Review of available sediment data to aid understanding of the provenance of the subtidal mud habitat within Whitsand and Looe Bay Marine Conservation Zone (MCZ)

October 2015

Introduction

In early 2015 the Marine Management Organisation (MMO) received advice from Natural England which stated the existence of an area of subtidal mud situated in the Whitsand and Looe Marine Conservation Zone (MCZ) which is in the proximity of the Rame Head disposal site. The origin of this mud habitat was unknown and consideration was required in order to ascertain if its existence could be attributable to anthropogenic factors.

The MMO took a precautionary approach regarding this advice and made the decision to suspend disposal activities at the Rame Head disposal site whilst the nature and origins of this mud habitat were explored.

The MMO commissioned its scientific advisors the Centre for Environment Fisheries and Aquaculture Science (Cefas) to review existing data collected during the annual “Dredged Material Disposal Site Monitoring Around the Coast of England” project (SLAB5) in order to provide advice on the origin of the subtidal mud and whether disposal at Rame Head South was the cause of its existence.

The review is provided below in its entirety:

COMMENCEMENT OF CEFAS REVIEW

1. Background

Cefas has been tasked by the Marine Management Organisation (MMO) to review historical sediment data that have been acquired under the auspices of the dredged material disposal site monitoring project (SLAB5) to help understand whether the existence of the subtidal mud habitat within the Whitsand and Looe Bay MCZ, identified in the Whitsand and Looe Bay MCZ Summary Site Report (Defra, 2015), results from dredged material disposal activity to the Rame Head South disposal site (PL031).

In compiling this minute Cefas have drawn on information provided by the SLAB5 project manager.

2. Approach

Four historical SLAB5 stations fall within the subtidal mud habitat within the MCZ (Figure 1). Data from these stations are reviewed in this minute with the aim of providing any insight as to whether this mud habitat is present as a result of the disposal activity at the nearby Rame Head South disposal site.

The time-series data of the physical (particle size) and chemical (organic carbon and contaminants) characteristics of the sediment from the four stations sampled under the dredged material monitoring project SLAB5 (formerly BA004) are presented. Sampling was conducted using a Shipek grab at each station to obtain an undisturbed sediment sample: the top 2-3 cm of sediment being carefully removed for all subsequent analyses. For details of any sampling or sample processing methods, please contact Cefas.

The four stations were positioned as part of a wider survey to address the aims of SLAB5 and their location within the subtidal mud habitat within the MCZ is purely coincidental, i.e., they were not established to acquire data to characterise or determine the provenance of the material within this habitat. The four stations are G2, G6, G35 and G36 (see Figure 1). G35 lies on the edge of the subtidal mud habitat but data from this station are included in this study. To allow the data from the four stations within the subtidal mud habitat to be put into a wider spatial and temporal context, data from stations located within the disposal site (G18, G19, G20, and G16 lying just outside the licenced boundary) are also provided, together with data from two stations located at the opposite side of the disposal site to the subtidal mud habitat, i.e. to the southeast (G28, G33) (Figure 1). The sample stations are grouped to the three 'regions' (the subtidal mud habitat (SM), the disposal site (DS) and, southeast of the disposal site (SE)) in the results tables (Tables 1-5) in Section 3 below.

