Animals Scientific Procedures Act 1986

Non-technical summaries for project licences granted during 2020

Volume 1 (January to June)

Home Office

NON-TECHNICAL SUMMARY

1. ADME Studies for Agrochemicals and Veterinary Medicines

Project duration

5 years 0 months

Project purpose

- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Rats	adult
Sheep	adult
Chickens	adult
Goats	adult
Pigs	adult
Rabbits	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project is to provide a service to Agrochemical and Veterinary companies by generating ADME (Absorption, Distribution, Metabolism and Excretion) and nature of the residue data on candidate test compounds to support the data package to the relevant UK, US, EU and Japanese regulators.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The ADME (Absorption, Distribution, Metabolism and Excretion) services offered to the Veterinary Medicines and Agrochemicals industries can be divided into studies conducted in laboratory animals to aid interpretation of data from toxicology studies and studies conducted in food-producing animals to identify the nature of the residue in products (e.g. meat, milk, eggs) consumed by humans. These studies are required by regulatory authorities as part of the approval process for Veterinary Medicines and Agrochemicals.

Studies required by regulatory authorities to investigate the ADME Properties of Veterinary Medicines and Agrochemicals in laboratory animals are specified and detailed in regulatory guidelines (Ref 1). These studies are conducted in rats.

Critically these studies demonstrate whether the rodents used in toxicology studies produce the same metabolites as are found in residues in the edible tissues of food-producing animals.
This information helps to underpin human safety by supporting the data generated from the toxicology studies.

Information on the ADME properties of a test compound aids the understanding of the mechanism of toxicology. Basic pharmacokinetic parameters determined from these studies will also provide information on the potential for accumulation of the test compound in tissues and/or organs and the potential for induction of biotransformation as a result of exposure to the test substance. These data can be used to assess the adequacy and relevance of the extrapolation of animal toxicity data (particularly chronic toxicity and/or carcinogenicity data) to human risk assessments.

In vivo dermal penetration studies are used as part of operator exposure assessments.

Dermal penetration studies in the rat are required to assess the exposure and safety of agricultural workers who work directly with agricultural products as per OECD 427 (Objective 3).

Studies required by regulatory authorities to identify the nature of the residue resulting from use of Veterinary Medicines and Agrochemicals in food producing animals are also specified in detailed regulatory guidelines (Ref 2). These studies are required to be conducted in ruminants (usually the goat) and poultry (usually the domestic chicken) for Agrochemicals and relevant target species (e.g. pig, sheep) for Veterinary Medicines.

The diet of food-producing animals may contain pesticide residues. It is therefore important to understand what happens to this material in the animal's body and the composition of the terminal residue in the animal products (meat, milk and eggs) that will be consumed by humans. Complete residue detection methodology and residue quantification data can then be developed. Based on the results of the characterisation and/or identification studies, the chemical definition of the total toxic residue (TTR) can then be proposed. All components of the TTR will normally be included in the tolerance expression for the pesticide and residue analytical methods are developed for all components of the TTR.

The human food safety evaluation of veterinary medicines helps ensure that food derived from treated food-producing animals is safe for human consumption. As part of the data collection process studies are required which assess the quantity and nature of residues in food derived from animals treated with a veterinary drug. These metabolism studies provide data on (1) the depletion of residues of concern from edible tissues of treated animals at varying times after drug administration, (2) the individual components, or residues, that comprise the residue of concern in edible tissues, (3) the residue(s) that can serve as a marker for analytical methods intended for compliance purposes (i.e. monitoring of appropriate drug use) and (4) the identification of a target tissue or tissues, as applicable to national or regional programme's.

All animal studies are conducted in a facility which operates in compliance with International Good Laboratory Practice Standards (Ref 3).

What outputs do you think you will see at the end of this project?

Outputs arising from this Project include:

- Confirmation or refutation that laboratory animals used in toxicology studies produce the same metabolites as are found in residues in the edible tissues of food-producing animals

- ADME data following the oral, intravenous and/or dermal dose routes, which will assist in the interpretation of toxicology studies

- Rate and extent of oral absorption of test compounds

- Determination of PK parameters (C_{max}, T_{max}, AUC, Bioavailability (F)) of test compounds

- Assessment of potential for bioaccumulation of test compounds

- Plasma half-life of test compounds

- Distribution of a test compound in major organs and tissues

  Distribution of a test compound in blood cells

  Determination of Metabolic pathways of test compounds

  Identification of Metabolites of test compounds

- Determination of route and time course of excretion of test compounds and their metabolites
- Investigation of whether and to what extent enterohepatic circulation of test compounds takes place
- Assessment of rate of dermal absorption of test compounds

Outputs from food-producing animal studies:

- Estimation of total residues of test compounds in the edible livestock commodities, as well as excreta of test compounds
- Identity of the major components of the terminal residue in the edible tissues of test compounds, thus indicating the components to be analysed in residue quantification studies
- Elucidation of metabolic pathways of test compounds
- Provision of evidence for whether or not a residue should be classified as fat soluble
- Demonstration of the depletion of the marker residue upon cessation of drug treatment to the regulatory safe level
- Generation of data suitable for elaboration of appropriate withdrawal periods/withholding times to address consumer safety concerns

Ultimately these outputs will be used to assess the safety of veterinary products and agrochemicals resulting in only safe products reaching the market.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The principal beneficiaries of the studies conducted under this Project are:

- The Veterinary Medicine and Agrochemicals industries as the studies conducted form part of the dossier submitted for regulatory approval of their products.

  The general public who benefit from food that has been produced using new safer agrochemicals and veterinary medicines which have a lower impact on the environment.

  The farming industry who will benefit from safer, more effective veterinary medicines and crop protection chemicals resulting in healthier animals and higher crop yields.

  The general public who benefit from an improved safety assessment process due to product registration/re-registration to ensure that only products which meet modern safety and regulatory standards enter/remain on the market and are assessed using modern experimental/analytical methodologies.

- Animals which will benefit from improved health and welfare as a result of more effective veterinary medicines.

How will you maximise the outputs of your work?

Subject to approval from Study Sponsors we will endeavour to publish as much information as possible from studies conducted under this Project License.

Species and numbers of animals expected to be used

- Pigs: 20
- Goats: 20
- Sheep: 20
- Domestic fowl: No answer provided
- Rats: 1000
- Rabbits: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically the following will be done to animals under this project:

- Animals will be singly housed in a metabolic cage for up to 1 day prior to dosing

  Administration of a test substance by the intravenous, oral, subcutaneous, intra muscular or topical routes.

  Following dosing animals will be singly housed in a metabolic cage for the collection of urine and faeces for up to 15 days in the case of pigs, sheep, goats, rabbits and chickens but generally 8 days. Rats maybe singly housed for up to 8 days for the collection of urine, faeces and expired air.

Less typically:

- Rats may have food withdrawn for up to 14 hours prior to dosing but normally no longer than 12 hours
- Administration of a test substance by the intravenous, oral, subcutaneous, intra muscular or topical routes.
- The collection of blood samples by direct puncture of a jugular vein after dose administration for pigs, sheep and goats. Chickens will have blood samples collected by direct puncture of a wing vein and limited to 2 blood samples only. Rats and lagomorphs will have blood samples collected from an indwelling catheter over the first 8 hours following dosing. Samples collected beyond 8 hours post dose will be collected form all species by direct venepuncture. Direct venepuncture is limited to 10 occasions only over any 24 hour period (apart from the chicken).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We do not expect to see any adverse effects in the studies we perform through investigation of the compound prior to a study being initiated. This involves the understanding of the compounds safety in previous studies so carefully selected dose levels are administered minimising the chances of any adverse effects being seen.

Following completion of each project animals will be humanely killed.

The withdrawal of blood samples from superficial vessels, by direct vene puncture, may cause a small period of discomfort as the needle is inserted and blood sample collected. Pressure is applied to the site following collection via cotton wool.

When orally dosing, animals will be restrained and the drug administered directly into the stomach via a syringe and gavage tube. This may cause a period of discomfort whilst the procedure is being performed.

Intravenous doses are administered directly into a cephalic vein generally over a 1 minute period whilst being continually held by a technician.

When a study requires the individual collection of urine and faeces animals will be singly housed in a metabolic cage to enable the separate collection of these samples. During this period the animals may become quieter and less active compared to normal due to the change in type of housing and no direcontact with other animals. To mitigate this the animals will be housed adjacent to each other so they have visual contact at all times. The time period animals are allowed to be singly housed in metabolic cages is strictly controlled. Where possible we use environmental enrichment such as playing background music and hanging toys.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Approximately 50% of rats will experience a moderate severity limit and 50% a mild severity limit.

All pigs, sheep, goats, rabbits and chickens will experience a moderate severity limit.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Various international regulatory guidelines specify the generation of safety data in two species, one of which must be a rodent. The use of rodents in safety evaluation has been generally accepted by scientific and regulatory bodies, because of the ease of breeding and availability, straightforward husbandry, growth rate, ease of handling under experimental conditions and broad physiological similarities to man. Extensive background data is available in any particular procedure to enable meaningful statistical evaluation to be performed.

In support of the regulatory guidelines, ADME studies in animals:

- confirm whether toxicology studies produce the same metabolites as those found in edible tissues of food producing livestock
- provide PK statistics (e.g. C_{max} and T_{max}) to assist in the interpretation of toxicology studies
- estimate the total residues in the edible livestock and excreta
- identify the major components of the terminal residue in the edible tissues, indicating the components to be analysed in residue quantification studies
- demonstrate the depletion of the marker residue upon cessation of drug treatment to regulatory safe level

What was your strategy for searching for non-animal alternatives?

Various *in vitro* and *in silico* evaluations are being used to provide predictive information and where such information is available this leads to the replacement of animals. For example, in some situations, the use of ethically procured human skin can provide information directly applicable to humans without recourse to initial evaluation in animals.

Why were they not suitable?

Despite the advance in non-animal methods it is still a requirement to use animals where there are no

viable alternatives in order to produce information on the safety of Agrochemicals and Veterinary Medicines for Regulatory authorities.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

As a Contract Research Organisation the number of animals used will primarily be based on the number of studies performed for clients. The number of animals used can then be estimated according to the regulatory guidelines the studies are being run to meet.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have a vast amount of knowledge with Principal scientists, Team leaders and Study directors who have extensive experience of designing studies of this type, with the aim of keeping the number of animals used to a minimum. All of these people within the organisation have statistical expertise as this is one of their primary functions when discussing and interpreting data.

We always use the minimum number of animals required on a study whilst still providing robust scientific data which will be accepted by international guidelines for the safety of agrochemicals and veterinary products in man.

What other measures apart from good experimental design will you use to minimise numbers?

Prior to any study initiating we actively source relevant information regarding the test item which will have an impact on the study design and number of animals used. If group sizes of >3 are requested, our AWERB (Animal Welfare and Ethical Review Body) will rigorously check the study design to ensure the use of larger groups sizes is justified and if this cannot be, a group size of n=3 will be used.

Where possible in rodent studies, and as long as the burden is not too great for the animal, each animal will have multiple outputs to reduce the overall number of animals required on a study. For example

where animals are used for the collection of excreta, following the last collection the animals would be used for blood collection under general anesthesia which would not increase the overall burden on the animal but reduce the number of animals required for terminal blood collection. Apart from the blood collection under general anesthesia no additional burden would be placed upon the animals.

When the animals are procured generally a certain number of additional animals (~5%) are procured for each study in case of any miss-dosing, such as part of an intravenous dose going subcutaneous or part of an oral dose refluxing into the mouth. Prior to an ADME (Absorption, Distribution, Metabolism and Excretion) experiment starting various in-vitro and in-vivo studies could have been performed which would highlight any need for increased group sizes to prove significance in the data provided and ensure the study objectives are met.

Where group sizes requested are more than generally used, we will consult with a statistician in order to ensure that the study is conducted with the minimum number of animals whilst still producing scientifically significant data.

The group sizes above are also dictated by the individual compound characteristics such as solubility. For example a solution dose will yield much tighter results compared to a suspension dose given orally.

For the smallest possible group size great care is taken to ensure all samples are collected exactly on time and to a high standard. The exact time of sampling is calculated to ensure all samples are collected on the minute to help ensure the data produced is as significant as possible reducing the variability between animals.

Examples of strategies reducing the total number of animals used:

• The continuing drive for repeated serial blood sampling in rats, as opposed to a composite design, reducing the total number of rats used in ADME studies.

• Obtaining multiple samples from a single animal, e.g. in ADME studies using the 7 day balance excretion animals (collection of urine and faeces) for the 7 day QWBA (Quantitative Whole Body Auto Radiography) phase - reducing the number of animals used on the QWBA phase.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The choice of species and models used in this Project are effectively directed by Regulatory International Guidance's and/or relate to prior safety models and ensure that the species used are the most refined for the intended purpose.

The international guidance for safety assessment in agrochemicals mandates two mammalian species including at least one non-rodent species. In practice this means rat for the rodent species. The use of pig, sheep goat or rabbits is to help determine human exposure via the food chain. In the case of veterinary medicines the rat will be used as the rodent species and the non rodent species will generally be the target species receiving the end medicine which will either be the pig, sheep, rabbit or chicken.

- withholding of food for a single period in rats only, generally not more than 12 hours, but not exceeding 14 hours

We withhold food for the minimum period only, which normally involves a PIL holder coming back to in the evening to withdraw food as this gives rodents part of their dark cycle to feed, which causes the least distress to the animals.

- withdrawal of small blood samples of blood from a superficial blood vessel in rodents and large animals and/or via an indwelling cannula (rats and rabbits only)

If multiple samples are being collected in the rat or rabbit an indwelling cannula will be inserted into a lateral tail vein or marginal ear vein in the rabbit to ensure the least number of vene punctures are performed. The withdrawal of blood samples from a superficial vessel is a quick and easy method to provide blood samples and we have extensive experience of performing this procedure to a very high standard. The minimum amount of blood required will be collected at all times to the recommended volumes. The indwelling cannula used in the rat and rabbit will be primed with heparinised saline following each blood sample collection to maintain patency and will not be left in place overnight.

- Confinement in a metabolism cage (large animals up to 15 days only) or metabowl (rodents up to 8 days)

There is currently no other option that causes less harm and uses less number of animals to collect excreta from animals at defined time periods. Rats and large animals will be singly housed but visual access to other animals will be insured by housing the metabowls/metabolism cages side by side in the same room. If any clinical signs are observed in any animals whilst in the metabowls/metabolism cages the NACWO/NVS will be consulted and if required the animals killed. Rats in metabowls will be checked at least twice daily when expired air is collected as the possibility of asphyxiation is increased due to the pumps relying on an electrical source. All pumps drawing air through the metabowls have a backup UPS battery supply, which lasts for at least three hours, which is adequate time for a PIL holder to be called out to remove the air traps from the metabowls.

Administration of substances by one of the following routes:

- Intravenous injection,
  Infusion via cannula, intramuscular, Intraperitoneal injection, cutaneous, subcutaneous injection

Irritation caused by injection will be avoided as much as possible by injecting small volumes and administering one dose only via all routes. If clinical signs are observed, and deemed necessary, animals will undergo an evening health check.

- Oral gavage

Damage to the mouth or osophagous be minimised by the use of flexible polypropylene gavage catheters and continuous monitoring of the animal. If clinical signs are observed, and deemed necessary, animals will undergo an evening health check

- Topical application

After topical application, particular attention will be paid to the possibility of inflammation of the dose site. The smallest area of skin will be used for administration whilst adhering to the regulatory guidelines on the defined area to be dosed.

- Killing via a Schedule One method

This is terminal procedure carried out by highly trained licencee's and as such will cause no distress apart from the anesthetising procedure in the rat or intravenous administration of substances causing death in large animals, domestic fowl and rabbits.

- Killing via non Schedule One method

This is a terminal procedure specifically used only on rats. It involves the sacrifice of an animal via rising concentration of CO_2 then once confirmed dead, immersion in a liquid mixture of cardice and hexane (ca.-120 degrees C).

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We strive to use the least sentient animal species where possible whilst still meeting the objectives of the study and adhering to the International Regulatory guidelines the study is being run to meet. Ultimately the species used is governed by the requirements of regulatory authorities that the client is conducting the work to meet.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

A system of continuous refinement of procedures operates such that the least severe option is maintained, as illustrated in the following examples:

• Using large fun tunnels, chewing blocks and fruity chews for rabbits

• The use of aspen balls for rats

• The continual use of a simple blood vessel cannulation procedure in rats and rabbits to minimise serial venepuncture.

• The use of micro sampling in rats reducing the volume of blood required when multiple sampling.

• Ensuring the minimum quantity of blood is collected to achieve scientific objectives

There are no severe protocols in this programme of work with no surgical procedures being performed under this license.

If any clinical signs are observed which are manageable and do not exceed the project license evening checks will be performed to ensure the animal does not deteriorate and if it does, the appropriate intervention can be made.

We always strive to adhere to the highest possible welfare standards for the animals, for example the use of high top caging for the rats to ensure they can fully rear up.

We are a GLP accredited facility and as such conforms to the highest possible international standards with our internal Quality Assurance department conducting routine (~3 months) inspections of non-procedural work such as weighing of the animals and monitoring their cage cleaning.

We will also request prior compound data from the client that could aid dose levels and species selection. Prior *in vivo* and *in vitro* data will be used to select the most appropriate species to meet the scientific objective. The overriding decision will be to use the lowest order species first such as the rat prior to using any higher order species such as the pig, sheep or goat. If limited rodent data is available we will ensure that the dose levels selected minimise potential clinical signs which may be seen in the sheep, rabbit, chicken, goat or pig.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Good Laboratory Practice Regulations:

- The United Kingdom (UK) Good Laboratory Practice Regulations 1999 (Statutory Instrument No. 3106) and subsequent amendment.

