of three was awakened by the noise of a carbon monoxide detector downstairs. He struggled for over half an hour to wake up his family who were in a very deep sleep like state. Although the detectors had been installed many years ago by a former owner of the property, this was the first time they had gone off.

Three days before this incident a drilling company had begun to work at a site which bordered the house. This was the preliminary phase of a house building project and they had been contracted by a developer to remediate the site, by drilling to locate the underground mine workings and then grout the voids.

The site was located over a coal seam which the Coal Authority had identified as a seam which had a high risk of spontaneous combustion. The drilling company had not consulted the Authority prior to the work commencing and thus did not have the appropriate amount of information on which to make an adequate assessment of the risks of drilling in this area. They were drilling using air flush and left several boreholes open in order to establish the gas levels rising from the holes. However, this only made the situation worse.

The following morning, HSE inspectors arrived on the site and suggested additional measures
to be taken by the drilling contractor before the drilling could recommence. This included re-housing the family in a hotel, venting the house using fans and negative pressure units, creating a trench on the perimeter to trace the pathways and adopting a better testing regime for CO movement. This placed a huge additional cost upon the drilling company which could have been avoided by a desk study and use of the Coal Authority's expertise of the location of high risk sites.

HSE hadn't encountered this problem before but has helped with this guidance which represents reasonably practicable precautions to address the issue. Whilst this guidance is not compulsory, assessing and controlling risk is, and those who fail to do so may expect formal enforcement action to be considered.

**Case 3**

A drilling contractor was commissioned to drill into coal measures strata to determine the engineering properties of the ground prior to the construction of a new building.

A desk study had been undertaken and being in coal mining area this included an assessment of the mining risk. The coal mining report had indicated that shallow coal was likely to be present below the site and further investigation had narrowed this down to a zone of between 10m to 20m below the surface. The properties closest to the site were about 50m from the nearest borehole and the seam which was anticipated was not known to be susceptible to spontaneous combustion. The risk of hazardous gases being present in the workings and the potential for pathways to be present was considered but was not able to be quantified and as such it was assumed that they could be present.

The Coal Authority's Permissions team had been contacted and the agreed methodology had been that the contractor would use air mist flush through the overburden into rock before changing to coring techniques employing air mist flush within the rock. After encountering rock the contractor would check for hazardous gases each time rods were added. The overburden was typically 0.9m of loose fill material over 6.8m of boulder clay, with a sandstone rockhead.

At 11.6m, within the sandstone a 0.3m deep void was encountered, the flush return was lost and drilling stopped. The borehole was checked for the presence of hazardous gases. Elevated concentrations of carbon dioxide, 9.9% v/v, and low levels of oxygen, 6.4% v/v were found.

The Lead Driller stopped drilling and informed the Site Engineer who contacted the organisation's Contracts Manager for instruction. The Contracts Manager called a meeting with the client, their Safety and Geotechnical Managers to discuss the situation.

It was considered that the likely source of the gas was from coal workings below through broken ground created by the collapsing of the workings.

As the gas encountered was at dangerous concentrations it was decided to carry out a gas spike survey adjacent to the residential premises nearby. No hazardous gases were detected. Coring was allowed to proceed but it was decided to utilise water flush, along with gas monitoring, to ensure that the gases could not be mobilised and displaced.

The first coal workings were encountered at 15.8m and the flush was stopped and gases within the borehole checked. Again elevated carbon dioxide, 3.3% v/v, was found with low levels of oxygen, 17.5% v/v. No other gases were detected.
Coring proceeded with gas monitoring each time a drill rod was added. A further set of coal workings were encountered at 20.6m and again a check for gases undertaken. No hazardous gases were detected.

Coring stopped at the required depth and a gas monitoring installation was inserted into the borehole with post site monitoring carried out by the Consultant Engineer for a period of 6 months, over differing barometric conditions.