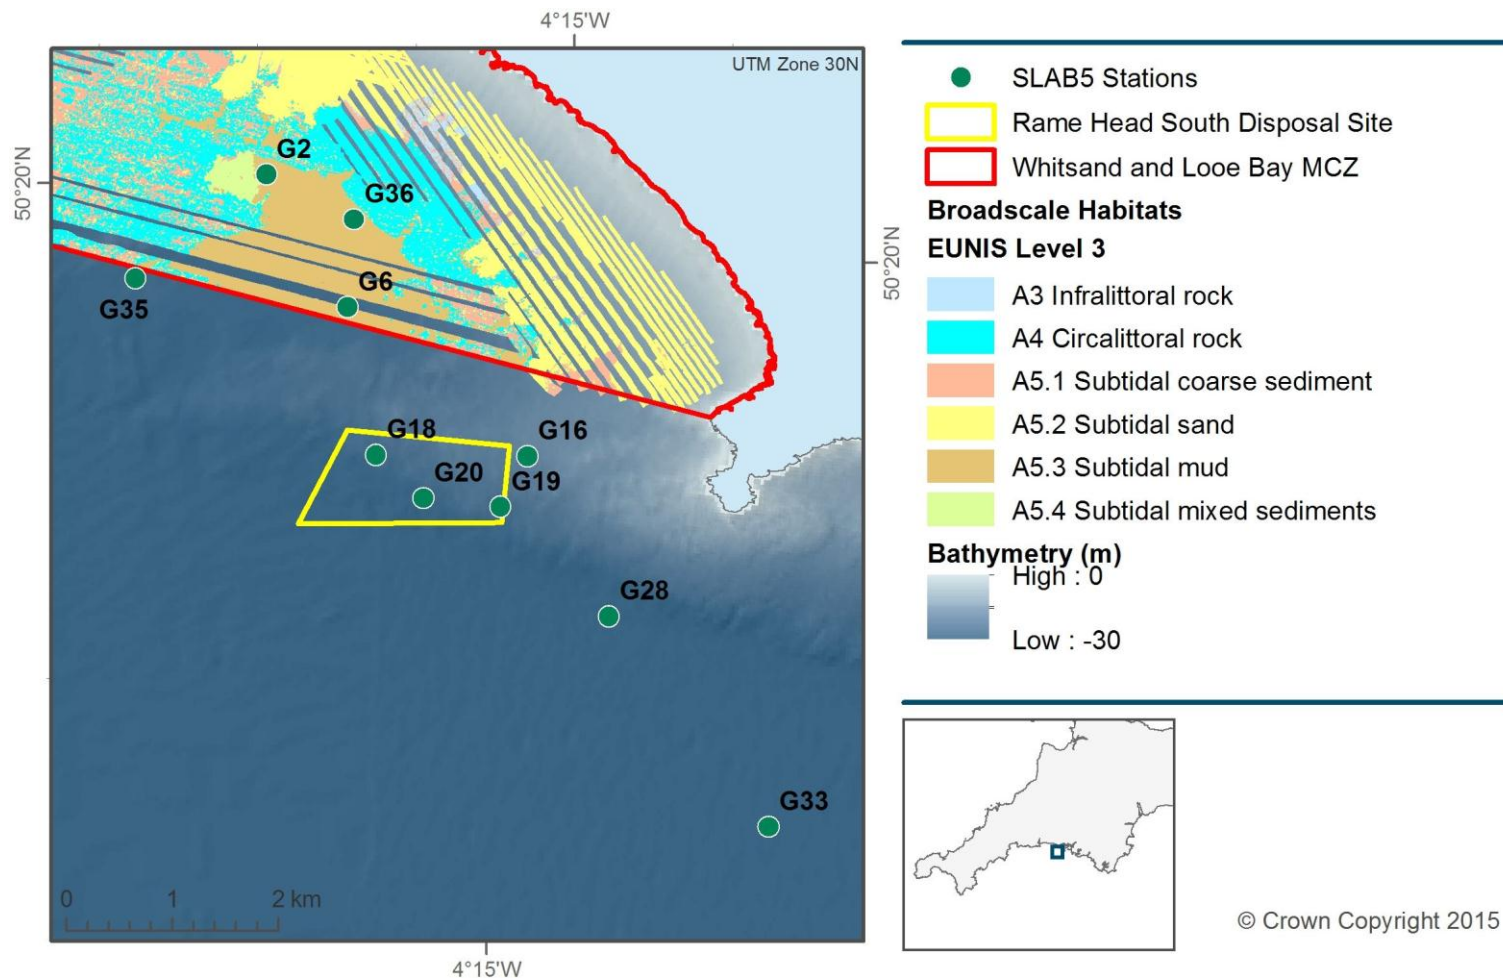

Figure 1. Location of the stations for which sediment data are reviewed under the current review. The four stations located northwest of the disposal site lie within the subtidal mud habitat region as indicated by the Whitsand and Looe Bay MCZ. Bathymetry is from the Defra Digital Elevation Model (Astrium, 2011). The MCZ information is from the Whitsand and Looe Bay MCZ Summary Site Report (Defra, 2015).