- The Organisation for Economic Co-operation and Development (OECD) Principles of Good Laboratory Practice (Paris 1998)

- European Commission (EC) Commission Directive 2004/10/EC (February 2004)

All studies will be performed to the standards of GLP.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

All PIL holders and the Project license holder go on relevant training/refresher courses annually and keep up to date with reduction and refinements by attending NC3R/RSPCA workshops or equivalent as part of our continual development programme. This information is then shared among the animal care staff.

Explain the choice of species and the related life stages

We are using these species of animals as the data they produce is a regulatory requirement for the submission of agrochemicals and veterinary medicines.

Only adult animals will be used.

Home Office

NON-TECHNICAL SUMMARY

2.Affect and cognition in rodents

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
Rats	juvenile, adult, aged
Mice	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To identify and characterise the psychological and biological mechanisms underpinning the affective and cognitive processing of rewarding and punishing stimuli and dysfunctions/disturbances of such processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Psychiatric disorders are a major health burden in the UK (and worldwide). One bottleneck in developing novel treatments is a lack of targets for drug discovery. This project will develop the understanding of emotion and cognitive function in rodents, and how these fail in rodent models of psychiatric disorders. In particular, the project will characterise the relationship between affective, motivational, and cognitive processing of rewarding and punishing stimuli. This knowledge will be used to determine how biological (e.g. variation in risk genes for particular disorders) or environmental (e.g. early life stress) risk factors are related to specific aspects of the affective and cognitive processing of rewarding and punishing stimuli; and illuminate the biological pathways mechanisms linking these risk factors to their behavioural effects. Such outputs will aid the drug development process by identifying targets for new therapeutic techniques.

The psychological and biological mechanisms underpinning affective and cognitive processes are also of particular interest in the domain of lab-animal welfare. Many thousands of rodents are used annually in laboratory work based involving techniques such as injections. The welfare impact of these techniques - in particular the degree to which they disrupt normal cognitive and affective function - has received relatively little direct scientific investigation. Thus in many cases, the aversive impacts, and means to minimise them, are not known. This project will provide information about how aversive some common techniques are and about ways to minimise or avoid that harm.

What outputs do you think you will see at the end of this project?

The primary outputs from the project will be new information. This will typically communicated by scientific publication or presentation (but also engagement with non-specialist audiences).

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

In the short-term, the primary benefit will be to other academic and industrial scientists working in the field. Previous work has been well cited - indicating its use by others. In addition, I am part of ongoing collaborations with representatives of the pharmacological industry that were established in part due to work undertaken on previous projects - suggesting that the results from the current project will also be of benefit to industry.

In the longer-term, the cumulative gains in knowledge will support application and translational extension. For example, some of the work to be performed on this project concerns key risk-genes for psychiatric disorders. Understanding the function of such genes could contribute to the development of novel therapeutic strategies.

How will you maximise the outputs of your work?

I am involved in a number of academic collaborations within the field (across several institutions within and outside the UK) and outside the field (relating to the application of hedonic assessment methods to pig production). In addition, I have ongoing collaborations with the pharmaceutical industry. These collaborations will continue and will support the impact of the current work.

In addition, I have a strong track-record of academic publication and conference dissemination (including the organisation of an annual conference on associative learning and neuroscience). This will continue across the life of the current project - supporting the wide dissemination of the outputs of the current work.

Finally, I am committed to open science (including the dissemination of reliable null results) - which will ensure that a fully representative impression of the outputs of the current work will be widely available.

Species and numbers of animals expected to be used

- Rats: 1400
- Mice: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A maximum of 1600 animals will be used across the life of the project. The bulk of the experiments will use rewarding stimuli (its primary purpose is the investigation of the mechanisms involved in processing rewards, and dysfunction in these mechanisms in models of risk factors for psychiatric

disorders), but a subset (approximately 25%) of experiments will involve aversive stimuli (e.g. pain from foodshock or nausea from LiCl injection). Approximately 12.5% of the animals will also receive surgical implantation of an oral cannula under anaesthesia and approximately 12.5% will receive direct exposure to stress-inducing stimuli/events. The typical duration of experiments will be 3-6 months, however for aged animals (e.g. experiments relating to dementia or aging) animals may be in the laboratory for up to 24 months (although this will typically involve only 3-6 months of direct experimental work).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The bulk of procedures will produce (at most) transient pain or distress, with minor disturbance of normal behaviour. Extended or excessive distress would lead to the discontinuation of experimental work and either termination of the animal or appropriate treatment under veterinary advice. Some treatments (e.g. stress exposure) can have extended effects on behaviour - although these are typically subtle and do not involve large changes in voluntary feeding/drinking or bodyweight. Excessive changes in behaviour or bodyweight loss would lead to the discontinuation of experimental work and either termination of the animal or appropriate treatment under veterinary advice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Rats - 1400 overall. Expected to be approximately 75% mild, 25% moderate.

Mice - 200 overall. Expected to be approximately 75% mild, 25% moderate.

What will happen to the animals at the end of the study?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are two main reasons why it is necessary to use animals to understand the psychological and biological mechanisms underpinning affective and cognitive processing.

The first is that affect and cognition fundamentally involve a behaving organism interacting with its environment. With respect to the investigations of disorders of affective and cognitive function, no

currently available in vitro model systems can capture the full range of molecular, cellular, physiological and behavioural consequences of environmental or genetic risk factors for neuropsychiatric disorders.

The second is that animals are necessary for a range of other laboratory studies and the assessment of such manipulations on their welfare (and means to minimise adverse impacts) requires the use of the relevant species.

What was your strategy for searching for non-animal alternatives?

As noted above, the key questions for this project relate to the behaviour and biological function of whole animals. There are no non-animal alternatives for this project. That said, the animal based work will be supplemented by both ex-vivo analyses (e.g. of brain tissue) and computational modelling.

Why were they not suitable?

As noted above, the key questions for this project relate to the behaviour and biological function of whole animals - non-animal alternatives do not meet this need.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The primary basis for estimation was the level of work currently funded and in progress, with a projection of future funding at similar levels. These experiments have been planned using power analyses (where sufficient information exists to estimate effect sizes) or on the basis of Bayesian methods for cumulative data collection.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

I teach experimental design and statistics - as such, professional development includes keeping up- to-date with optimal design and analysis strategies. This knowledge will be applied in the design phases of all experiments to minimise animal numbers.

What other measures apart from good experimental design will you use to minimise numbers?

Where appropriate, pilot studies will be used to provide data for power analyses to determine optimal group sizes. Alternatively, cumulative data collection supported by Bayesian analysis will be used to ensure that only the minimal number of animals are used where power analyses are not likely to be accurate (i.e. in the absence of reliable information about effect sizes).

In addition, re-use of animals will reduce overall numbers. Tissue will be collected for post-mortem analysis - and shared where useful to others.

Finally, data will be archived for open access - supporting additional analyses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The animals used in this project will primarily be tested with reward-based procedures - the main scientific focus is on the processing of rewarding stimuli and the failures of this processing in models of risk factors for psychiatric diseases. Mild food or water restriction will be commonly applied to motivate consumption of rewards. However, the reward-based procedures are sometimes used in combination with - or comparison to - procedures that can cause pain or distress. For most applications of these aversive procedures, the experience of animas will involve mild procedures such as injections or exposure to short-term stressors. Individually, these cause only transient harm - but in combination or with repeated application they can contribute to cumulative suffering. A subset of the animals used in this project (approximately 12.5%) will receive the surgical implantation of an oral cannula under general anaesthesia.

These behavioural methods were chosen to reflect validated tests of the hedonic (e.g like/dislike), motivational (e.g. subjective effort for acquiring reward), and cognitive (e.g. bias to or away from rewarding or punishing stimuli) processing of rewarding and punishing stimuli. Although some harms are inherent in these procedures (e.g. nausea from exposure to lithium-chloride), they have been designed to involve the minimum of harm consistent with the scientific purpose of the project.

The animals to be tested are chosen to isolate the effects of known risk factors for psychiatric disorders - including genetic and environmental risks (e.g. exposure to stress), or appropriate control animals to investigate normal functioning. Because the project is based largely on behavioural testing, models that produce severe harm or distress would be entirely inappropriate as this would interfere with voluntary behaviour.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Affect and cognition are properties of a whole, behaving, animal. They cannot be fully investigated under terminal anaesthesia. In addition, for the work to be directly translatable to humans, a mammalian species is also needed. The majority of the studies will use rats, because they have a high degree of behavioural flexibility and there are optimised behaviour-analysis methods appropriate to the

scientific goals of the project for rats. In some cases mice will be used where genetic manipulations of interest are only available in mice.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Because the bulk of the experimental work on this project uses behaviour analysis, it involves regular (typically daily) contact with the experimental staff. Disruption of ongoing behaviour is a particularly sensitive sign of ill-health - often occurring before clinical observation could detect changes. Thus the experimental work for the project itself provides an additional layer of monitoring.

One of the aims for the project is the investigation of potential harms produced by common laboratory procedures (e.g. injections). If this work reveals unexpected harms from such procedures, they will be modified to reduce those harms (e.g. changes in the method of restraint for injections).

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

There are no specific best practice guidelines for the specific behavioural procedures used on this project (many of which have been developed/optimised for bespoke use in this laboratory). More general best practice guidelines (e.g. for husbandry or blood sampling) provided by the NC3Rs will be followed, as will the recommendations of the BUAAW/FRAME/RSPCA/UFAW working group on refinement of procedures for administration of substances.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The REDACTED has the benefit of anREDACTED and runs annual 3Rs workshops. I also subscribe to the NC3Rs newsletter. In addition, prevoious scientific work includes direct contributions to the 3Rs. Thus general academic reading includes coverage of the 3Rs as well as coverage of the behavioural techniques to be used on the project.

The behavioural methods to be used are already optimised for their scientific purposes, and chosen as the most well refined methods for 3Rs purposes on the basis of current knowledge. Should further refinements be made, they will be implemented as they have been in previous work undertaken on past projects (e.g. the use of lick analysis assays of hedonic behaviour to replace some taste reactivity tests previously based on the use of surgically-implanted oral cannula). In addition, 3Rs advances in husbandry (e.g. tunnel rather than tail handling of animals) will be adopted when they are demonstrated (e.g. work on a previous project included a contribution to the demonstration of the general improvements in mouse welfare produced by tunnel handling).

Explain the choice ofspecies and the related life stages

There are two main reasons why it is necessary to use animals to understand the psychological and biological mechanisms underpinning affective and cognitive processing.

The first is that affect and cognition fundamentally involve a behaving organism interacting with its environment. With respect to the investigations of disorders of affective and cognitive function, no currently available in vitro model systems can capture the full range of molecular, cellular, physiological and behavioural consequences of environmental or genetic risk factors for neuropsychiatric disorders.

The second is that animals are necessary for a range of other laboratory studies and the assessment of such manipulations on their welfare (and means to minimise adverse impacts) requires the use of the relevant species.

Rats and mice are used because they are mammalian species that afford translation to humans, allow the implementation of targeted genetic manipulations, and display high levels of behavioural flexibility needed for the experimental procedures to be implemented.

Adult and juvenile animals will be used to reflect both stages of development and the fact that early-life experience can impact on adult behaviour and function.

NON-TECHNICAL SUMMARY

3. Age and agents to minimise radiation-induced cardiovascular disease

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

Age, Ionising radiation, Athersclerosis, Cardiovascular disease

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Cardiovascular disease is one of the most common cause of death in developed world. The main cause of cardiovascular disease is atherosclerosis, which is a swelling inside the wall of blood vessels (plaque) causing obstruction to blood flow that may result in heart attack or stroke.

Exposure to radiation is known to increase the risk of cardiovascular disease development and there is some evidence that age at exposure may affect this risk. However, this has been shown in cultured cells and it is unknown if a whole animal would respond in the same way. There are also drugs that we have shown to reduce early stage development of atherosclerosis in cultured cells, but again it is not known if these effects will be seen in the complexity of a whole organism.

We will investigate in a systematic manner to meet our objectives:

1. Establish whether age at exposure to ionising radiation affects likelihood of cardiovascular disease development.

2. Discover whether drugs can reduce the development of atherosclerosis following radiation exposure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Establishing whether age at exposure to ionising radiation affects likelihood of cardiovascular disease development would allow for individual risk assessments and practical use of the information. For example, those that have a higher chance of developing radiation-induced cardiovascular disease can have the amount of radiation they receive kept to an absolute minimum during medical and occupational exposures. Whereas individuals from an age group that is less sensitive may be able to tolerate higher doses without additional risk of cardiovascular disease; therefore, beneficial medical/economic effects of additional scans, radiotherapy treatment for cancer or time spent in areas with increased levels of radiation can be achieved.

In addition, the project will test drugs that have been shown to reduce the number of senescent cells (cells that no longer divide but secrete harmful substances) that have been shown to be central for atherosclerosis development. These drugs are already licenced to be used in humans for other purposes and could be re-purposed to minimise cardiovascular disease.

Both aspects of the project will also help scientists to understand the links between person age, cell age and radiation-induced cardiovascular disease. Long-term this will be the first step in the development of new approaches to reduce radiation-induced cardiovascular disease in the population.

The primary aim of this project is protection of human health, however there may also be veterinary application.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

This project will use a maximum of 530 mice over 5 years.

Initially 24 mice will be used in a pilot experiment to establish the most suitable X-ray dose to study atherosclerotic plaque formation in a mouse model that has not been used for radiation research before and so these is no existing data is available.

Then we will use up to 200 mice in the first part of the project to establish the effect of age-at-exposure on radiation induced atherosclerosis.

If these results are clear, we expect to use up to a further 240 mice in phase two of the project to treat with drugs following radiation exposure; with the aim of preventing radiation-induced cardiovascular disease. If a significant age effect is not seen in stage one, only 120 additional mice will be required, as mice of a single age group only will be tested.

All mice used will be genetically altered strains that lack a gene involved in controlling cholesterol levels (Apoe-/- or Ldlr-/-) so are predisposed to form atherosclerotic plaques. These mouse models have been proven as a successful model in previous atherosclerosis research.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The project is anticipated to have no adverse health effects. It is possible that a small number of mice may experience moderate effects as a result of exposure to ionising radiation or the effects of the genetic background of the model and associated atherosclerosis development, although this is unlikely within the timeframes proposed.

The animals will receive an X-ray dose (0.5-4 Gy, depending on strain) at either a young or older age, which may result in a small and transient weight reduction. This is most likely to occur in the pilot experiment where the response to radiation has not been tested previously. Any mice receiving drugs are expected to have a beneficial effect on their health. All mice will be monitored daily, those showing any adverse effects will be monitored more closely and any signs of severe pain, suffering or will be euthanised. Mice will be kept for up to 6 months following X-rays (or sham) exposure to allow atherosclerotic plaques to develop.

The mice will be group housed and provided with enrichment. At the end of the experiment all animals be killed by a humane method, after which, tissues (blood, aorta and other organs) will be removed for analysis to assess atherosclerosis development and ageing in the mice.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We have set up and tested a method to investigate atherosclerosis resulting from radiation in cultured cells isolated from humans, including young and old donors to determine age effects in this non-animal alternative model. Having established the mechanism of the early steps involved in radiation-induced plaque formation and assessed the effect of drugs in this system, it is necessary to confirm these results in an animal model.

Lower species such as non-vertebrates and fish are not appropriate for this research as they have very different circulatory systems and have not been proven to be a good model for studying atherosclerosis.

Numerous resources including NC3Rs, PREPARE guidelines and Norecopa have been used to investigate additional non-animal alternatives.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Good experimental design (including randomising treatments and blinding) have been used to maximise effect and reduce unwanted variability. We have also used all existing data available from our own cell culture models and other researchers that have used these mouse models to gain a best estimate of the expected effects. Therefore, group sizes and overall number of mice used can be kept to a minimum while still getting a clear result on the effect of age on radiation-induced atherosclerosis and the use of drugs to prevent this.

For the ApoE-/- mouse model, we are using a low dose of radiation, but slightly higher than the minimal dose published to have an effect. This is to provide higher power of the data while using fewer animals (without significant increase in negative effects). As radiation effect in LDLr-/- mice has been studied, the inclusion of a small pilot will prevent using larger numbers in the main experiment with uncertain outcomes.

Throughout the project, we will consider results that may allow a reduction of mice used in later stages. For example, if out pilot experiment shows that LDLr-/- mice do not demonstrate radiation-induced atherosclerosis then no further experiments will be carried out in this strain, considerably reducing overall numbers.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The removal of tissue for analysis only after the death of the animal means procedures in living animals are reduced. Post-mortem techniques required will also be practiced beforehand on cadavers to ensure they are carried out correctly on experimental animals.

Drugs will be used at doses reported not to be toxic to the animals and where possible will be provided orally in food/water to minimise handling and distress.

Genetically altered mouse models will be used in order to study plaque formation, which does not occur in normal mice fed a normal diet, and also prevents feeding a high-fat diet that can allow plaque formation but results in obesity and metabolic syndrome.

A single sub-lethal X-ray dose will be selected that is the minimum dose required to see a clear increase in plaque formation.

We have chosen a radiation dose and end-point where we anticipate that plaque development will have progresses enough for analysis, but before any negative effect is expected to be experience by the mouse.

All animals will be provided with comfortable group housing and enrichment. We do not anticipate the animals to experience any pain, but analgesics and increased monitoring will be used if considered appropriate.

Home Office

NON-TECHNICAL SUMMARY

4. Analysis of Fish Development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult, pregnant
Giant Danio	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We use fish to investigate how, from a single fertilised egg, cells organise to form organs such as the eye, or how nerve cells connect to form the central nervous system. We would like to understand how the brain receives information from its environment, and, ultimately, how it processes this information to evoke behaviour responses.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The projects described in this application will contribute to a better understanding of a range of human eye diseases, as well as human brain diseases and their effects on behaviour (e.g. autism, dyslexia, schizophrenia), and thus contribute research data that can be used in drug development, or for diagnostics in the health system and, thus, will ultimately benefit human health. In addition, we are using the fish to understand defects in cell functions that lead to diseases linked to abnormal levels of metals in the cells. Such changes can cause, for example, childhood Parkinson's disease and, in collaboration with others, we are trying to find new drugs for treatment.