**Case 4**

A series of drilling tests were carried out at the location of a planned opencast site where exploratory drilling operations had been ongoing. A line of six boreholes using air flush was drilled extending over a distance of 60m with the shortest separation of the holes 5m and the longest 20m. The seams in this location were prone to spontaneous combustion. The drilling encountered mining voids at different seam levels. The degree of voiding suggested that the mine workings were still substantially open rather than collapsed. Continuous monitoring on the second drilled hole during the drilling operations indicated peak levels of about 5% v/v carbon dioxide. However these peaks were also associated with peaks of carbon monoxide in excess of 30ppm and hydrogen in excess of 100ppm. Pressures at the drilled holes were monitored during drilling of the next hole when it contacted void or broken ground. Recorded pressures due to the air flush did not exceed 5Pa, which was of the same order as the pressures potentially induced by wind moving over the site. However, flows were detected at the drilled holes out to 60m where they reached a level indistinguishable from wind induced flow. Nevertheless, on drilling the final hole it was found that at the first three holes, at distances between 50m and 60m away, the carbon dioxide concentration rose from about 5% v/v to between 8.7% and 10%. This final result appears to indicate that another body of mine gas had been contacted and was being displaced into a location over 50m away.

**Appendix B- Legislation, Standards and Industry Guidance**

The following is some of the principal legislation, as well as some useful British Standards and guidance documents published by various industry bodies applicable to drilling within coal and former mine workings at the time of publication. This list is by no means comprehensive and users of this guidance are advised to make themselves aware of all the current legislation including any amendments, which may be applicable to their particular work activity.

**Acts**

The Health & Safety at Work Act 1974 (HSWA)

The Coal industry Act 1994

The Mines and Quarries Act 1954

**Regulations**

Construction, Design and Management Regulations (CDM) 2015

The Mines Regulations 2014

The Borehole Sites and Operations Regulations
Management of Health and Safety at Work Regulations (MHSWR)

Dangerous Substances and Explosive Atmospheres Regulations (DSEAR)

The Building (Approved Inspectors etc.) Regulations

Flow chart showing the application of the guidance

1. Is it anticipated drilling will encounter unworked coal, former coal mine workings, shafts or adits? (Section 4)
   - No: Guidance does not apply
   - Yes: Has permission been granted by the Coal Authority? (Section 7)

2. Has permission been granted by the Coal Authority? (Section 7)
   - No: Apply for permission from the Coal Authority
   - Yes: Does desk study (Section 8) identify risk of mine gas? (including asphyxiating, toxic and flammable gases) and/or seams prone to spontaneous combustion

3. Does desk study (Section 8) identify risk of mine gas? (including asphyxiating, toxic and flammable gases) and/or seams prone to spontaneous combustion
   - No: Check Coal Authority permission. Use appropriate flush medium
   - Yes: Is suitable flushing medium being used (Section 6) – usually water flush – as stipulated in Coal Authority permission

4. Is suitable flushing medium being used (Section 6) – usually water flush – as stipulated in Coal Authority permission
   - No: Ensure appropriate control measures are in place before drilling commences
   - Yes: Are measures in place to control risks to those working on site (Section 10.5)

5. Are measures in place to control risks to those working on site (Section 10.5)
   - No: Ensure appropriate control measures are in place before drilling commences
   - Yes: Is there a risk of mine gas entering nearby properties? (Section 10.9)

6. Is there a risk of mine gas entering nearby properties? (Section 10.9)
   - No: Can suitable controls be put in place:
     - Method of drilling
     - Flushing medium
     - Monitoring holes
     - Yes: Have all identified safety measures been implemented?
     - No: Can mitigation measures be put in place that the occupier will accept:
       - Install gas alarms in at risk properties
       - Undertake gas monitoring
       - Consider evacuation
     - Yes: Drilling can commence
   - Yes: Ensure appropriate control measures are in place before drilling commences
Guidance on managing the risk of hazardous gases when drilling or piling near coal – Version 2
April 2019

When drilling unworked coal or coal workings are alarms triggered levels (Section 5.6.2) exceeded/methane or coals ignited in the general working area?

Yes

Has drilling ceased and personnel withdrawn from the affected area with no return until competent person has investigated, appropriate mitigation measures have been employed and area is safe (Section 10.5 and 10.10)?

Yes

Have appropriate mitigation measures (Section 10.3) been employed and is the area safe?

Yes

Does the elevated gas level reduce to a safe level following a period of venting?

Yes

Following investigation and risk assessment, drilling can continue with appropriate monitoring and controls in place

No

Consider sealing the borehole (Section 10.8)

No

Contact the Coal Authority to inform them of any incident at the earliest practicable opportunity

Yes

During gas monitoring are conditions of a possible heating detected (Section 10.7)?