3. Results

3.1 Sediment particle size

The sampled sediments were assessed for their granulometric properties through particle size analysis (PSA). Of particular importance is the percentage of the finer mud fraction or the silt/clay content, as it is this component of the sediments with which the majority of the contaminants tend to be associated.

It can be seen (Table 1) that there is a notable spatial variability in the silt/clay component across the stations. While some stations are generally low in silt/clay (e.g. G16, G19) others are relatively silty (e.g. G18, G28). The four stations in the subtidal mud habitat within the MCZ are muddy, except for G35 which lies on the edge of the subtidal mud habitat (Figure 1). There is generally no indication of any temporal change in the mud content of these stations, apart from some increases at G2 and G36 in 2014. G16 was the only station sampled from the disposal site in 2014, as it lies just outside the licenced boundary G16 alone may not be representative of the disposal site.

Table 1. Silt/clay content (%) of the surficial (top 2-3 cm) sediments of the stations reviewed under the current study. Data from 2001 to 2014 are presented. Blank cells indicate either no sample was taken or the sample was not processed.

3.2 Organic carbon content

The organic carbon contents of the sediments vary between approximately 1% and just over 3% (Table 2). The higher organic carbon content values tend to be found at the stations within the disposal site. These data do not indicate any temporal trend in organic carbon contents of the sediments in the region.

Table 2. Total organic carbon content (%) of the surficial sediments of the stations reviewed under the current study. Data from 2001 to 2014 are presented. Blank cells indicate either no sample was taken or the sample was not processed.

3.3 *Tri-butyltin (TBT)*

The concentrations of the TBT in sediments within the Rame Head region are low (Table 3), predominantly below limit of detection (or LOD). Only one sample in the subtidal mud habitat within the MCZ showed detectable concentrations (0.009 mg/kg at G36, 2003). Concentrations within the disposal site are noticeably higher, with detectable (although still low) concentrations being observed, particularly during 2002. No samples were processed for TBT in 2014 due to the low levels in previous years.

Table 3. TBT concentrations (mg/kg dry weight) of the surficial sediments of the stations reviewed under the current study. Data from 2001 to 2014 are presented. Blank cells indicate either no sample was taken or the sample was not processed. † represents concentrations measured were below limit of analytical detection (0.002 mg/kg).

3.4 *Trace elements*

The concentrations of a number of trace elements for the stations sampled under SLAB5 are presented within Table 4. The regional background assessment concentrations for each element are also presented. These assessment concentrations represent the concentrations of each element for the sediments of the

western Channel, and are more appropriate for the assessment of disposal activity than the OSPAR background assessment concentration values (Cefas, 2011) as they allow for the natural variations in element concentrations across the coast of England and Wales. Trace elements are a natural feature of marine sediments and their concentrations vary across the UK shelf, partly due to differences in the mineralogical characteristics across the region (see Section 5) and also due to variations in sediment particle size as finer grained sediments usually have higher trace element contents. The data acquired under SLAB5 indicate that for all the eight elements, concentrations are slightly elevated above the regional assessment concentrations within the disposal site, but generally appear similar to these regional values within the subtidal mud habitat and SE stations. No temporal trend can be observed for the three regions.

Table 4. Trace element concentrations (mg/kg dry weight) of the surficial sediments of the stations used for the current review. Data from 2001 to 2014 are presented. Blank cells indicate either no sample was taken or the sample was not processed. The eight elements presented here are those for which regional assessment concentrations exist to allow comparisons with concentrations expected for non-disposal conditions. Trace element concentrations that are at or below the regional assessment concentrations are presented in grey cells. Data result from total digest of the < 63 µm fraction of the sediments (Cefas, 2011).