Our proposed programme of research will contribute knowledge of genes that are candidates for inherited human eye (ocular) diseases, a better understanding of the processes that these genes control, and novel animal models of human eye disease phenotypes. As such, our research is of relevance to and has the potential to have impact upon a) clinical research scientists, who will use our data to screen cohorts of patients for genetic changes (mutations); b) pharmaceutical industry researchers who could develop our novel disease models and transgenic animals for drug screens. Our knowledge will provide the basis for understanding the genetic and mechanistic basis of eye disease phenotypes such as microphthalmia (small eyes), anophthalmia (absence of eyes) and coloboma (the failure to close the eye cup completely). The information that we acquire from genetic analyses of zebrafish with eye defects will be shared with collaborators who will screen for comparable genetic defects in human patients with eye malformations. Our studies exploit novel techniques and resources to bring an unprecedented level of insight to the complex events that characterise early eye development and through this will help us to diagnose, model and understand human eye disease phenotypes. Proteins we study in the eye are also involved in the growth of other tissues and organs and some have been linked to cancer. In parallel, we will continue to investigate the mechanisms underlying the specification, function, behaviour and survival of specific classes of stem cell in the eye and brain which will allow us insight into which processes are affected in certain developmental defects (such as Human coloboma; 1:20,000 live births) or human degenerative diseases affecting the eye and the brain, as well as understanding signals that influence cell divisions in these cells. Thus, our research will benefit understanding of cancers in the nervous system, with their key hallmark of uncontrolled cell division.

Our studies of the mechanisms of differentiation of neural (brain) tissue into different brain nuclei and their connections (brain circuits) has led us to address links between defined brain circuitry and animal behaviour. Our current area of specific interest and expertise lies in asymmetry of the central nervous system (CNS), the brain. Altered CNS asymmetries are thought to be involved in a variety of human disorders from schizophrenia, dyslexia, depression and other mood disorders, as well as neuro-degenerative diseases such as Alzheimer’s disease. Diagnosis of these disorders is often problematic

and thus the number of officially diagnosed persons is likely to be a low estimate. However, it is estimated that more than 1 in 100 people may be affected by autism spectrum disorder in the UK (about 700,000), a similar number of people suffer from schizophrenia. Some people suffer a schizophrenia episode at least once in their lifetime and for some it becomes a chronic disease. Treatment is often restricted to pharmacological intervention; a better clinical outcome is achieved when treatment commences at a pre-symptomatic stage. Zebrafish show a range of complex behaviours from 5 days post fertilisation and offer a valid alternative to using rodents (mice or rats) for preliminary behaviour analyses and to test which small molecules, such as drugs, are effective to bring about a change in behaviour. For our research we are using and developing new behaviour tests for the zebrafish to make models for diseases we see in humans in which behaviours and brain function are affected. We are using these tests together with trying to identify new drug targets and find new genes that lead to disease symptoms. We hope that we will identify biological markers and molecules that may lead to the identification of drugs that are more effective for treatment in humans as well as help with early genetic diagnosis.

Finally, we are using zebrafish to model some aspects of early childhood diseases that affect metal metabolism in tissues and cells. In humans, changes in the concentration of metals, such as manganese for instance, leads to early onset Parkinson's disease affecting movement and cognitive functions. One therapeutic route currently tried in humans, is the use of drugs (chelators) which bind to metal ions in the cell and thus lower the effective cellular concentration. However, there are currently no drugs that specifically target, for example, manganese metabolism, thus patients treated with such 'chelators' have less severe Parkinson's disease presentation but suffer from side-effects such as osteoporosis. Therefore, developing and testing drugs that target the metal transporter defect more specifically is vitally important. Our research not only facilitates correct diagnosis of patients with such diseases, but may also provide an avenue for effective treatment.

What outputs do you think you will see at the end of this project?

1) We will have identified new candidate genes that are likely required for normal eye development. We will also have progressed in our understanding of the genetic interactions of different genes and what genetic conditions predisposes a person to suffer from the eye diseases we study. This information can be compared to current data bases of information of patients with abnormal eyes and vision defects. In addition, there has been a big effort to sequence all the genes of 100,000 (and more in the future) people with rare genetic diseases. We are collaborating on this project and we will use information from the project as well submitting information gained from our work.

2) We will have a greater understanding of the processes and proteins that maintain cells as more stem cell like progenitor cells. We are studying the properties of this important class of cells, stem cells, in the eye and also in the brain. What factors in their environment or within the stem cells helps them to maintain the stem-cell -like character and which factors push them towards committing to a specific cell fate, such as a specific class of eye cells or nerve cells?

3) We will have a better understanding of the involvement of specific neurotransmitters in the brain of fish that are involved in specific tasks, for example exploring their environment. We will compare normal (wildtype) fish with fish in which we have changed the function of genes which might be defective in human diseases and mood disorders. This will give us a handle on how a fish reacts to its environment, for example with increased anxiety. We will build an 'atlas' showing where and when different

molecules are released during brain activity. This can be used by other researchers and avoids duplication of work

4) We will have tested new molecules in our attempt to identify those that are more effective in helping with the symptoms of childhood Parkinson's disease.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

1) Several human genetically inherited eye diseases arise from abnormal cell specification or cell behaviour at early stages of eye development. Our proposed programme of research into the development of the eye in health and disease will contribute knowledge of genes that are candidates for human inherited eye diseases, a better understanding of the processes that these genes control, and new animal models of abnormal human eye phenotypes. As such, our research is of relevance to, and has the potential to have impact upon a) clinical research scientists, who will use our data to screen groups of patients for mutations; b) pharmaceutical industry researchers who could develop our novel disease models and transgenic animals for drug screens.

2) In parallel, we will investigate the mechanisms underlying the specification, function and survival of stem cell in the eye and brain which will allow us insight into which processes are affected in certain developmental defects or degenerative diseases affecting the eye. Our research data on stem cell maintenance and survival will give important information for potential clinical use in stem cell treatment/replacement in degenerative diseases of the eye tissue (for example due to damage, genetic predisposition or age) or for degenerative diseases affecting specific areas of the brain.

3) Our study of neuronal circuit formation aims to link functions of neuronal subsets to animal behaviour. Our area of specific interest and expertise lies in brain asymmetry. Altered brain asymmetries are implicated in a variety of human disorders from schizophrenia, dyslexia, depression and other mood disorders, as well as neuro-degenerative diseases such as Alzheimer’s disease. The zebrafish offers a valid alternative to using rodents for preliminary behavioural analyses and to test the efficacy of novel drugs. The zebrafish community (and other research communities) benefits from the atlas showing whole brain activity.

4) Besides informing other researchers and clinicians, we hope that patients are benefitting from novel drugs more specifically targeting problems with metal transport into and out of cells and help with symptoms of movement and learning disabilities. Our research not only facilitates correct diagnosis of patients with this disease, but may also provide an avenue for effective treatment.

How will you maximise the outputs of your work?

In addition to publishing our findings in scientific journals, we present our work online on our website where anyone can download information and read about ongoing projects. Our work proposed in the application will generate a wealth of data on gene interactions in the eye that are of interest to developmental biology as well human genetics communities and we will create a data base with the information from our genetics screens that is readily accessible. Our data on the functioning of brain networks during specific tasks and genes that are necessary to build and maintain the left-right

difference in our brain will be shared with other researchers and our project of the brain atlas will be a reference tool for the whole scientific community and will be made available online.

We also present our research as invited speakers at conferences or research institutes which allows direct exchange of information, including the best (or worst) approach to a particular scientific question. Finally, having worked in my chosen field of research for over 30 years, we have a vast network of collaborations with individuals as well as institutes in the UK and all over the world. We often have visiting scientists working with us to learn new technologies, similarly, we send our researchers to other groups to broaden their technical skills. We also have direct collaborations with clinicians working on eye diseases and also metabolic diseases in children.

Species and numbers of animals expected to be used

- Zebra fish: 222,000
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The vast majority of the fish we use (>90%) will be for maintaining the fish stock and for breeding to provide us with eggs to use in our research. A smaller number will be used e.g. for studying animal behaviour where we watch their response to another fish, or another stimulus. In some studies we might add substances to the water to study the effect of a drug on the animal's behaviour, or we might look for a drug that will treat a disease or abnormal behaviour.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We do not expect that most animals will be much affected. Most animals are used for breeding and in behaviour analysis, and, generally, the animals should not experience pain. Experimental animals might experience temporarily mild discomfort or mild pain. On rare occasions, animals might experience moderate discomfort or longer-lasting mild discomfort or mild pain. We do not expect weight loss, tumours or other gross abnormalities. The possible exception are animals which might, for example, experience some effect on their movement (swimming) behaviour in our model of human diseases that affectthe nervous system.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of our fish (about 88%) should experience levels of pain and discomfort that is less than mild pain and discomfort, and should not affect them. Some fish (about 10%) might experience mild discomfort, not more than the prick of a needle. In a small number of animals (<5%) it is possible, although unlikely, that there is a temporary moderate discomfort. All animals will ultimately be killed using humane euthanasia methods in accordance with guidelines.

What will happen to the animals at the end of the study?

- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our studies examine complex interactions between the cells in the organism and their organisation into tissues and organs in the developing embryo. In particular, we focus on how the eye develops from the embryo to the adult animal and how information that is received by the sense organs is processed by the brain. Finally, we study how information received by the animal via their sense organs and the organisation of the brain influence how an animal behaves.

The eye of a vertebrate such as a fish or human, the complexity of the brain organisation, and animal behaviour such as social preference, are very different than the eye, brain and behaviour we see in less sentient animals such as worms or flies. We are also trying to model human diseases of the eye and nervous system which we cannot study it in less complex animals, or in a tissue culture dish or in a computer simulation.

Zebrafish is an ideal model because its brain is a simpler version of that found in mammals such as humans. By studying zebrafish, we are using an animal considered less conscious/aware than mammals to achieve our research goals and to answer our scientific questions.

We have, however, started a pilot project using the nematode *C. elegans* for some of our genetic analysis into the genetic and molecular interactions of proteins thought to be required for normal eye development, as well as identifying novel players. This represents a true achievement of replacement.

What was your strategy for searching for non-animal alternatives?

We use bioinformatics and computational analysis to analyse our data from animal research in the most efficient way.

We are using animal research data to build a standardised reference brain atlas to give temporal and spatial information of the expression of neurotransmitters and other small molecules in a behaving

animal, that is an animal involved in a behavioural response.

We have developed an 'organoid' system of the developing eye in which we can study the less complex cellular interactions of early eye development. This system, although useful, has its limitations as environmental factors form surrounding tissues, including tissue tension, cannot be modelled in this system yet. The 'organoid' eye is radially symmetrical, unlike the normal eye.

Why were they not suitable?

The vertebrate eye is a very complex structure. We cannot study the role that particular proteins play in the development of a normal eye, or what happens when they do not function properly except in the whole animal. Similarly, we are studying how the left and right side of the brain become different in their structure and function during development, similar to that what is seen in humans. This cannot be modelled adequately on a computer. Lastly, we study the complex interaction of an animal with its environment, again this has to be done using animals and modelling can only give us suggestions of what to explore further.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of fish are estimated based on our experience on how many fish we need for breeding, and on power calculations for animals used in experiments. The majority (ca 75%) will be used for the generation of new genetic lines and for breeding and maintenance, about 60,000 (ca 25%) will be used to study, e.g. animal behaviour.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We use statistical design to determine the number of animals we need to use for each experiment to get a valid result. It is important to balance the need to have statistically significant results with the desire to reduce the number of animals we use as much as possible.

We are also building a standardised reference brain which, once established, will reduce the number of animals that are used dramatically. REDACTED

We are also using the nematode *C elegans* for some pilot studies of genetic interactions, instead of fish.

What other measures apart from good experimental design will you use to minimise numbers?

Most fish we use are for the generation of new fish lines. We have developed new techniques that allow us sample fish that might be of scientific interest to us at the embryo stage instead of having to wait until they have reached sexual maturity to identify those of interest.

We also will be using worms instead of fish for some preliminary studies to identify new interactions of proteins involved in the normal development of the eye.

Finally, we use bioinformatics, i.e. using computers to analyse our data to ensure we make excelent use of all data we received from our experiments. This is especially helpful in finding genetic changes that might be the causes of diseases or developmental abnormalities. This also helps to share our information with the zebrafish community locally and internationally and avoids duplication.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We are using the zebrafish to model the development of the eye and the brain in health and in disease. Unlike mammals, zebrafish lay their eggs externally and we can simply collect them from their home tank, no harm done to the females laying the eggs. The embryos are transparent which allows us to gain much information by simply examining them under a microscope.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

A large amount of our work is using animals at the immature, embryonic stage or after after they were killed humanely. Only for some of our studies we need to use larvae (young fish). For example, in our study of animal behaviour, we need to use larvae that show a robust swimming behaviour, and in some cases are old enough to show social preference. We are using the least sentient model animal that shows a similar eye and brain structure and organisation as we see in humans.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We are making every effort to balance harm/benefit and to refine our methods and to use fewer animals in accordance with the 3Rs.

Advances in ‘reverse’ genetics now enable us to generate mutations in specific genes or establish transgenes at specific places in the genome. Thus, for genes of interest, we can now induce targeted

mutations as well as test for ‘rescue’ of a defect instead of generating a large number of randomly mutagenised fish to be screened for a specific mutation. This results in a substantial reduction in the number of animals that are used to identify a specific mutation. In addition, the transgenic lines generated are incredibly useful to answer our research question more specifically and often non-invasively, and thus helping to reduce the number of animals that have to be used to obtain valid data, as well as severity levels, in observance of the two of the 3 R’s, Reduction and Refinement.

If a new effective method to identify transgenic and mutant animals in embryos or fry is established that avoids fish to be grown to maturity, e.g. by removing small number of cells in early embryos to be used for genotyping instead of fin biopsies, we will adopt a different method for identifying genetically altered animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Local AWERB guidelines; ARRIVE guidelines of the NC3Rs; guidance on Animal Testing and Research from the Home Office; Good research practice guidelines from the Wellcome Trust; LASA and RSPCA guidelines; PREPARE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

For example, the information given on the websites of organisations involved setting policy and also in the advancement of the 3Rs (e.g. the National Centre for the Replacement, Refinement and Reduction of Animals in Research; Institutional guidelines, Home Office). In addition, I stay informed through communication with my project manager who is a longstanding member of our institute's Animal Welfare and Ethical Review Board. In conjunction with other longtime senior members of my group, we ensure implementation of the 3Rs and Home office guidelines, and monitor compliance and training of all members of our research group.

Explain the choice of species and the related life stages

Our studies examine complex interactions between cells and how they become organised into tissues in the developing embryo. In particular, we focus on the interactions between structures of the sense organs and the brain, and how an animal reacts to signals from its environment. We cannot model the development of the vertebrate eye and brain adequately in animals such as worms or flies or in a laboratory dish. Wherever possible, we are, however, also using computational analysis of our data to help us reduce the number of animals we use in our research. We have also started to complement our work in the fish with preliminary research on how specific gene and their proteins, that are candidate genes for eye diseases, interact in the worm *C. elegans*.

Zebrafish is an ideal model because the way its brain and eye are build is a simplified version of that found in mammals such as humans. By studying zebrafish, we are using an animal considered less aware than mammals to achieve our research goals and to answer our scientific questions. Through our work we have contributed to reducing research with mammalian species.

For most of our studies we will use very young embryos without a mature nervous system. However, to study how an animal behaves in response to its environment we will need to use young fish that can swim and show social behaviour.

Home Office

NON-TECHNICAL SUMMARY

5.Analysis of psychological stressors in cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to understand how stress can influence how cancer develops, progresses and spreads in mice. In addition, we aim to test novel treatments such as stress hormone blockers and immune modulators on improving cancer progression and response to treatments. The project is focused on 3 cancers; breast, ovarian and prostate because these cancers are all solid tumours, and also because in some cases they have a gene in the gene called BRCA1 which can make these cancers aggressive.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

1 in 7 women will develop breast cancer, 1 in 8 men will develop prostate cancer and ovarian cancer is one of the deadliest diseases. It is well established that stress (e.g social isolation, anxiety and depression) can play a role in cancer progression; however much of this work is based on epidemiological evidence and the exact mechanisms are currently still not yet known. In addition how stress affects treatments are not fully established. The immune system, which is also affected by stress hormones, plays important activating and suppressing roles in controlling cancer. Tumour cells can evade immune recognition. However, the cellular mechanisms whereby stress hormone exposure mediates changes in immune cell trafficking, function and the effects of stress on the outcome of immune therapies are largely unknown.

Therefore this project will result in a better understanding of the link between stressors, the immune system and disease progression to improve treatment strategies and patient outcome.

What outputs do you think you will see at the end of this project?

1) Understand the effects of psychological stressors on cancer progression and response to drug treatment in mice bearing human xenografts of breast and ovarian cancer and syngeneic mouse models.

New information:

i) Understand how different types of stress can impact the immune system and cancer spread

ii) Determine if stressors can impact cancer progression by measurement of tumours.

iii) Determine if stressors can affect the response to drug treatments such as chemotherapy and PARP inhibitors.

2) Analyse the role of the REDACTED in cancer

New Information:

i) Determine the Impact of stress and the microbiome on tumour establishment and spread

3) Use of stress and immune therapies and novel drug delivery methods as a strategy to treat cancer using the models described above.

Our long-term goal is to identify new personalised approaches to improve outcomes for cancer.

1) test the central hypothesis that stress influences cancer progression by modulating immune cell recruitment into the tumour and how it works e.g killing of tumours.

ii) test combined treatment of immune therapies with a stress hormone receptor blocker (propranolol or Mifepristone and other glucocorticoid receptor blockers) to improve treatments of cancer.

These will lead to publications in high quality journals such as breast cancer research, cancer research etc.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

What are the benefits?