Yes

DO NOT INJECT WATER INTO A COAL SEAM ON FIRE
- Switch off drill flush
- Continuously monitor CO
- Immediately grout any coal workings encountered and open holes
- Contact Fire Brigade stating use of water may be inappropriate
- Coordinate action plan and assess implications on properties adjacent to the site

No

Have on or off site buildings where alarms are installed been inspected by Contractors site management?
Guidance on managing the risk of hazardous gases when drilling or piling near coal – Version 2
April 2019

Completion of the borehole

Have detailed records been kept while drilling (section 10.11)?

Drilling Supervisor to record method and date of boring, water strikes, flush and strata along with gases and atmospheric pressure (Section 10.11)

Is the borehole drilled for the treatment of mine workings?

Permanently seal treatment holes with specified grout (Section 10.8) until the grout overflows at surface

Is the site investigation/non treatment hole to remain open for operational purposes?

Seal with a suitable cementitious based material (Section 10.8):
- Throughout the full depth of the borehole
- Inject from the bottom of the hole upwards
- Contain suitable and sufficient swelling material such as bentonite
- Should be chemically inert once set

Temporarily plug or seal pending permanent sealing at the earliest practicable opportunity

Appendix E – Guidance Leaflet for Site Operatives

Guidance for site operatives on the risk of hazardous gases when drilling or piling through coal

To report an emergency call 01623 646 333
Drilling into old coal mine workings can cause a serious hazard with mine gases being known to cause illness and fatalities among local residents as well as posing a risk to worker safety.

This leaflet is based on a guidance document, which uses a ‘source-pathway-receptor model’ to outline how hazards and incidents relating to mine gas can occur.

- the source is the origin of the mine gas such as a coal seam
- the pathway is a route along which gases can move from one place to another such as mine entries, old workings, boreholes, service ducts, fractures and permeable strata
- the receptor is where mine gases can accumulate or have an immediate impact on human health
- mine gases can affect receptors at significant distances from the drill site where the two locations are connected by pathways
- it is crucial that the sources, pathways and receptors relating to the site are considered when risk assessing any intrusive investigation, treatment or piling works that are likely to come into contact with past coal mine workings.

Source pathway – receptor diagrams

The following diagrams illustrate the mechanisms that lead to both on and off site mine gas incidents through the source-pathway-receptor mechanism.

They cover different combinations of sources, pathways and receptors in an effort to highlight how gas migration can affect both worker and the public.

Diagram 1 - shows how drilling works can lead to mine gas hazards affecting worker safety on site

Diagram 2 - shows how mine working investigations can cause hazards outside the site boundaries

Drilling flush and injected materials

Atmospheric pressure together with pressure differences from injection materials, such as grout, or from rising mine waters, can all encourage the migration of mine gases through pathways:

- any material that is injected into mine workings will have the effect of displacing any gas that is already present
- before selecting a drilling fluid, the risk assessment should consider the possible presence,
creation or mobilisation of hazardous gases
• a selected drilling fluid should eliminate or minimise the risk
• air/air mist flushes have a greater potential to mobilise gases due to the increased pressure
• the use of air/mist flush is not generally recommended within a 50 metres radius of any receptor
• a guideline risk matrix for flush selection is available in the full guidance document

Gas monitoring

It is highly recommended that gas monitoring should take place when drilling or piling into coal workings. Gas monitors and alarms should be positioned close to those who might be affected such as drilling operators and properties on or near to the site. The layering of gases should also be considered. CO2 will be found at lower levels whereas methane will be found at higher levels.

All gas monitors being used need to be calibrated and tested, with copies of supporting certificates available on site. Contractors must ensure that site staff or the occupants of any buildings have been briefed on their operation and understand the need for them.

Spontaneous combustion

During spontaneous combustion coal catches fire without an external heat source, usually as a result of air flowing over it. This poses a particularly high risk during the use of air flush. Spontaneous combustion occurs when heat is produced by the mechanical action of the drill on the coal and the oxidation of coal due to the injected air.

If a coal seam spontaneously combusts, it is possible for the fire to spread through old workings threatening the safety of any properties lying above them. It is important that the Fire Service is informed as water added to burning coals can dissociate, releasing oxygen and hydrogen, leading to an uncontrolled and unpredictable explosion.

The full guidance document can be found at www.gov.uk