3.5 Hydrocarbons

The spatial and temporal variations in the total hydrocarbon (or THC) concentrations for the SLAB5 stations are presented in Table 5. Cefas use THC concentrations as a screen to identify sediment samples with high hydrocarbon levels. The data from the SLAB5 stations presented here are low compared to those observed at many disposal sites around the coast of the UK, with values of up to ten times higher being found at sites off the north east coast (Rumney et al., 2015). These data, akin to the situation reflected by the trace elements data, indicate that no temporal trend in THC concentrations are evident for the samples taken from within the subtidal mud habitat.

Table 5. Total hydrocarbon concentrations (mg/kg dry weight) of the surficial sediments of the stations reviewed under the current study. Data from 2001 to 2014 are presented. Blank cells indicate either no sample was taken or the sample was not processed.

4. Discussion

The purpose of this minute has been to review SLAB5 monitoring data from the Rame Head South disposal site to ascertain if they can provide any insight into the origin of the subtidal mud habitat identified in the Whitsand and Looe Bay MCZ. Recent subtidal sampling conducted by Environmental Agency (EA), to support the Defra MCZ field survey program and verify the presence of the subtidal features proposed for designation (Arnold & Godsell, 2014), used a different grab type (a mini-Hamon grab) which does not allow acquisition of undisturbed sediments nor contaminants to be assessed, therefore SLAB5 data currently represents the only source of contaminants data for the subtidal mud habitat.

The sediment physical (granulometric PSA) and chemical (organic carbon and contaminants) data presented for the four stations within the subtidal mud habitat, together with those within the disposal site and those to the southeast of the site, provide a spatial and temporal assessment of the variability of the sediments in this region. The data have shown that while the three 'regions' (i.e. the subtidal mud habitat, the disposal site, southeast of the disposal site) display some spatial variability, both within and between regions, there does not appear to be any obvious trend over time.

Contaminants concentrations within the subtidal mud habitat and SE stations generally appear similar to the regional background assessment concentrations. Contaminant concentrations within the disposal site are slightly elevated above the regional assessment concentrations, but not appreciably higher, which is what we would expect at a dispersive disposal site. A dispersive disposal site is where dredged material may either be dispersed during deposition or eroded from the bottom over time and transported away from the site by currents and/or wave action. The Rame Head South disposal site, like the majority of those across the coast of England and Wales, is a dispersive site being located in a hydrologically dynamic area. Dredged material disposed at the site will, therefore, generally be moved in the direction of the prevailing tidal currents i.e. in a north-west to south-east direction. It has been shown that the predominant residual movement of disposed material is in a south-easterly direction away from the disposal site (Cefas, 2005 & 2007) and the MCZ site. While storm conditions may periodically move the material in different directions the long-term residual sediment transport pathways are not affected. The presence of contaminants at the monitoring stations does not necessarily mean that they are derived from the disposal operations as there are other sources of contaminants, for example natural inputs of metals and other anthropogenic sources of hydrocarbons such as road run-off and the discharge of industrial and sewage effluents (Cefas, 2007).

While prevailing tidal currents will take material in suspension from the disposal site in the general direction of the MCZ, over part of the tidal cycle, the long-term residual sediment transport pathway is away from the MCZ (Cefas, 2005 & 2007). The monitoring data reviewed under this minute spans a relatively short time period (thirteen years) relative to the lifespan of the disposal site (greater than 100 years). No pre-disposal data for the region or, more specifically, for the subtidal mud habitat

area, are available. As such, it is impossible to unequivocally state that the subtidal mud habitat within the MCZ was or was not muddy prior to any disposal activity taking place. Material is transported naturally out of the Tamar Estuary, a proportion of which would inevitably end up in the Whitsand Bay area including the MCZ (Siddorn et al. 2003, Elliott & Mazik 2011). The dredged material disposed at the Rame Head South site consists of material from within the Tamar Estuary and therefore it is extremely difficult to distinguish between the natural deposition and that resulting from disposal activity in this region. All of these factors make it impossible to determine the origin of the mud and to determine how long it has existed. Historical evidence may, however, provide a useful source of information, for example Crawford (1937) refers to an area called 'Rame Mud' when reporting on surveys of crustaceans in the area from 1934 and 1935.