This project will allow us to develop a better understanding of the signalling mechanisms involved in stress, the immune system and cancer and further help us understand the role of the REDACTED in treatment efficacy. Ultimately, the results of this research will allow the improved diagnostics and drug efficacy in cancer

Who will benefit

Patients with breast, ovarian, prostate cancer, clinicians and academic researchers will benefit.

How they will benefit

To improve benefactor's understanding of 1) stress management; a major societal impact, 2) improve efficacy of drug treatments and design of clinical trials; resulting in a refined management of economic resources 3) Improve our understanding of stress in the context of disease and use novel technologies to treat and diagnose disease.

When will they benefit

The short term benefit will be that our findings are published in peer reviewed journals within 1-2 years (please see results from last project license to prove this). The longer term benefit is that we aim to translate this animal research to a clinical trial and interventions within 5-10 years. For example, Researchers in MD Andersen, USA discovered that catecholamines can influence ovarian cancer progression and within 5 years clinical trials are being designed using beta blockers to limit catecholamine influence.

How will you maximise the outputs of your work?

Scientific: Data from this proposal will be published in high impact journals such as Cancer Research, and will be presented at both national and international conferences (e.g. American Association for Cancer Research, National Institute of Cancer Research Annual meeting).

REDACTED We plan to promote and discuss our work at patient forums by giving talks and offering leaflets on our research. We will hold forums such as public lectures and Q & A sessions and also to promote a road show stall in a charity event such as Independent Cancer Patients' Voices. Also, the PI and team plan to engage in the electric 5 k run for cancer charities to raise funds for the charity and wear T shirts to promote their work. I will offer lab tours"-about 4x/yr for their fundraisers and volunteers - lay members of the public

Species and numbers of animals expected to be used

- Mice: 1000 BALB/c and 1200 C57BL/6

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Stressors

To assess the effects of psychological stress on immunity and cancer progression, groups of mice will undergo restraint stress: standard confinement in a tube that prevents turning, or social isolation: single

housing in a standard cage. After stress, mice will be killed humanely and sera will be collected immediately following restraint stress.

Immune Adoptive transfer

Mice will be injected with cells into the dorsal flank. Some groups will receive immune cells adoptively transferred from mice above.

Cancer cell injections

Mice will be injected with ovarian and prostate cells by IP injection on week 1 and by injections into the mammary fatpad for breast cancer cells.

Stress hormone blockade.

For cortisol blockage, glucocorticoid blockers will be administered daily by oral gavage or by IP injections. Mice may receive drugs through an Alzet minpump.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Mice will undergo tumour implantation and growth of tumour to a maximum size of 1.2 cm (1.5 cm for treatment experiments). This will result in some mild to moderate discomfort. Mice will receive treatments by injection resulting in mild and transient pain and discomfort. Some mice will be exposed to a stressful situation: restraint for 2 hours per day or singly housed for 4 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Moderate (100%).

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Investigations using these models will allow cellular mechanisms of cancer to be studied in detail as well as the effectiveness of novel diagnostics and therapies. These animal models of cancer must ultimately be used as these are the models which most closely resemble the pathophysiology observed in patients. More specifically, these models are able to reproduce the complex interactions observed between different systems which prevail in cancer such as the interactions between the immune and nervous systems. Many years of research mean that we now have established animal models of stress and cancer.

What was your strategy for searching for non-animal alternatives?

In-vitro work such as cell line models are considered to be a replacement alternative, and we are currently using in-vitro models of cancer in our lab. In addition we will be using human cancer tissue to develop organoid models of cancer to complement this research.

Why were they not suitable?

At present, cell culture methods cannot fully recapitulate the 3D nature of tissues, the diverse environment of differentiated tissues, or the bioactive compounds e.g enzymes found in the tissue and blood. In addition, cell culture methods necessarily use immortalised cells, which are cancerous in nature, rather then primary cells. Tissue culture cells are known to have different responses to the environment than primary cells, therefore cannot create a true environment for studying cell communication.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used statistical methods to determine that we will require around 10 mice per experimental group and typically experiments will compare 3 or 4 groups. We aim to test around 5 different potential treatments in three types of cancer over five years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have used both expertise from statisticians and also we have used the NC3Rs' Experimental Design Assistant

What other measures apart from good experimental design will you use to minimise numbers?

From our current project license we have garnered enough information to allow to perform power calculations to reduce our animal numbers. In addition we routinely share tissue with several other PIs and these have included: brain, spleens, lymph nodes, gut tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mice with or without a particular genetic changes because we can directly look at the effects of stress on cancer cells in the absence of a an immune system. We have carefully considered each of the procedures described in this application in order to minimise pain and distress experienced by animals, and to enhance their well-being. Anaesthesia and analgesia are used whenever appropriate and possible. Careful consideration has been given to the endpoints and measurable parameters obtained from each procedure and as much information as possible is gained from each animal. At the end of each experiment, the most humane method of euthanasia is always chosen.

We will inject the minimum number of cancer cells in the smallest volume into the mammary fatpad. Measurement variations will be minimised by ensuring that the same well-trained technician is involved for the duration of the study. For an animal carrying a single tumour, the mean diameter will not normally exceed 1.2 cm in mice.

Stress Method: We will use a 1h (acute) or 2 h daily over several weeks (chronic) restraint stress or social isolation.

Rationale: This is a well-established method for activation of the hypothalamic adreno pituitary axis resulting in elevations of stress hormones and to study the effects of psychological stress in rodents. We will use this method to examine the effects of stress on ageing, cancer spread and on the immune system.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The experiments proposed will use the simplest possible animal system, which has an intact immune and endocrine (stress response pathways) which is the mouse model.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to

the animals?

We weigh the mice weekly and if a procedure is more complex e.g insertion of Alzet pumps will monitor the animals daily and we have created a Standard Operating Procedure (SOP) for surgery in mice.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Before the start of any animal experiment we discuss this with our NACWO and write up a project outline. We also have SOPs in place for more complex experiments e.g. those requiring anaesthesia and surgery. We will follow the guidelines of Workman et al (2010) paper 'Guidelines for the welfare and use of animals in cancer research' British Journal of Cancer (2010) 102, 1555–1577 for tumour injections and the LASA Guidelines on administration of substances, LASA Guidelines on aseptic technique.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will check the following website: https://www.nc3rs.org.uk/ monthly for updates and will address any updates at our weekly lab meeting and disseminate this information to all personal license holders. In addition our NACWO and NIO often provides NC3R updates.

Explain the choice ofspecies and the related life stages

The adult mouse model is relevant to our studies because they are the lowest species in which we can address our questions regarding stress, immune and cancer models. The mouse model is most widely used and accepted animal system for these type of studies

Home Office

NON-TECHNICAL SUMMARY

6.Animal Models of Human Disease

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	juvenile, adult, neonate
Mice	juvenile, adult, neonate
Guinea pigs	adult, juvenile

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The objective of this project licence is determine how the body processes potential new medicines and whether these new medicines are a cure for human diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to perform this work because there are still many human diseases (e.g. Alzheimer's, lung fibrosis) for which there are no cures or because the cures that exist are not effective.

What outputs do you think you will see at the end of this project?

The outputs from this project licence will include the following;

- Study reports which describe how the body reacts to the new medicine and whether the new medicine is likely to be effective if given to human patients.
- Peer-reviewed publications
- Data presentations at conferences/internal meetings
- Blogs/webinars (internal and external)

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Enabling the development of successful medicines will benefit society through diagnosis, treatment or prevention of disease.

Identification of toxic reactions can prevent future harms to human volunteers or patients by resulting changes to drug development programs.

The wider scientific community will benefit from publication of data demonstrating improvements in study conduct that improve the relevance of the animal model or lead to refinements and reductions in animal usage.

How will you maximise the outputs of your work?

- In-house collaborations and information exchange with others within the organisation worldwide, identifying successful and unsuccessful approaches.
- Collaboration with clients (knowledge gained on products).
- Hosting scientists and animal carers from other establishments, including universities, to promote best practice.
- Presenting outputs at international scientific conferences .The project licensee also liaises with local universities to share best practices.

Species and numbers of animals expected to be used

- Mice: 15,000
- Rats: 10,700
  Guinea pigs: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Many of the studies conducted in this licence require that lung injury is induced which leads to inflammation and sometimes lung fibrosis. Animals will be administered with different agents to cause lung injury on one or more occasions. The process of administering agents to the lungs will be performed under anaesthesia and therefore the animals will not feel any discomfort from the process.

Animals will be then be treated with potential cures given by a clinically relevant dose route e.g. by mouth, by infusion into the blood or by inhalation to the lungs. All these dose routes are expected to cause only momentary discomfort. For injections into the blood, the injection site will be alternated to reduce discomfort. Treatments may continue once or twice daily for 1 or 2 days (e.g. short term studies) or for one month (e.g. longer term studies investigating fibrosis).

Animals maybe monitored during development of the disease using methods to assess shortness of breath; in this process, animals are placed in a small chamber and measurements taken. The animals are not expected to feel much discomfort during this respiratory assessment since they are free to move in the chamber. Generally, when they are first placed in the chamber they are investigate their surroundings (10 to 15 mins) and then fall asleep. However, it may also be necessary to asses breathing using a system in which the animals are held in restraint tubes and may feel some temporary discomfort. To reduce discomfort, the animals will be acclimatised to the restraint tube and offered a treat after the procedure. On average this procedure takes approximately 30 mins and the may be performed once on a short term study or a couple of times on a longer term study.

Animals may also be transported to another facilities (and project licence) for whole body imaging assessments as used in human patients. The animals may feel some temporary discomfort moving from their home cages to a travelling box and during transit. However, to reduce any discomfort, the animals will be transferred with their cage mates. The animals will have access to food and water during transit. Transport will be performed for same day delivery and in temperature controlled vans.

Other study types on this licence will investigate the development of new cough medicines and in these studies animals will be induced to cough for periods up to 20 mins one one or a couple of occasions. Animals may feel discomfort during the coughing period (about 20 mins) but soon return to normal once the coughing has subsided. Animals may be induced to cough a couple of times over a 2 week period; in our experience, repeated coughing has no detrimental effects.

Other study types are designed to investigate how new medicines are processed by the body animals. In these study types the new medicine will be administered by a clinically relevant route of delivery (e.g oral) and blood samples taken to assess drug levels. As described above, animals may feel a momentary needle-stick pain for blood sampling,. Typically, these types of studies take place over a 24h period and the animal exhibits normal behavior for the duration of the study.

Finally, some studies may be undertaken to assess severe acute lung injury as occurs in patients who have had major trauma. In these studies, animals will be anesthetised and put on artificial ventilation from the start of the study and will therefore not feel any pain or discomfort.

At the end of all studies in this licence, animals will be humanely killed under terminal anesthesia.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Previous experience has shown that most animals with lung injury lose their appetite leading to weight lose. Animals also develop shortness of breath as observed by an increased rate of breathing. These changes are generally seen during the first few days of a study and gradually decline in longer term studies. Animals are supported in this phase by being offered high energy food supplements REDACTED to encourage weight gain. Also, the animals are very closely monitored during the study and charts are generated on a daily basis to monitor individual animals and humanely kill animals who exhibit other signs. In longer term fibrosis studies, the animals recover and are indistinguishable from normal animals.

In studies designed to evaluate new cough medicines, animals may cough for a 20 min period and therefore the extent of discomfort is expected to be temporary.

In studies designed to investigate blood levels of a new medicine, the animals may feel mild discomfort during blood sampling but will otherwise act normally.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Using data from Home Office returns the following is expected

Mild: 80%

Moderate: 20%

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are useful to identify test item effects on individual cell types and on individual chemical pathways, they are currently not able to predict effects on whole body systems or to provide information on how a body reacts to a new medicine. Therefore, it is not currently possible to acquire all of the information on how the heart, brain and lungs may be affected by new drugs, without using animals. This information is essential, to protect human volunteers and patients. Although the studies conducted in this project license are not governed by regulatory authorities (e.g. MHRA) it is generally accepted by scientists that non-animal alternatives are not able to predict the dose in humans of a potential new medicine.

What was your strategy for searching for non-animal alternatives?

Our laboratories, are developing and validating new in vitro assays to assess toxicity using human cells. However, these in vitro systems currently do not mimic all the processes that happen in the body. Therefore, it not yet safe to predict the safe dose of a medicine based on the results from non-animal alternatives.

Why were they not suitable?

There currently remains general scientific agreement that to protect human volunteers and patients, non-animal alternatives do not, as yet, provide enough information to replace animal studies. For example, it is not yet possible to use non-animal alternatives to predict a safe dose for the first clinical trial studies in healthy volunteers.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Statisticians have provided advice on experimental design for all standard study designs within the project. This ensures that studies are correctly designed to meet the study objectives. Statisticians will be consulted on a case-by-case basis for any study that requires a non-standard design.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be used to investigate the potential of new designs to improve outcomes. These could include evaluation of new ways to analyse the data, or additional tests to conduct, leading to improved data quality and translation to humans.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rats, mice, guinea pigs.

We use the above species because they develop aspects of the human disease in relatively short-time frame (e.g. days to weeks) that can be improved by known cures (if available) (e.g. antibiotics for pneumonia, codeine for cough).

Individual animals are carefully monitored during the study in the form of daily observations. Charts are prepared for each individual animal so that welfare is closely monitored after treatments and the study design modified to reduce any harm (e.g lower dose of the new medicine).

Potential medicines are given to animals by common routes (e.g. in food, by mouth, by IV); all these methods are well established and common methods for the species to be used.

Volumes of potential medicines given to animals are in-line with published guidance on minimising discomfort, and/or are known to cause minimal discomfort based on extensive experience at the site.

Blood sampling follows published guidance on suitable volumes which can be taken while minimising harms to animals.

Collaborations are currently on-going to determine whether improvements in disease assessment could be implemented to reduce the study time from weeks to days in some models.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species used are selected based on known standards of outcome which will answer the scientific questions.

To enable comparisons with other data being generated in the same species as part of the safety assessment of potential new medicines.

The use of terminally anaesthetised animals would not model human disease and treatment (apart from the model of Adult Respiratory Distress Syndrome which is being performed in terminally anaesthetised animals).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

- Monitoring of on-going procedures will be refined as any causes for concern are identified; for example, reduced dose of a challenge agent.
- The surgery and anaesthesia/pain relief protocols will undergo continual assessment and refinement to improve outcomes.
- Continue collaborations to improve *in vitro* assessment (to better predict safe doses to humans)
- Continue collaborations to assess the effectiveness of a new cures in days rather than weeks and therefore reduce the length of studies and number of procedures per animal.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Following guidelines from relevant working group publications (e.g.An Official American Thoracic Society Workshop Report: Use of Animal Models for the Preclinical Assessment of Potential Therapies for Pulmonary Fibrosis, 2017).

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of REDACTED: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

document from 2010 on dose level selection for regulatory toxicology studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are involved with other groups working in the same field, and have participated in analysis and publication of data in the scientific field to assess methods of conduct and outcomes. This establishment has been involved with various working groups of the National Centre for the Replacement, Refinement and Reduction of Animals in Research over many years.

Explain the choice ofspecies and the related life stages

New medicines are approved for use in human patients by governmental bodies (e.g.Medicines & Healthcare products
Regulatory Agency) who authorise them as safe for the treatment and effective cures. The animal types used in this licence are recognised by regulatory bodies as providing information to help select a safe cure for human diseases.

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall goal of this research is to define how different configurations of antibody-antigen complexes, or Fc-antigen fusions, can lead to antigen presentation and T cell responses in cancer and autoimmunity.

A retrospective assessment of these aims will be due by 25 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is the cause of 25% of all deaths in the UK, with a prediction that by 2020, almost 50% of people will be affected by this disease. Despite the development of better diagnostic and screening methods, the incidence of cancer continues to increase and many cancers are diagnosed late. Although surgery followed by chemotherapy is frequently used to treat disease at diagnosis, this is often not curative due to incomplete removal of tumour cells that lead to spread i.e. metastatic disease. Similarly, autoimmune diseases affect about 6% of people in the UK and can have devastating consequences, in addition to causing death in a significant proportion of patients. Current treatments for autoimmunity frequently have undesirable side effects and, for some types of disease, have limited efficacy. Consequently, a detailed mechanistic understanding of the factors that result in anti-cancer immune responses or the silencing of damaging, self-reactive responses in autoimmunity is highly desirable. Our proposed research programme seeks to address this need.

What outputs do you think you will see at the end of this project?

The proposed programme of research comprises both basic mechanistic analyses and translational studies. It is expected to lead to new insight into how cells called macrophages can affect the behaviour of an important immune cell subset called T cells. The macrophages are able to modify proteins called antigens into a form that is recognized by T cells, using a process called antigen presentation. A substantial part of our programme will involve the use of different configurations of antigens, including antigens bound to proteins call antibodies, that are expected to show distinct behaviour in macrophages. This distinct behaviour is in turn expected to lead to varying responses by T cells. Although T cells can contribute to anti-cancer effects, they can also attack a person’s own components and lead to autoimmune diseases such as multiple sclerosis and arthritis. The predicted outcome of our five year study is that we will generate mechanistic information concerning how T cells can be activated to kill tumour cells (immune activation), or silenced to reduce their detrimental effects on self-components (tolerance).

Although we expect that our studies could ultimately lead to translation of possible therapeutics to the clinic, this is predicted to fall outside the five year time frame of the study. In this context, we have extensive experience in outlicencing of technologies that we have developed to biopharma that have to date resulted in late phase II/phase III trials using antibody engineering technologies developed in our laboratory.

Data from the planned studies is expected to be of interest to other researchers, clinicians and biopharma. The outcomes of our studies will be disseminated through publications and presentations at conferences. We will also participate in public outreach activities to inform the general public about our research and its relevance to human disease.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our findings during the five year research programme are expected to result in new insight concerning important immunological processes that relate to how antigens can be configured to result in T cell activation or silencing. As such, the research outcomes during this time period are expected to be of broad general interest to researchers (in both academia and biopharma) and clinicians. In the longer term we plan to be able to translate our findings to the development of antigen-based therapeutics that can be used to treat people who suffer from autoimmune disease or cancer. This translation is expected to fall beyond the five year time frame of the research programme.

How will you maximise the outputs of your work?

Outputs will be maximized by careful and rigorous experimental design/analysis, combined with efficient running of the laboratory.

Species and numbers of animals expected to be used

- Mice: 4976

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The typical experience of a mouse is as follows:

For pharmacokinetic experiments in normal mice (mild severity, 100% mice): mice will be injected with radiolabelled protein and the levels of radiolabel in blood (16 total samples and a maximum of 3

samples being taken per day) and whole body (18 total measurements and a maximum of 3 measurements being taken each day) determined for up to 14 days.

For pharmacokinetic experiments in tumour-bearing mice (mild severity, 95% mice; moderate severity, 5% mice): mice will be injected subcutaneously with tumour cells, and tumour size monitored using calipers. When the tumours reach a moderate size, mice will be injected with radiolabelled protein and treated as above. These experiments will last for a maximum of 30 days (including tumour growth phase).

For immunological assays in tumour-bearing mice (mild mild severity, 95% mice; moderate severity, 5% mice): mice will be injected with tumour cells, and tumour size monitored using calipers. When the tumours reach a moderate size, mice will be injected with engineered proteins of different configurations. 1-10 days later, organs and tissues will be isolated from the mice. These experiments will last for up to 30 days.

For immunological assays in mice with MOG-specific immune responses (mild severity, 97-98% mice; moderate severity 1-2%; severe severity, 1% mice): mice will be immunised with peptide (passive immunisation model) or protein antigen (active immunisation model). Peptide-immunised mice will be injected with MOG-specific antibodies on day 10-15 following immunisation. 0-1 day following MOG-specific antibody delivery, or 9-15 days post-immunisation with MOG protein, mice will be injected with engineered proteins of different configurations. 1-10 days later, organs and tissues will be isolated from the mice. These experiments will last for up to 26 days.

For immunological assays in mice with autoimmune disease (EAE) (moderate severity, 35% mice; severe severity, 65% mice): mice will be immunised with peptide or protein antigen, followed by injection of a protein called pertussis toxin on the same day (day 0) and two days later. The disease score of the mice will be assessed daily, and mice will be monitored three times per day when any mice reach a mild-moderate disease score. Peptide-immunised mice will be injected with antibodies when they reach a mild-moderate disease score of 1-2 (day 9-15). 0-1 day following this, or when protein-immunised mice reach a mild-moderate disease score (day 9-15), mice will be injected with engineered proteins of different configurations. 1-10 days later, organs and tissues will be isolated from the mice. These experiments will last for up to 26 days.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

In a subset of our proposed experiments, mice will be injected with tumour cells under the skin. These experiments will last for up to a maximum of 30 days, with the tumours growing from being undetectable to measurable during this time. Mice will be carefully monitored and, typically, the tumours will not grow to a size where they interfere with the normal behaviour of the mice such as their ability to move, eat or drink. We therefore do not expect to observe body weight loss. In the unlikely event that we observe effects of the tumour on the behaviour of the mice, or if the tumours ulcerate, the mice will be humanely killed. In addition, for studies investigating the behaviour of the antibody/antigen/Fc-antigen fusions of different configurations in tumour-bearing mice, the short-term nature of the experiments and regulated procedures that will be used are expected to primarily result in effects of mild severity, with a small

percentage (around 5%) of mice showing moderate effects. Typically, therapeutic antibodies and antibody-based proteins are well tolerated and will be used at doses that are expected to be well below the maximum tolerated dose, which is the highest dose that can be delivered without observing significant, undesirable side effects.

For anaesthesia, we will follow current, best practice methods and do not expect the mice to suffer adverse events. For non-invasive methods such as delivery of antibodies/antibody-based agents by intravenous injection, mice will not be anaesthetised since these procedures result in only transient pain and/or distress.

For harvesting of blood samples from mice, we will use volumes that are substantially lower than those likely to cause adverse effects such as anaemia. Mice will be bled using best practice methods by trained personnel. Based on many years of using similar protocols, we do not expect the effects to be greater than the mild level. Wherever possible, we will use whole body counting of mice, as an alternative to bleeding, since this procedure involves placing the mouse in a cylindrical body counter for around one minute, whilst still allowing some movement of the mouse. Whole body counting involves placing the mice in a cylindrical container (similar to an MRI machine) for several minutes and results in minimal disturbance to the welfare of the mouse.

For experiments involving the immunisation of mice with MOG peptide or protein in adjuvant, following by transfer of MOG-specific antibodies for peptide-immunised mice, we expect to observe skin lesions at the injection sites for a low percentage of mice (2-3%) that resolve within 1-2 days. In about 1% mice, these skin lesions persist and these mice will be humanely killed.

For experiments in which the autoimmune disease called experimental autoimmune encephalomyelitis, that involves paralysis similar to that seen in multiple sclerosis patients, is induced in mice, about 35% of total mice used in two different models are expected to get low grade disease i.e. limp tail, partial hind limb weakness. These effects will be classified as of moderate severity. In about 65% of mice, we expect to see higher disease activity that includes severe or complete hind limb paralysis, and in the majority of mice, this will not last for more than 1-4 days. In a total of about 20% mice used in both disease models, we may see moderate disease that lasts for longer or is more severe and these mice will be humanely killed.

All mice will be humanely killed when the experimental goal or, if sooner, humane endpoint has been reached.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The expected severities for each type of experiment and mouse numbers over the five year study period are:

1. Pharmacokinetic studies in normal mice: mild severity (100% mice).

2. Pharmacokinetic studies in tumour-bearing mice: mild severity (95% mice); moderate severity (5% mice).

3. Immunological studies in tumour-bearing mice: mild severity (95% mice); moderate severity (5% mice).

4. Immunological studies in mice that have been immunised with autoantigen (MOG): mild severity (97-98% mice); moderate severity (1-2% mice); severe severity (1% mice).

5. Immunological studies in mice with autoimmune disease (EAE): moderate severity (35% mice); severe severity (65% mice).

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 25 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our goal is to replace animals with in vitro methods wherever possible. We will therefore carry out extensive analyses of the engineered antigen delivery vehicles using in vitro assays to identify promising candidates for use in mice. Unfortunately, the complexity of the persistence of an antigen delivery vehicle in the blood circulation cannot be modelled with in vitro systems. In addition, investigation of the immune responses that result from the delivery of antigen delivery vehicles in mice with tumours or autoimmune disease cannot be modelled by in vitro systems.

What was your strategy for searching for non-animal alternatives?

We have considered using in vitro methods (e.g. cell culture, microscopy, binding analyses) and will used these whenever possible to identify lead candidates for in vivo testing. However, whole body pharmacokinetic behaviour and immune responses cannot be replaced with in vitro systems due to the complexity of the body.

Why were they not suitable?

Cell culture-based methods cannot be relied upon to predict immune responses and pharmacokinetic behaviour in vivo. For example, the distribution of a protein to a tumour cannot currently be modelled by in vitro cell culture models. In addition, diseases such as cancer and autoimmunity, that involve multiple cell types and complex environments, cannot be modelled by cell culture models.

A retrospective assessment of replacement will be due by 25 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A major contribution to our experimental design will be consideration as to how the animal numbers can be reduced. We will use inbred strains of mice (i.e. with the same genetic makeup) for all of our experiments to reduce the variability that would typically be expected with outbred strains (that are not genetically the same). This results in a need for lower mouse numbers. Our aim is to use the minimum number of mice that we can to obtain statistically robust results that are reproducible across experiments. We will use both our prior experience in carrying out the proposed experiments, combined with power analyses, to determine the numbers of mice that we need for each experiment to draw reliable conclusions. In addition, we will carry out smaller, pilot experiments with low numbers of mice, to define tumour growth rates etc. prior to expansion to larger experiments if we have not prior experience with the tumour model. Nevertheless, the use of tumour cell lines that are well validated in our studies or those of others will form the basis of many of our analyses, and this is expected to contribute to a need for lower numbers of mice.
The immunisation and autoimmune disease models that we plan to use are well characterised and will not need pilot experiments of this type.

Where possible, we will use data from experiments that are associated with lower severity of adverse effects to reduce the numbers of mice that we use in higher severity procedures. An example of this is our plan to carry out initial experiments with engineered proteins in mice that have been immunised to induce an autoreactive immune response prior to experiments with a subset of lower numbers of these engineered proteins in mice that are expected to show adverse effects of higher severity due to the induction of autoimmune disease. The choice of this subset of proteins will be informed by the lower severity experiments in immunised mice.

Technologies such as whole body counting for pharmacokinetic analyses also result in lower numbers of mice since they allow longitudinal follow-up of the same mice over time. These alternatives avoid the need for increases in mouse numbers due to limitations of the number of blood samples that can be taken from the same mouse. However, for determination of blood levels of a potential antigen delivery vehicle, we need to collect multiple blood samples. Our experience in carrying out pharmacokinetic experiments is that longitudinal sampling of the same individual mice leads to more reliable results than cycling blood collections between different groups of mice. This results in a need to use substantially lower numbers of mice.

We will also make every effort to decrease experimental bias and minimise experimental variability. An example of this will be if the humane end points are based on an assessment of the condition of the animal, such as during EAE experiments, an experienced and blinded animal technician will be asked for their assessment. Objective measurements such as tumour measurement, whole body counts etc. generally do not need blinded observers. Allocation of mice to experimental groups is carried out by a technician in the breeding colony prior to transfer to the experimental housing and is therefore not likely to be biased. Related to this, we use age and sex-matched mice that have been bred in the same housing for experiments to minimise variability.

Statistical considerations

Based on earlier experiments that we have carried out, we have used power analyses to determine optimal sample size for the pharmacokinetic analyses (using the PS: Power and Sample Size Calculation programme: www.biostat.mc.vanderbilt.edu/twiki/bin/view/Main/PowerSampleSize):

Pharmacokinetic analyses (Protocol 1)

Using data from earlier experiments, we expect that the smallest difference in means between test and control groups that we will need to be able to detect is 20 (hours) with a common standard deviation of 15. Based on a two sided t-test using a power analysis with a level of significance of 5% with 80% power, the number of mice per group is 7. We typically carry out repeat experiments to ensure reproducible results, and based on around 25 years of experience with these assays, will use 5 mice per group.

The total number of mice that we estimate we will need for these experiments is predicted to be:

Per year, we expect to generate 8 antibody/antigen/Fc-antigen fusions for testing in mice (normal and tumour-bearing). We will typically test 2 proteins per experiment with one control antibody (i.e. 5 mice per group, resulting in 15 mice per experiment). Hence total number of mice used per year is estimated to be:

15 mice/experiment x 4 experiments x 2 repeats x 2 mouse types (with or without tumours) = 240.

Hence, over 5 years the total number of mice is expected to be 1200.

Immunological, microscopy and immunohistochemical analyses (Protocols 2, 3 and 4)

Based on our extensive experience assessing serum antibody levels and T cell responses in mice, we will use 3 mice/treatment group for these experiments to determine antibody responses combined analyses of immune cells in tumours (Protocol 2) or the central nervous system (Protocol 3) following the use of the engineered antibody/antigen/Fc-antigen fusions. T cells and antigen presenting cells will also be isolated from lymphoid organs such as spleen and lymph nodes (Protocols 2, 3 and 4). Similarly, 3 mice/group will be used for tumour or CNS isolation from tumour-bearing mice or mice with EAE, respectively, for use in immunopeptidome, microscopy or immunohistochemical analyses. A subset of experiments will also be carried out involving the use of both antigen delivery vehicles and immunotherapeutic antibodies. We usually carry out repeat experiments to ensure reproducible results. For each of protocols 2 and 3, the numbers of mice needed have been estimated as follows:

Protocol 2: Assessing immune responses in tumour-bearing mice

We plan to test 8 different antibody/antigen/Fc-antigen fusions per year in mice with tumours, and will use 2 delivery vehicles and 2 controls per experiment with 3 mice per group. Also, two different tumour models expressing different antigens will be used. We will start each experiment with 15 mice, since we need to select 12 from these with matched tumour sizes. Hence total number of mice used per year is estimated to be:

15 mice x 4 experiments per year x 2 (immunological responses or microscopy/immunohistochemistry and immunopeptidome analyses) x 2 tumour models x 2 repeats = 480 mice.

Hence, over 5 years the total number of mice is expected to be 2400.

Protocol 3: Assessing immune responses in mice with EAE

We plan to test 4 different configurations of antibody/antigen/Fc-antigen fusions per year in mice with EAE, and will use 2 delivery vehicles and 2 controls per experiment with 3 mice per group. We will start each experiment with 20 mice, since we need to select 12 from these with matched EAE scores and several mice in control groups (with higher disease activity) may need to be euthanised during the course of the experiment. Hence total number of mice used per year is estimated to be:

20 mice/experiment x 2 experiments per year x 2 (immunological responses or microscopy/immunohistochemistry and immunopeptidome analyses) x 2 repeats = 160 mice.

Hence, over 5 years the total number of mice is expected to be 800.

Protocol 4: Assessing immune responses in autoantigen-immunised mice

We plan to test 8 different configurations of antibody/antigen/Fc-antigen fusions per year over a 4 year period in immunised mice, and will use 2 delivery vehicles, an average of 5 controls per experiment and two time points per experiment with 3 mice per group. Hence total number of mice used per year is estimated to be:

21 mice/experiment x 4 experiments per year x 2 time points x 2 repeats = 336 mice.

Hence, over 4 years the total number of mice is expected to be 1,008.

The projected use of mice in this application is based on a combination of our past experience in using mice to assess the in vivo behavior of antibodies and antibody-based therapeutics, combined with power analyses such as those given as examples above. The numbers are also based on expected numbers of laboratory personnel and potential antibody/antigen/Fc-antigen fusions that we plan to generate.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have used power analyses and our prior experience to use the minimum number of mice that we expect to be necessary to give us reliable data (see section above). If necessary, we will seek advice of statisticians or use online resources (e.g. https://www.nc3rs.org.uk) to determine the numbers of mice to use in each experiment to obtain useful and statistically robust data.

What other measures apart from good experimental design will you use to minimise numbers?

When indicated, we will carry out pilot studies using smaller mouse group sizes etc. prior to performing larger experiments. Advice from statisticians will be sought if necessary to optimise experimental design. All work will be carried out in accordance with the ARRIVE guidelines.

A retrospective assessment of reduction will be due by 25 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The overall goal of this project is to investigate the effects of using different engineered proteins (called antibodies, antigens or Fc fusions) on immunological responses involving cells called T cells. Mice are the least sentient of the species that are appropriate for this research and have been widely shown to be suitable preclinical models for immunological studies. The mouse models of cancer and autoimmunity that we plan to use have been used extensively and are well validated as appropriate models for our proposed studies. An important property of mouse models is also that there are suitable inbred GA mice that have, for example, human forms of key receptors that increase their predictive value as models for humans.

The methods that we and others for the planned experiments are designed to minimise suffering and distress to the mice whilst at the same time, result in useful experimental data. For example, the effects of the engineered proteins in mice with relatively small and non-metastatic tumours that grow subcutaneously will be assessed and this is expected to result in mild effects in most mice, with moderate in about 5% of mice. Humane endpoints in tumour bearing mice are designed to limit suffering (e.g. mice will be culled if and when the tumours reach a moderate size, or mice start to show signs of ill-health such as hunching).

The engineered proteins will be delivered into mice with experimental autoimmune encephalomyelitis (EAE) of mild-moderate severity that can subsequently progress to severe EAE. Two slightly different models of EAE will be used since they give different experimental information. We have chosen to use EAE models instead of other autoimmune disease models since many of these autoimmune disease models cause considerable suffering (e.g. arthritis models, skin blistering disease such as pemphigus vulgaris) and do not have the reagents available to assess immunological responses. If we elected to use these other models, substantial optimisation of new reagents would therefore need to be carried out which would necessitate the use of large numbers of mice with possible failure to generate the reagents/assays combined with needless suffering of the mice. We have spent a considerable amount of time developing and implementing EAE protocols so that the disease activity is at the lowest level necessary to achieve our experimental goals. However, it is possible that quadriplegia could occur in a low percentage of the mice (1-5%). To avoid this, an enhanced monitoring regime will be implemented (more than 3 times daily where appropriate). If any mouse begins to show signs of neurological problems with a forelimb, it will be immediately killed.

Prior to carrying out experiments in mice with EAE, we will perform experiments in mice that have ongoing immune responses (immunised, and in some cases, with passively transferred antibodies) to identify the engineered proteins that are the most effective in reducing inflammatory responses following delivery. The most effective proteins (estimated to be about 50% of the test engineered proteins) will be used in subsequent EAE experiments. This approach represents a significant refinement since it results in the use of reduced numbers of mice in EAE experiments that are associated with higher incidence of adverse effects compared with the effects in mice that are immunised under conditions that induce inflammatory responses but not disease.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We need to use adult mice for these experiments since we need to assess the distribution of antibody/antigen/Fc-antigen fusions at the whole body level over a period of up to two weeks and this cannot be assessed in mice that are terminally anaesthetised. Similar constraints apply when using mice as models for cancer and autoimmune disease, except the time frames of the experiments are longer.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Mice are broadly taken to be instructive models for the analysis of immune responses, with the goal of modifying these immune responses to treat human diseases such as autoimmunity and cancer. A further advantage of using mice is the availability of genetically altered strains. To ensure high welfare standards, good animal husbandry, including environmental enrichment, is employed. Generally, for this project licence application we expect that the severity of the procedures will be mild for the majority of mice/procedures, but the procedures are categorised as severe for a low percentage of total mice. For all procedures, the mice will be carefully monitored and if adverse events are observed, steps will be taken to alleviate them or the affected mice will be humanely killed.