Recent sampling of the surface sediment and benthic communities within the MCZ, undertaken by the EA (Arnold & Godsell, 2014, Defra 2015) does, however, suggest that the subtidal mud habitat is a stable habitat supporting a well-established benthic community. Seabed images captured from stations within the subtidal mud habitat clearly show the presence of benthic organisms on the surface and the evidence of burrowing activity (Figure 2).

Figure 2. Seabed images of the subtidal mud habitat captured during the Whitsand and Looe Bay MCZ 2013 habitat verification survey (Arnold & Godsell, 2014).

Based on the data reviewed here it is currently very difficult to address the origin of the subtidal mud identified in the MCZ and determine how long it has been there.

However, it is clear that the area has been muddy for at least 14 years (Table 1) and it may have been muddy for some 78 years or more based on information in Crawford (1937).

5. Potential approaches to provide additional information on the subtidal mud

As indicated earlier, the capacity of the data from the small number of surficial sediments taken under SLAB5 to ascertain the origin of the material occupying the subtidal mud habitat within the MCZ is very limited (Section 3). There are, however, a number of alternative approaches that may offer the potential to provide further information and/or data to help aid our understanding of the subtidal mud habitat located within the MCZ. These could be employed in a step-wise approach to ensure resources are targeted cost effectively. The first two approaches below would be relatively low cost and quick to undertake, and would determine if further work is required, these are:

- Literature search/review of historical evidence relating to the 'Rame Mud' area, and;
- Interviews with fishermen to explore their local knowledge of the subtidal habitats in the area.

The following approaches would provide more information on the extent and volume of the subtidal mud which could potentially provide information of the source of the subtidal mud:

- An acoustic (multibeam bathymetry and backscatter) survey to map out the full spatial extent of the subtidal mud habitat, and;
- A spatial assessment of the sediment depth profiles of the subtidal mud. Employing sub-bottom profiling and a suitable corer (e.g. vibrocorer), it would be possible to determine the depth of the mud throughout the subtidal mud habitat (using spatial extent information from the above-mentioned mapping approach). This would allow an estimation regarding the volume of material that presently lies within the subtidal mud habitat.

The following could also potentially provide information of the source of the subtidal mud:

- Radioisotopes in the sediment could be analysed to provide evidence on the age of the material, and;
- A detailed hydrological and sediment transport pathway survey of the wider coastal region may offer some insight regarding sediment movement (sources and sinks) between the Tamar Estuary and adjacent coastal areas.

While hydrological and/or tracer studies may be of help in predicting the fate of material disposed over relatively short time-scales (tidal, monthly, seasonally), their capacity to determine the long-term fate of material is very limited. Decadal storms, for example, may ultimately be of overriding importance in determining the sedimentary nature and the fate of material disposed. With no pre-disposal data, a long-term study is arguably required to address this long-term issue.

6. Conclusion

Based on historical sediment data from the dredged material disposal site monitoring project (SLAB5) and the further evidence reviewed in this minute it is at present not possible to determine the origin of the subtidal mud habitat within the Whitsand and Looe Bay MCZ, however while it is likely that disposal activity at the Rame Head South disposal site contributes fine material, it is highly unlikely that it is responsible for the presence of the mud habitat located within the MCZ. The alternative approaches suggested above (Section 5) to help aid understanding of the subtidal mud habitat would provide further information on the characteristics of the subtidal mud, however even if undertaken it would still be difficult to confidently ascertain the origin of the subtidal mud habitat.

END OF REVIEW

MMO post-script

Based on the conclusions of the Cefas review provided above, along with the best available scientific evidence, the MMO has determined that the Rame Head South site is a viable option for disposal of dredged material and therefore it will now consider applications for disposal at the site on a case by case basis.