Animals will be maintained by qualified technicians who have familiarity with many different disease models. Mice will be monitored daily by the animal house technician(s) and the researcher(s) carrying out the experiments. If one or more animals are anticipated to be close to reaching a humane endpoint (the humane endpoints are well defined for the disease models that we plan to use), they will be monitored more closely. If the animal shows signs of approaching a humane endpoint, the animal will either be killed immediately (with a humane method) or the corresponding researcher will be informed that the animal needs to be killed immediately (using a humane method). If mice show signs of distress for which a cause cannot be identified, onsite veterinary assistance will be sought.

Death will not be used as an acceptable endpoint in any of our studies. The tumour and autoimmune disease models that we plan to use are well characterised and humane endpoints have been identified. In many cases, we can assess the size of the tumour and use a limit of this as an endpoint. Occasional ulceration of tumours can also occur, usually in outlier mice, and if observed such outlier mice will be humanely culled.

In the autoimmune disease model that we plan to use, mice may have paralysis in their hind limbs and typically recover from this within several days (65% mice have severe or complete hind limb paralysis). Such mice will have damp food placed on their cage floor and their weight will be carefully monitored. They will also be housed in groups so that they can huddle to maintain body warmth.

During all experiments, other measures of distress for the mice will be assessed, such as hunched posture, abnormal feeding and drinking, or poor condition that can be detected using other methods such as alterations in facial expression. We have onsite veterinary assistance to provide advice if and when necessary.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

https://www.nc3rs.org.uk

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The personnel involved in this project will regularly review the literature and websites (e.g. https://www.nc3rs.org.uk) for refinements etc.

Explain the choice ofspecies and the related life stages

Mice will be used in these studies since they are the most suitable model. They have been used extensively in studies to model the immune response in humans. In addition, mouse models are accepted as instructive for human diseases such as autoimmunity or cancer. We will use adult mice (6-12 weeks old) throughout our studies since these are of an appropriate age for the disease models that we plan to use.

A retrospective assessment of refinement will be due by 25 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To assess the toxicity and pathogenicity of microbial pesticides to fish. These data are required by European Member State regulatory authorities for the registration of new plant protection products under Regulation (EC) No 1107/2009.

A retrospective assessment of these aims will be due by 13 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The assessment of aquatic ecotoxicity, which includes effects on algae, aquatic plants, invertebrates and fish, is an essential component of the risk assessment process for plant protection products. This testing is mandated and codified by regulatory authorities in most developed countries, including the EU and the US.

What outputs do you think you will see at the end of this project?

This project will result in the generation of the mandatory regulatory data that are essential for the environmental safety assessment of new plant protection products. This assessment is a critical aspect of the registration process for such products in Europe and the US in order to identify and mitigate any negative environmental impacts that may arise from the use of the products.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The benefit of the outputs from the project will be the authorisation of novel products with modes of action that present greatly reduced risks to the environment compared to more conventional materials.

Where these data are required by regulatory authorities as part of product renewal procedures the benefits will be realised over short timescales of a few months; where they are required as part of regulatory submissions for the approval of new active substances the benefits will only be realised once the evaluation process has completed. This can range from 18 months in the case of the US to up to 5 years in the case of Europe.

How will you maximise the outputs of your work?

Whilst the environmental risk assessment and the information on which it is based is made public by the European Food Safety Authority during the public consultation phase of new active substance evaluation, as a contract research organisation the work we undertake on behalf of our clients is commercially confidential and can thus not be published or disseminated by us.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Fish are exposed to varying concentrations of experimental products in their aquarium water. Fish are observed closely for the duration of the study to determine any adverse clinical signs arising from exposure.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Various clinical signs may be observed throughout the tests, depending on the nature of the test material. These can range from no observable effects at one extreme to death at the other, with the following observations lying in between: dark pigmentation, slight increase/
decrease in
respiration, swimming at tank base/water surface, hyperactivity, lethargy, irregular breathing or
occasional gulping, slight ortemporary
loss in equilibrium, increased mucous secretions, very hyperactive, very lethargic, greatly increased respiration or gulping/ irregular breathing at water surface, loss of equilibrium
with violent, erratic movements, and muscle spasms.

Severe reactions to the test material will be identified and may constitute a valid endpoint without the need to prolong the exposure, thus avoiding any potential for unnecessary suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Due to the nature of these tests the expected severity threshold is set at severe. This can potentially be the case for all animals within each test except for those in the control group. It is always the case that animals are exposed following step wise procedures and observed continuously to avoid any potential for unnecessary suffering.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 13 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

EU and US regulatory authorities require data from vertebrate test systems, including fish, in order to identify and mitigate any adverse environmental effects that may arise from the use of new plant protection, biocidal, animal health or pharmaceutical products. The evaluation of these studies, all of which are performed in accordance with highly prescriptive internationally recognised guidelines, forms a critical part of the mandatory environmental risk assessment for all new products.

What was your strategy for searching for non-animal alternatives?

Currently there are no accepted non-animal alternatives available for aquatic ecotoxicity testing. However, steps will be taken within each study to ensure that the minimum number of test organisms is used. These steps include the minimising the use of attenuated test item and sterile filtrate control groups where no adverse effects were observed in prior *Daphnia* studies, and sharing controls between concurrent studies wherever possible.

Why were they not suitable?

EU and US regulatory authorities require *in vivo* data from vertebrate test systems in order to identify and mitigate any adverse environmental effects that may arise from the use of new plant protection, biocidal, animal health or pharmaceutical products. *In vitro* alternatives are either unavailable or unsuitable, particularly for microbial test items for which no validated *in vitro* methods exist.

It will be company policy to consult with the DB-ALM, ECVAM, NC3Rs and FRAME websites frequently and research any viable replacements for *in vivo* testing as part of the AWERB agenda.

A retrospective assessment of replacement will be due by 13 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A standard OECD 203 / OCSPP 885.4200 microbial pathogenicity study would require between 20 and 40 fish depending on the requirement for attenuated test item and sterile filtrate groups.

2500 fish is the maximum number the facility is currently able to test for the duration of this project.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Regulatory studies will be conducted in accordance with OECD or OCSPP guidelines, which specify the minimum number of fish required to achieve statistically valid scientific outcomes. The minimum number of fish stated within any required guidelines will be used wherever possible, with any deviations from the guideline documented and scientifically justified within the study data.

Prior to conducting any studies on fish, information on the likely toxicity or possible effects of the test item will be requested or researched. If no such information is available dose ranging tests can be performed prior to the main definitive test.

It is often the case that work involving fish will be part of a larger suite of studies conducted on terrestrial and aquatic invertebrates. When this is the case, and where possible, studies will be conducted on invertebrates first in order to identify approximate toxicity and therefore minimise adverse effects in fish studies.

What other measures apart from good experimental design will you use to minimise numbers?

For chemical test items, the data sharing rules implemented under the REACH (Registration, Evaluation, Authorisation and restriction of Chemicals) legislation will help to reduce unnecessary animal testing. Toxicity data are also publicly available on the ECHA database which may preclude the need for additional testing.

For microbial test items there are limited options for reducing the need for fish testing. Survival in water studies, even if they demonstrate rapid mortality of the test organism, do no preclude the possibility of infection and pathogenicity within a more suitable environment, such as the body of a fish. Furthermore, as many microbial pesticides are entomopathogenic and fish are entomophagous, the effect on fish of consuming infected insect cadavers must be addressed via the consumption of dosed feed. However, as microbial studies are all conducted as limit tests at a single concentration of 1 x 10^6 cfu/ml the animal requirement per study is low.

A retrospective assessment of reduction will be due by 13 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The only animal models that will be used during this project are rainbow trout and carp. Protocols 1 and 2 are designed to provide regulatory information on the acute toxicity, sub-lethal effects and LC_{50} values of the test item, the latter being determined from inferred clinical signs and avoiding death as an endpoint where possible, although mortality may be expected. Dose ranging tests and careful interpretation of clinical signs (and resulting euthanasia) will minimise distress as much as possible.

For acute studies, fish will be added to test systems individually or in small batches. Severe reactions or effects of the test material immediately after exposure will be identified and staff may then justify a valid endpoint without the need to continue exposing fish to the test system. The exact method used to introduce fish to a test system will be outlined in company Standard Operating Procedures and Study Plans (e.g. addition of fish at 1 minute intervals followed by close observation prior to the addition of the next fish).

An internal policy document containing guidance on clinical signs may be used to assist in implementing endpoints, as required. Protocol 1 tests that estimate the LC_{50} should follow the

ENV/JM/MONO (2010)17 document as closely as possible. This allows information required for regulatory purposes to be acquired, whilst minimising suffering and reducing animal use. Where possible, this approach will also be used for Protocol 2 tests.

The fish species to be used is carefully considered in relation to the test material. For example, volatile chemicals should be tested on a species which can endure lower oxygen contents and survive static conditions. For chronic studies, the use of robust species which reproduce easily and achieve life stages in a shorter time frame reduces the exposure period.

Environmental enrichment, with an emphasis on minimising stress, will be used where possible whilst holding, culturing and testing fish. This is mutually beneficial, as many observations thought to be related to the test material could result from stress.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In vivo fish testing is mandated by the regulatory authorities in Europe and the United States, and studies must be conducted in accordance with internationally recognised guidelines that specify the fish species that can be used. There is thus no scope for using less sentient animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

By using defined observation strategies we will ensure constant monitoring of all fish whilst under all regulated procedures. Thus, any issues are dealt with in a timely fashion and the appropriate action is taken. All test designs are continuously scrutinised to ensure that only the minimum number of fish are used, and where possible further reduced, such as by reducing animal numbers within control groups or performing limit tests with a reduced number of exposure groups. The protocols defined under this project will adhere to current guidance, with any new or revised guidance being adopted at the earliest opportunity.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

It is a requirement of EU and US regulatory authorities that studies are performed in accordance with current published and ring-tested designs, such as the OECD and OCSPP guidelines. These guidelines specify the number of fish that should be used to determine scientifically valid endpoints. In addition, the ENV/JM/MONO (2010)17 document (Series on Testing and Assessment No. 126: Short Guidance on the Threshold Approach for Acute Fish Toxicity) will be followed as closely as possible in order to determine the information required for regulatory purposes, whilst also minimising animal use. This document details the use of information from acute toxicity testing on non-vertebrates such as *Daphnia* and algae to determine a suitable threshold concentration at which to expose fish, in order to

determine the species most sensitive to a particular test substance. Where possible, this approach will also be used for Protocol 2 tests.

The selection of species is carefully considered in light of the properties and the end use of the test material. The CVMPIVICH/790/03 2004 document discusses how the potential use of the test item aids in species selection for environmental testing. For example, chemicals and biopharmaceuticals intended for use with terrestrial animals should only be tested on freshwater species. Testing of volatile chemicals requires a species which can endure lower oxygen contents and survive static conditions. Chronic studies investigating early life stage development require robust species which reproduce easily and achieve life stages in a shorter time period, thereby reducing exposure periods.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

It will be company policy to consult with the DB-ALM, ECVAM, NC3Rs and FRAME websites frequently and research any viable replacements for *in vivo* testing as part of the AWERB agenda. Any updated strategies and best practice available will be discussed at the AWERB and implemented if viable, and when global regulatory authorities confirm their acceptance of new study protocols.

Explain the choice ofspecies and the related life stages

The animals selected for the project are those required by internationally recognised regulatory guidelines. The species and life stages selected for each test design are naturally robust, with low natural mortality and are widely accepted by regulatory authorities worldwide.

A retrospective assessment of refinement will be due by 13 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

9. Autoimmune diseases of the CNS and their treatments

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand how the insulating material around nerves (myelin sheaths) is destroyed by the autoimmune disease, multiple sclerosis (MS), and then to identify and screen agents that are reparative or control the associated symptoms of this disease, with particular attention to neuronal death, loss of myelin, axonal damage and degeneration.

A retrospective assessment of these aims will be due by 29 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

At present there are no therapies that reverse the debilitating disease symptoms of MS, current treatments are palliative and only provide support to the body's natural defence system (the immune system) to fight the consequences of MS rather than tackle the underlying causes. We wish to identify and test effective therapeutic agents that change the immune system to fight the development of MS and to test agents that will ultimately protect neurons and their associated cells and prevent neuronal death, axonal damage, loss of myelin and eventual loss of nerve function.

What outputs do you think you will see at the end of this project?

The primary outputs of this work will be the information on identifying new therapeutic targets to prevent the development of MS or promote repair after MS. As well as identifying new targets, we will also specifically target an already identified therapeutic molecule called AMIGO3 that can promote myelin repair in MS.

We will establish if targeting the intestinal lymphatic system is a viable way to reach concentrations of cannabinoids that are required to treat the clinical signs of MS.

We will also establish if inhibiting DNA damage sensing can promote RGC survival and axon regeneration and hence preserve visual function in models of optic neuritis.

Specific academic outputs will be to publish the findings. This is important for the development of the project but also to provide a knowledge base for other academics working in this field.

Specific product outputs will be to support the development of the intellectual property already filed and allow it to be translated into a commercially viable proposition for the REDACTED of Birmingham.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term the benefits would be to provide high impact publications and work for the academics involved and in raising the profile of early career researchers. This work will also potentially support an application to the MHRA for a clinical trial of the AMIGO3 or DNA damage antagonist and the intestinal delivery route for cannabinoids.

In the longer term this work has the potential to have an immense impact on the lives of patients with MS. There is currently no treatment that reverses the pathological effects of MS and the functional loss. Our AMIGO3 therapeutic would provide a suitable, clinically viable antibody-based treatment that can potentially reverse the signs of MS. If the intestinal lymphatic system can deliver high amounts of cannabinoids, this will have a huge impact for MS sufferers and provide an alternative treatment for the debilitating symptoms of MS. Our DNA damage inhibitors, specifically one which has been used in Phase 2 clinical trials in cancer, is a potential fast track route to the clinic after we have been able to show efficacy in our optic neuritis models.

A second beneficiary is health care providers, particularly the NHS. Currently around £50 million/year is spent on MS sufferers. If the AMIGO3 antibody/DNA damage inhibitor treatments and the intestinal lymphatic targeting therapies were successful it would relieve this pressure on the NHS significantly reducing this cost burden of treating MS patients.

How will you maximise the outputs of your work?

We will maximise the outputs of the work by collaborating with academics and companies working in this field to maximise the use of the data we obtain. We will rapidly disseminate the outcomes of the tests whether, negative or positive to inform the academic community and support other researchers developing technologies in this area. We are already working with several small and large pharmaceutical enterprises which we will seek to attract after proof-of-principle experiments have been successful. The AMIGO3 antibodies and the DNA damage inhibitors will need to be provided by companies collaborating with us, however, we are currently filing re-purposing patents for use in our disease models and hence there should be no problems with the freedom to publish our results and without restrictions. However, many companies require vetting of each publication prior to submission, but we will ensure this is completed in a timely manner.

Species and numbers of animals expected to be used

- Mice: 1,650
- Rats: 550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

For the EAE model: animals will undergo subcutaneous injection of myelin antigens emulsified in complete Freund's adjuvant with repeat injections of pertussis toxin at day 0 and 2 to sensitise the immune system. Animals will then be monitored until clinical signs of disease appear (typically between day 17-24). As soon as the clinical score reaches peak of acute disease (score 3 for EAE (hind limb paralysis)

For the optic neuritis model: animals will undergo subcutaneous injection of myelin antigens emulsified in complete Freund's adjuvant with repeat injections of pertussis toxin at day 0 and 2 to sensitise the immune system. Animals will then be monitored until clinical signs of disease appear (typically between day 9-12) and when clinical score of 1 is reached (i.e. limp tail), we will kill the animal and harvest tissues for analysis. Treatments will normally be administered both pre- and post-symptomatically to determine efficacy of therapeutics over a wide range of disease stages.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Induction of disease: During EAE induction phase an initial weight loss of <10% of pre-disease bodyweight observed overnight, then limp tail, ataxia and usually hindlimb paralysis for a period of 2-5 days with further weight loss (even when fed orally by gavage).

During optic neuritis, animals lose 5% of bodyweight prior to disease and then progress through the disease stages as in EAE and can lose a further 5-10% bodyweight. However, we will kill animals with a score 2 (limp tail and impaired righting reflex).

Weight loss is a feature of the disease but animals will be given soft mash in cage when hind limb paralysis occurs. Animals will be checked and weighed daily from day 0 and when in peak disease phase animals will be examined more frequently (not less than twice daily).

Subcutaneous injection of Freund's adjuvant: In less than 20% of animals, granulomas may form at the injection site. However, injection into the flank minimises these adverse effects and animals show no untoward side effects. Ulceration of the injection site is rarely observed (<1% of animals) but heal on their own and are minimised by good ascetic handling. If a granuloma increases to >5mm then animals or if an ulcer does not heal within 3 days, animals will be killed immediately.

Substances administered by injection: Stress due to restraint and transient discomfort from needle insertion is likely in 100% of animals. These are minimised by selection of Appropriate (minimum possible) sized sterile needle and syringe will beused.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

About 60% of animals will be used for EAE experiments and will be expected do develop hind limb paralysis with up to a maximum of 25% bodyweight loss. These are classed as severe. Animals may also receive injections of therapeutic agents or through the use of mini-pumps or slow release devices.

The other 40% of animals will be used for optic neuritis experiments which can be classed as moderate severity since animals are not required to display clinical signs of hind limb paralysis. Animals will be killed when they reach a score of 1 (limp tail). These may also receive therapeutic agents as described above.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 29 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst some elements of immunity, neuroregeneration and repair can be modelled in cell culture, the complex, clinical picture and interaction of the immune and nervous systems cannot all be currently modelled in cell-culture or computer-based models. The use of live animals is therefore unavoidable and essential for drug discovery and to demonstrate the activity of drugs in a situation relevant to human disease. Neurons are not present outside the animal kingdom and so an animal is required. Only mammals have a sufficiently developed immune-system to readily compare to humans, and rodents are the animals of lowest neurophysiological-sensitivity required to achieve the scientific aims.

It is not ethical to conduct experiments on humans in multiple sclerosis, especially where those experiments require the removal of parts of the immune or nervous system for ex-vivo investigations. Therefore, there is no feasible alternative that would entirely replace the use of a living animal that would allow the objectives to be met. However, we will use in vitro and ex vivo work prior to or in parallel with animal studies.

What was your strategy for searching for non-animal alternatives?

There are currently no alternatives to animal work for this disease. For example, no cell culture-based models exist that encompass all of the aspects of disease for any of the models described in this project. However, individual aspects will be modelled in vitro and ex vivo. For example, neuroprotective therapies are usually screened in a retinal cell culture model prior to in vivo use. So far we have successfully translated many neuroprotective therapies from this culture-based model to in vivo studies. Also, oligodendrocyte precursor cell differentiation has been studied in vitro. We have also used postnatal rat pups to investigate myelination.

Why were they not suitable?

The fundamental reason why the use of animals is required is to understand these processes that at present no in vitro methods can model the complexities of the systems involved in this disease. It is difficult to use primary cells to culture all of the different types of cells since they require different growth mediums and factors for survival. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment. Technologies are being developed to address this gap, including the development of 3D cultures. However, none of these model systems are yet able to phenocopy the integration and interplay between the numerous cell types that constitute MS/EAE/Optic neuritis as it is a full interplay of the immune and central nervous systems. Modelling MS in rodent is thus still required to fully model disease progression and identify novel therapeutic avenues.

A retrospective assessment of replacement will be due by 29 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Sample sizes have been calculated using the NC3Rs Experimental Design Assistant (EDA). In general, setting a significance level of 5%, a power of 80%, and a least biologically significant difference between groups of 30% (i.e. reduction in clinical disease severity after AMIGO3 antibody treatment or protection of 30% of RGC from death), returned group sizes of 8-10 animals/treatment group.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We used the NC3Rs EDA system to calculate animal numbers to be used from this project. We used sd values from several of our own and other's published data to facilitate power calculations and reduce animal usage.

What other measures apart from good experimental design will you use to minimise numbers?

We will seek to refine protocols, such as the development of novel quantitative outcome measure that will facilitate “reduction”. Experiments will be planned so they can be published in accordance with the NC3R’s ARRIVE guidelines.

As part of good laboratory practice, we will write a protocol for each experiment including: a statement of the objective(s); a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group), and the experimental material; and an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated). We will make appropriate arrangements to randomly assign animals to experimental groups and blind studies.

We will also use the $MOG^{TCR}xThy1^{cfp}$ mouse that has a fluorescent label on retinal neurons so that we will be able to monitor neuronal death in real-time without the need to kill animals.

A retrospective assessment of reduction will be due by 29 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Multiple sclerosis (MS) exhibits many pathological processes including relapsing and secondary progressive disease. We aim to use the mouse/rat to model these processes. All EAE models in rodents and primates develop autoimmune mediated disease of the CNS, but few exhibit reproducible relapsing disease and progression. Our chief mouse/rat model will be to examine EAE in Biozzi ABH mice/Lewis rats that have proved a reliable drug-screening tool that is far superior to most EAE models due to its reproducibility and the slow accumulation of disability, which limits endpoints being reached. However, to examine CNS autoimmunity we will also examine other mouse/rat strains that exhibit the most robust response to the defined antigen. Because the autoantigens in ABH mice are so hydrophobic and are not amenable to in vitro use, in some instances we will use other strains where autoantigens are more amenable for in vitro use (e.g. C57BL/6 or SJL mice) or where gene deletions have been generated other strains of mice will need to be investigated, e.g. C57BL/6 mice. Disease will typically be induced by subcutaneous injection of myelin antigens dissolved in complete Freund's adjuvant into the flank. This is very well tolerated and induces disease with high reproducibility, limiting the need for large group sizes and many repetitions of experiments. Although much is known about how to best use animal models to study autoimmunity, few studies have investigated use of EAE models to monitor neuroprotection, repair and symptom control. Using induced-relapses to synchronise relapse to detect neurodegeneration compared with treatment of spontaneous disease, requires animals to be in procedure for less time and requires fewer animals to detect effects. We aim to continue to refine these models and as we apply additional outcome measures such as rotarod analysis, we increase power to detect drug effects and enhance the utility of the models. Through the use of a reproducible system and define endpoints for each objective, we can limit the time in procedure and as a result the suffering that the animal will accumulate as a product of autoimmune attack of itself.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We cannot use non-mammalian species for this work, as mammals cannot recover from attacks of multiple sclerosis. For example, we cannot use zebrafish because they are able to regenerate their CNS spontaneously. In mice there is established and reliable transgene technology, and established models of MS. There are a large number of genetically modified mutants available and there is extensive amount of work that has already been performed and published using mouse and rat models of MS.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All therapeutic agents are evaluated and optimised in vitro prior to in vivo application. We keep our experimental time points in longitudinal studies to a minimum and use archival control results where

possible. Multiple analyses are done on harvested tissues. We use the minimum number of interventions and minimal volumes for drug delivery during experiments and continually seek methods to reduce these by studying alternative drug delivery strategies. Small numbers of animals (i.e. 10 mice) are used in these models to maximise the effectiveness of our post-disease care. These refinement steps significantly reduce animal usage and severity.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment.

Experiments will be conducted in accordance with the guidelines published by the Laboratory Animal Science Association (LASA).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed by advances in the 3Rs through attendance of seminars and conferences, as well as discussions with the NVS, NIO and NACWOs.

We will review each experiment on completion to determine any refinements that can be applied to future experiments.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

We will also stay up to date with guidance published by FELASA on the most refined experimental methods.

Explain the choice ofspecies and the related life stages

No single experimental model reproduces all of the aspects of human MS, but generally mice and rats are both used in this application to investigate individual aspects related to disease pathogenesis. For example, mouse models of EAE commonly display secondary demyelinated areas, in which both the axon and myelin undergo degeneration, with myelin degeneration being a secondary phenomenon to the death of the axon. In contrast, rats commonly display primary demyelinated areas, in which myelin damage occurs without primary changes in the axon. In human MS however, both primary and secondary demyelination is present with a prevalence of primary demyelinated areas in the brain and

spinal cord (Lassmann and Bradl, 2017, Acta Neuropathol 133: 223-244). Hence, both rats and mice are required to model these nuances.

In addition, the mouse lends itself easily to the creation of knockout models and hence offer the advantage of investigating the impact of a particular gene to MS disease progression. Moreover, both adult mice and rats are also chosen since all of the preliminary work and project tools have used these animals and hence is required for timely progress to be made.

A retrospective assessment of refinement will be due by 29 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

10. Autonomic control of cardiac function and rhythm

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Guinea pigs	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this programme of work is to investigate how the nervous system affects key processes in heart function and to gain an understanding of the relationship between dysfunction of this system and lethal abnormal heart rhythms (ventricular arrhythmias) which can lead to Sudden Cardiac Death.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This licence is essential to advance the understanding of why sudden cardiac death occurs and the role that the nervous system plays. The experiments are designed to identify key signalling pathways that will further scientific knowledge, which we hope will one day improve current therapies and develop new ones.

A new emphasis of this PPL is that data collected will be combined with mathematical modelling to improve and advance what is currently available which will incorporate up to date information on structure and physiology of nerves which plug into the heart.

- The current work is essential to advance the understanding of the mechanisms underlying autonomic modulation of ventricular fibrillation (VF) and cardiac function.

- The investigations may identify key signalling pathways that could lead to the development of new therapies for this lethal condition.

- Data will be published in academic journals that will be of interest to cardiac- and neuro-physiologists and clinical personnel with an interest in cardiac disease and the wider scientific community.

This PPL will follow the same theme of the previous PPL to facilitate the continuation of the research approved on our BHF programme grant. Of course, new data and new findings are accumulated everyday which drives the direction of the ongoing research and thus this application. The remit of the work in this PPL will still address the theme 'Autonomic control of cardiac function and rhythm' and will focus on molecular, cellular and whole heart models to investigate arrhythmia and sudden cardiac death.

What outputs do you think you will see at the end of this project?

This licence is essential to advance the understanding of why sudden cardiac death occurs and the role that the nervous system plays. The experiments are designed to identify key signalling pathways that will further scientific knowledge, which we hope will one day improve current therapies and develop new ones.

A new emphasis of this PPL is that data collected will be combined with mathematical modelling to improve and advance what is currently available which will incorporate up to date information on structure and physiology of nerves which plug into the heart. We aim to gain a better understanding into cardiac nerve distribution and ion channel distributions and the subsequent regional effects on the heart.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Data produced throughout this project will be presented at national and international conferences and published in academic journals.

Short term: Gain an understanding of the mechanisms underlying the modulation of arrhythmia which will inform studies using the myocardial infarction (MI) models of heart failure and enable comparison with disease models. Studies in cardiac cells will help us to identify ion channels that are important in modulation of arrhythmia. This data will also be used to determine relevant mathematical models of heart function. Colleagues and collaborators will benefit from data that will inform their experiments and approaches.

Medium term: The mechanisms and pathways identified will enable us to test target specific blockers/activators with potential to aid development of therapies. All of the above can be investigated in MI models to gain understanding on how these mechanisms and pathways are modulated in disease states. This data will also be used to determine relevant mathematical models of heart function. Colleagues and collaborators will benefit from data that will inform their experiments and approaches.

Long term: Advance the understanding of the mechanisms underlying ventricular fibrillation (VF) and cardiac function. The investigations may identify key signalling pathways that could lead to improvements in current therapies and the development of new therapeutic modalities for this lethal condition. Data will be published in academic journals that will be of interest to cardiac- and neuro-physiologists and clinical personal with an interest in cardiac disease and the wider scientific community.

How will you maximise the outputs of your work?

We will maximise the outputs of this group through collaborations with other departments within the REDACTED and with other universities. We will disseminate new knowledge at national and international academic meetings and conferences and through publication of our findings in scientific journals.

Species and numbers of animals expected to be used

- Guinea pigs: 250
- Rabbits: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Heart preparations will be prepared and removed during non-recovery anaesthesia for animals entering protocol 1. This will involve subcutaneous and intravenous injections, tracheotomy to expose of tissues of interest and isolation and resection of vasculature / muscle (optional i.e. for innervated heart preparation), all of which will occur under terminal anaesthesia. The heart and associated tissues will be removed immediately after intravenous overdose of anaesthetic. Animals in protocol 1 may also have optional blood sampling under anaesthesia.

Animals from protocol 2 will have general anaesthesia and surgical procedures performed to tie of a coronary artery (or not for Sham animals) to produce a myocardial infarct.This will involve subcutaneous and intravenous injections, optional blood sampling under anaesthesia, thoracotomy and exposure of tissue of interest, 1 or more coronary arteries will be ligated to cause an area of ischemia and infarct for a MI (Sham animals will not have a coronary tie) and administration of intrathoracic steroids. Surgical subcutaneous implantation of a telemetry device is also optional. Animals will be allowed to recover for up to 16 weeks, after which they will be prepared for terminal experiments which will involve subcutaneous and intravenous injections, optional blood sampling, tracheotomy to expose of tissues of interest and isolation and resection of vasculature / muscle (optional i.e. for innervated heart preparation), all of which will occur under terminal anaesthesia. The heart and associated tissues will be removed immediately after intravenous overdose of anaesthetic. Animals under this protocol can have optional administration of dietary supplements in food or water, for example Beetroot juice.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

To develop the heart failure model we perform an open-chest surgical procedure that is rated at moderate severity. Premature death is the most significant adverse effect that we try to keep to a minimum through sound aseptic surgical techniques and rigorous post-op monitoring with rapid

reactive treatments if symptoms develop. Rabbits do not commonly display symptoms of heart failure like humans, but the most common adverse harm is pain, which is controlled with good pain medication. At the end of procedure, animals are anaesthetised and the heart is removed for use in the laboratory for scientific study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

500 Rabbits - Moderate (50% of total rabbits)

500 Rabbits – Non-recovery (50% of total rabbits)

250 Guinea pigs – Non-recovery (100%)

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is impossible to investigate modulation of VF in humans due to its lethal nature. To get a better understanding of the mechanisms involved in the initiation and development of arrhythmia and SCD whole heart models are essential to understand the spread of electrical activity and thus the regional electrophysiology. Cellular experiments can then investigate deeper into the specific ion channels involved and their heterogenous distributions in the heart. Hence animal models are essential to advance our understanding of the mechanisms involved. This data will inform the development of relevant mathematical models which will hopefully allow for some replacement in the future.

Currently there are no non-animal alternatives and no appropriate mathematical models available.

What was your strategy for searching for non-animal alternatives?

Mathematical modelling has provided some useful tools to investigate some aspects of cardiac physiology.

Why were they not suitable?

Mathematical models are in development, incomplete and are currently not suitable; as they do not fully address complex cardiac rhythms owing to the lack of a comprehensive understanding of all the processes involved.

To note: we have a 5-year BHF programme grant that will use our data to incorporate into current mathematical models. Through continued development this will hopefully allow some replacement.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Group size calculation is informed by expected differences in parameters based on our previous data (e.g. heart rate, action potential duration, ventricular fibrillation threshold) to provide adequate statistical power.

These are calculated based on the standard deviation (SD) of the data and estimated detectable change (DC) of the parameters studied. The least number of experiments required to demonstrate a scientific effect are used. Experiments are carefully designed and performed under tight control conditions and analysed in acceptable small cohorts, so statistical differences are analysed as work progresses and discovered early, so unnecessary additional experiments can be stopped

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

- We perform experiments in-vitro as confounding effects of circulating hormones/autonomic reflexes in in vivo setting would increase variance
- This allows our experiments to be tightly controlled from a homogenous population of animals, so the smallest number is used to achieve the objectives
- Statistical analysis is discussed with our departmental statistician when needed

What other measures apart from good experimental design will you use to minimise numbers?

- Use of good laboratory practice (GLP)
- Rigorous experimental data appraisal to ensure quality and low failure rates
- Sharing of tissue e.g. sharing of muscle tissue with collaborators
- Covering more than one objective for each animal

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Protocol 1

Amongst small experimental animals, Rabbits have the most comparable cardiac electrophysiological and ion channel characteristics to humans. The physiology of the Guinea pig action potential is different to rabbits and is more influenced by the potassium current known as IKs which plays an important role in the development of arrhythmias. This is the most refined model for the intended purpose of investigating of the autonomic nervous system (ANS) as it allows tightly control studies without confounding influences.

For isolated heart, single cell, molecular biology and immunohistochemistry experiments, the isolated heart is the most refined method for these intended purposes. The preparation is harvested during non-recoverable general anaesthesia following a sub-cutaneous injection of sedatives, which is the least painful injection route which has been refined from previous use of intramuscular routes. Previously, animals were ventilated with room air but we have since refined this method with use of an oxygen concentrator which helps to maintain the rabbits oxygen saturation levels. We now also use continuous propofol infusion as oppose to boluses to allow better control of anaesthesia.

Protocol 2

Inducing myocardial infarction (MI) has clear adverse effects on the animal. The procedure involves a thoracotomy and the induction of a myocardial injury, which results in pain and other complications such as ventricular failure, thromboemboli and death. Experience with this model indicates that the expected harm can be controlled and minimised with resultant pathophysiology that can be used with human relatable data.

Refinements related to the MI model

- Use of rabbits 2.5-3kg to reduce mortality rate seen previously in lighter rabbits
- Refining anaesthetic protocols to ensure calm induction for the animals
- Anaesthetise vocal cords with local anaesthetic before endotracheal tube (ET) tube insertion, without using the stylet
- Steroids used prior to closing thorax to reduce adhesions
- reduction in mortality rate from <30% to <20% (with refinement and control of procedures, our more recent data over the past 2 years would support a mortality rate of 5-10% of which the majority occur under anaesthesia)

- Use of effective analgesic regimen
- Frequent monitoring including pain scoring

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rabbits are preferred as the structure and physiology of the heart is more similar to humans, than rats or mice. We use guinea pigs because the physiology of the Guinea pig heart is different to rabbits and is more influenced by potassium ion channel currents (e.g. IKs) which plays an important role in the development of arrhythmias.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

- Use procedures designed to cause the least pain, suffering or lasting harm
- Transport stress is minimised by acclimatising animals to handling and animals are box trained prior to delivery and assessed as fit to travel before transport.
- Pre-emptive, intra- and post-operative analgesia, antibiotics, and antiarrhythmic drugs under aseptic conditions used wherever possible
- Best practice post-operative monitoring of animals and rapid intervention in cases of post-operative complications
- Use the Rabbit Grimace Scale (Keating SC et al, 2012. PlusONE 7(9).e44437 and Body Condition Score

- Continued collaboration on the MI-model

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

REDACTED

LASA guidelines for administration of substances http://www.verutech.com/pdf/lasa_administration.pdf

How will you ensure you continue to use the most refined methods during the lifetime of this project?

- Attending NC3Rs conferences
- Keeping up to date with relevant literature
  relating to 3Rs advances and discuss advances at our group meetings
- Consider adopting any advances that will refine techniques
  based on the latest science and technologies

  Periodically review new 3Rs information, experimental data and success and failure rate of procedures.
- Ensure minimal number of animals is used for each project and discontinue animal use for projects that are not showing promising data
- Design animal experiments that are robust and reproducible and ensure thorough analysis and regular review of data
-

- Use animal data to address important scientific questions and develop appropriate mathematical models of the heart to reduce the need for animal experiments in the future

Explain the choice ofspecies and the related life stages

It is impossible to investigate modulation of ventricular fibrillation (VF) in humans due to its lethal nature. The precise nature as to how neural and cardiac remodelling and their interaction in MI leads to increased incidence of VF cannot be studied in a controlled manner in patients as experimentation would require repeated episodes of lethal arrhythmias to explore the effects of nerve effects. Hence animal models are essential for scientific advancement relating to understanding the mechanisms involved. The use of whole animals and in vivo experiments are not ideal for studying pure effects from direct nerve stimulation on the heart due to substances in the blood and brain mediated reflexes that are difficult to control. Mathematical modelling is imperfect and still being developed to a point that would be acceptable to replace procedures requiring animals.

Hence we use the most refined model for the intended purpose of investigating the autonomic nervous system (ANS) as it allows tightly control studies without the confounding influences. Amongst small experimental animals, rabbits have the most comparable cardiac electrophysiological and ion channel charcteristics to humans.

NON-TECHNICAL SUMMARY

11. Basic mechanisms of chronic neurodegeneration

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Overall, this project aims to investigate the mechanisms underlying neurodegenerative diseases (diseases in which the structure and function of the brain are progressively lost) in particular those involved in human and animal prion disease pathogenesis.

More specifically this will include identification of new disease strains, modelling of human prion diseases, defining interactions between the immune system and neurodegenerative pathways and could lead to identification of therapeutic targets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodegenerative disease is an overarching term which covers a range of conditions in which the neurons (cells in human brain) are damaged or die and are unable to be replaced by the body. Neurodegenerative diseases include Alzheimer's disease, Parkinson's disease, Huntington's disease and prion diseases. There is currently no cure for these diseases; they are progressively debilitating and involve both issues with movement and mental ability (dementia). In the UK, 850, 000 people live with dementia disease and the cost is in the region of £26 billion/year expected to more than double by 2040. Current therapies have only a modest impact on symptoms and limited impact on disease progression. Identifying pathways and potential therapeutic targets in these diseases could aid in future treatment development.

The prion diseases, sometimes referred to as transmissible spongiform encephalopathies (TSEs) are a family of diseases in which the infectious agent lacks any genetic material (DNA) and consists of the misshapen (misfolded) and aggregated forms of one of the body's own proteins; prion protein or PrP. Some forms of the disease can be infectious and they are recognised as both animal and human diseases with potential to transmit between species including humans. They can be used as a model of chronic neurodegeneration but are also important diseases in their own right. Although the incidence of animal prion diseases such as scrapie and BSE in the UK are now low and no longer perceived as a threat, cases of variant Creutzfeldt-Jakob disease (vCJD), the human form of BSE, still occur. Retrospective studies in anonymised appendix samples have indicated that up to 1 in 2000 individuals in the UK have evidence of abnormal prion protein, a characteristic of vCJD, this poses risks to public health because of the risk of transmission of disease through blood transfusion and surgery. We do not know if these individuals will develop disease or if they are indeed infectious at this stage. One of the studies in this project will include characterisation of prion protein in both brain and anonymised appendix material in order to assess whether this protein is infectious and will aid in future public health risk assessments. We will also continue to carry out characterisation of both human and animal prion diseases in order to identify new diseases and ascertain any risks to humans from animal disease. Characterisation of the abnormal prion protein and disease progression through the body may lead to improved diagnostic and therapeutic strategies in these diseases.

What outputs do you think you will see at the end of this project?

By the end of this project we expect that we will have identified or confirmed the strain of prion isolates and their transmission potential. In particular, we should have defined the nature of abnormal prion protein observed in the appendix of anonymised individuals. Overall we expect to have a greater understanding of prion disease pathogenesis and transmission and an insight into mechanisms of disease.

These results will be written up as open access publications, presented at conferences and shared with the general public through lay summaries and/or social media.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The immediate beneficiaries will be the scientific community with whom we share our knowledge and research materials. In the longer term, towards the end or post project, information will be shared with clinicians and public health officials if appropriate. The results of some of our studies will feed directly into public health remit and could impact on areas such as medical decontamination and blood donation as well as confirming or informing on clinical diagnosis of human prion diseases.

How will you maximise the outputs of your work?

Publications and presentations at scientific conferences will enable the scientific community to access our results and request research materials. Data will be deposited in appropriate open access databases. Where appropriate we will work with relevant communication teams to generate press interest in our publications and engage the public in our science. Myself and my team are active in public engagement and sharing our science with the general public and we aim to produce lay summaries for both the public and for patients and families; these will be shared via our website and potentially through patient support groups.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In a typical study animals will undergo an inoculation into the brain under anaesthesia and allowed to recover. The animals will then be monitored for clinical signs of disease until either signs of disease are observed or the study endpoint is reached at which point the animal will be humanly killed. Animals will stay in their home cages with cage mates throughout this period. From inoculation to end of study can vary anywhere between 50 to ~600 days dependent upon study.

In some cases, animals may receive an additional inoculation of material such as a bacteria or virus during the course of the study.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

No severe effects are expected.

Development of clinical signs of disease is required for a number of scientific objectives to be met; these can include weight loss or gain and changes in movement and behaviour. We have a well defined scoring system in place to recognise when these signs occur and allow clear recognition of when the humane endpoint is reached. Animals are only allowed to show clear defined signs of disease for 2 out of 3 weekly scoring sessions, when this occurs or if significant deterioration occurs, the animals are humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The maximum severity for these studies is moderate and it is estimated that up to 80% of the animal will experience this. Primarily this is due to the method of inoculation (into the brain) and the appearance of clinical signs of disease. The other 20% will be sub-threshold/mild as they won't undergo inoculation via this route and/or are used for breeding purposes.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The focus of this project is to study disease characteristics and progression of prion disease as well as mechanism of diseases. This cannot be done in human cases of disease. Laboratory techniques (referred to as *in vitro* techniques) methods or lower organisms such as invertebrates cannot replicate the complexity and biological context of real disease.

What was your strategy for searching for non-animal alternatives?

At present there are no non-animal alternatives which are able to measure infectivity or disease characterisation. Biochemical and pathological methods can only measure certain characteristics and are generally only available post-mortem in human and animal cases.

We utilise *in vitro* techniques where possible to assess protein misfolding and in a current study are using one such *in vitro* technique, referred to as protein misfolding cyclic amplification (PMCA) to amplify samples and identify positive isolates for inoculation into our experimental animals. In this way, we hope to decrease the number of transmission studies which would result in a negative result and reduce the number ofanimals required overall.

Why were they not suitable?

Currently *in vitro* techniques cannot tell us about disease progression and how it moves through the body. Although we will endeavour to use them a screening step before animal studies, they can give rise to false positives and are not suitable/compatible with all disease strains or tissues of interest.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are estimated on our current usage and projecting anticipated studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The experiments are designed so animal studies are kept to a minimum, this includes the use of *in vitro* screening techniques where possible. Numbers are continually reviewed in order to reduce them where possible.

We consult with an in-house statistician during experimental design to minimise the numbers of animals required while still providing meaningful data outputs.

The use of animals is restricted to critical samples or situations where alternatives would give ambiguous results.

What other measures apart from good experimental design will you use to minimise numbers?

We use both males and females as a matter of course in our studies and tissues and data are shared with other researchers where appropriate or possible.

Any animals that have been used for breeding also have tissues collected. These tissues can be used as negative controls, for use *in vitro* studies (reducing our need to breed specifically for this purpose), for optimising certain laboratory procedures and for training purposes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In these studies wildtype and transgenic mice (mice in which their DNA has been altered) will be used because prion disease progression in mice closely resembles that observed in higher species such as sheep and humans. In some cases, the disease will remain subclinical and no overt signs of disease can be identified in the animals. Where animals do proceed to the clinical signs of disease we have a well-defined clinical coring system in place. The use of this system prevents unnecessary suffering and is reviewed as new data becomes available.

Inoculations are performed under anaesthesia and animals are expected to recover quickly after the procedure. All animals are monitored to ensure that they are not in distress.

We utilise *in vitro* approaches where possible but these can require GA animal tissue as a substrate. In these cases, animals do not undergo any procedure and are humanely killed as young adults. The use of *in vitro* screening had the potential to allow us to decrease the number of animals undergoing a transmission study.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In order to study and characterise prion diseases we must study the disease process. Less sentient species cannot provide us with the relevant information or are not suitable hosts. Young adult animals are used as they provide us with the most relevant information and can be compared against an archive of previous studies avoiding us having to repeat studies in younger mice.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Over the past project licenses that I have held or been working under we have made continual refinements to our studies. These have included increased monitoring of animals where required, continual training of staff in clinical monitoring of animals, environmental enrichment and ensuring that we avoid single housing animals where possible. Where animals are required to carry out specific tasks, we ensure that they are familiarised with their environment beforehand.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow a variety of best practice guidance including:

- Guidance on the operation of the Animals (Scientific Procedures) Act 1986
- Local guidelines for specific procedures e.g. blood sampling
- ARRIVE guidelines

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I read the NC3Rs newsletter and regularly check their website for news and updates. I am a member of an AWERB and also receive updates through that. I ensure my group are aware of the latest updates and that all are aware of NC3Rs and Understanding Animal research websites.

My group consults and uses ARRIVE guidelines when preparing studies/manuscripts. We also have a close working relationship with the animal unit staff and local NVS.

Explain the choice ofspecies and the related life stages

The major aims of our studies centre on characterising prion disease and disease progression. Mice are used as prion disease in experimental mice closely reflects the disease in higher species such as sheep and humans. In particular, mice can show clinical signs of disease, dementia and have the same disease characteristics present in their brains (vacuolation and presence of the disease associated abnormal protein). These characteristics are not present in lower order species such as invertebrates or fish.

We tend to use young adult mice in our characterisation studies as these allow experimental procedures to be carried out more efficiently and we have comparable data in this age. Young and/or aged mice may be used if required to address the effect of age on a disease process.

NON-TECHNICAL SUMMARY

12. Behavioural neuroscience in transgenic zebrafish

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Zebra fish	juvenile, adult, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Under this licence, we want to breed and maintain genetically modified zebrafish lines to provide larvae for experimentation. These experiments will investigate how the brain of this animal produces and modifies movements.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our ability to move in a controlled and directed manner allows us to look for food, escape predators and dance the boogie-woogie. These movements are produced by precise sequences of activity in our muscles that are started by neurons in our brain and our spinal cord. Even though this process is central to how we move, it is still unclear how the brain does this. We use the larval zebrafish to study this process, as many of the brain structures involved can be found in its brain. We can much more easily study how these brain areas allow the fish to move, as we can use a large number of powerful tools to record and change the activity in specific portions of the brain.

One such brain area, the olivocerebellar system, can be found in all higher vertebrates. It is thought -but not yet proven- that it receives information from the brain on what the muscles have been instructed to do, which it then compares with information on what the muscles are actually doing. This allows it to see whether the animal is moving exactly according to plan. The importance of this has been seen in many patients who develop difficulties when this brain structure is disrupted: poor balance, tremors, and an inability to perform rapid movements. Treatment options for these patients is very limited, involving mostly rehabilitative exercises. While the causes are varied, a greater fundamental understanding of the olivocerebellar system will help future efforts to understand and remedy these conditions.

What outputs do you think you will see at the end of this project?

The main outputs of the project will be:

- Peer-reviewed publications: in these we will share our findings with the academic community;
- Datasets: the data underpinning the publications will be shared freely online;
- Transgenic zebrafish: these are powerful tools to address a host of questions in the biomedical research field. They will be shared with any interested party (by supplying the researchers with the embryonic offspring of the relevant adult fish).

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This project will use cutting-edge tools to investigate fundamental questions in neuroscience. Our findings will benefit the global motor systems and zebrafish research communities, and will help researchers closer to home by providing training and facilities.

Motor systems research: Our experiments, which would be extremely challenging in other model organisms, will produce important results, which will be shared in publications and at conferences with data shared online at publication. We will inform researchers working on motor systems globally: computational biologists can use our insights to update their models on these circuits, and experimental scientists can use our insights to inform their experimental design.

Zebrafish researchers: We will characterise the expression patterns of existing transgenic zebrafish, and develop new ones. These lines are powerful tools in the investigation of the function of specific cell types in neuroscience, developmental biology, and other biological fields. Our results will therefore benefit other zebrafish researchers across the biomedical field.

Project personnel: The personnel working on the project will benefit from the research as it will give them the opportunity to develop new skills and further their training to prepare them for a successful career at the forefront of science and beyond.

Further 3Rs agenda: The larval zebrafish is rapidly becoming a premier experimental model for biomedical research. Our project will help strengthen this position further in the UK. We will help achieve the UKRI's stated aim to advance further improvements in humane animal use in research through partial replacement. For other researchers aiming to do the same, this project will provide an example of a clear pathway towards that goal.

How will you maximise the outputs of your work?

We will ensure maximum benefit by sharing all our findings –whether or not they are of direct relevance to the project– informally, at conferences and in publications. The new transgenic zebrafish lines will be made freely available to any interested party.

One of the ways UKRI aims to support innovation is by fostering the development of collaborative research programmes. As part of the project, we will collaborate with researchers locally and internationally. This effort will help establish international research links, and will help foster future collaborative projects between institutions.

Our research also lends itself particularly well to be presented to a lay audience, as the output can be presented in striking visualisations. The findings are also relatable and their biomedical importance apparent. We therefore intend to organise activities we think leverage these qualities best, including an annual science festival, and an

We will use the larval zebrafish to chart its neural activity and discover which areas in the brain are involved in generating movements. Computational modelling cannot reveal this, as there is currently insufficient data to generate accurate models

- Cultured neurons are unlikely to recapitulate the organisation of the brain and spinal cord of the larval zebrafish. Using this technique is therefore unlikely to produce insights into how the neural circuitry in the brain and spinal cord interact to produce behaviour

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimated how many animals were required in our experiments using standard calculations. Using common assumptions about the variability of our data, we estimated we needed more than, or equal to, 9 animals per experiment. In some experiments, where we compare a biological process before and after a manipulation, we found that we need at least 15 animals per experiment to ensure we have confidence in our findings.

We expect to be performing 3-7 full experiments per week. If we perform an equal number of descriptive and manipulation experiments, we will require 60 pre-feeding animals per week. For the 5-year duration of the project that makes ~15,000 animals. From experience, we know that ~20% of all offspring can be used in experiments. This is because each cross typically results in a large number of embryos, most of which will not be the right genotype (these will be killed before they reach 5dpf using an SK1 method), and some of which will die of natural causes. This suggests a total number of offspring required of ~75,000. In order to obtain these numbers, we require ~1,500 crosses. Assuming 15 different genotypes will be used for the project, this can be achieved with 2 holding tanks per genotype, with ~25 fish each. Assuming a mean lifespan of ~1 year per fish, this will require 3,750 fish.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice was sought from previous PPL applicants. Furthermore, the NC3Rs' Experimental Design Assistant was consulted, and dedicated software was used to do power and sample size estimations (G*Power, see reference).

What other measures apart from good experimental design will you use to minimise numbers?

For our breeding and maintenance procedures, we will carefully adjust the number of animals we use according to our requirements and the constraints posed by the animals. For instance, the number of breeding animals for each mating will be tailored to the number of offspring we require from them for each experiment; the fertility of each particular stock of zebrafish will also be taken into account (i.e., a stock that has a low fertility rate will need to have its numbers increased). This means we will not use more than the required animals for each experiment; nor we will use too few, which would not allow us to do statistically rigorous work. Furthermore, we have done power analyses to estimate required sample sizes for our experiments on larval zebrafish.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project aims to understand how the brain produces behaviour; the use of animals therefore cannot be avoided. We will use the larval zebrafish as a model organism, which due to its transparency makes it ideal for non-invasive imaging. Its brain is assumed to share many functional similarities with mammalian homologues. It is an excellent model system for this project, and ensures we adhere to the UKRI's rule to "Use the simplest possible (or least sentient) species of animal as appropriate to the experiment in question."

For our experiments we will use well-established protocols to breed and maintain transgenic zebrafish and prepare them for experiments, ensuring minimal harm and distress. GAA passports for each line are established on a local level, frequently updated with new information, and include details relating to changes to the phenotype, breeding performance, colony management, mortality rates etc. A list of the GAAs kept at the establishment plus the GAA passports are held with the PPL, and will be provided to the Home Office Inspector on request.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In order to generate transgenic larval zebrafish, we need to use animals that have reached sexual maturity. The use of adult zebrafish is therefore required. Furthermore, the experiments described in protocol 4 use the earliest life stages that produce behaviour similar to adult zebrafish, namely between 5 and 7 dpf.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

When using anaesthetics, type and depth of anaesthesia will be carefully selected and monitored in consultation with the NVS. Following fin clipping in >5dpf fish peri-operative analgesia will be provided; agents will be administered as agreed in advance with the NVS. The procedure will be carried out using sterile equipment, and the site and amount of tissue removal for genotyping will be such that there is no compromise to normal swimming. Infections can result from fin clipping (<1%) or from damage to scales or loss of mucous surface from swabbing. Any fish exhibiting any abnormal behaviour or signs associated with infection will be humanely killed.

When we create GA founders, embryos will be assessed for morphological phenotypes before the stage of independent feeding using standard light and fluorescence microscopy, and any showing morphological abnormality not required for the scientific purpose would be humanely killed. Some genetic alterations may result in a harmful phenotype during post-hatching development evidenced as failure of larvae to inflate the swim bladder, difficulty swimming, altered morphology, failure to feed or breathing difficulties. If fish exhibit any of these adverse effects they will be killed immediately by a humane method. On occasion (<5%) late onset mutations in more mature stages may lead to lines of fish with mild lordosis (defined as less than 20% curvature of the spine), poor growth/body condition or difficulty swimming. Any fish showing harmful phenotypes will be humanely killed as soon as the phenotype is visible. During our experiments on larval zebrafish we will monitor the heart rate and blood circulation of experimental animals, and will check animals for signs of injury to ensure there are no signs of distress or harm. Any fish showing these signs will be humanely killed as soon as possible.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use well-established protocols to breed and maintain transgenic zebrafish, ensuring minimal harm and distress. These protocols have been described by the Zebrafish International Resource Center, REDACTED of Oregon, USA, sourced from "The Zebrafish Book", see reference.

Westerfield, M. (2007) THE ZEBRAFISH BOOK, 5th Edition; A guide for the laboratory use of zebrafish (Danio rerio), Eugene, REDACTED of Oregon Press. Paperback.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The NC3Rs is the pre-eminent UK-based scientific organisation dedicated to replacing, refining and reducing the use of animals in research and testing. We will monitor the NC3Rs' output to stay aware of the latest developments in animal welfare, and implement these whenever possible.

Explain the choice of species and the related life stages

We will use the larval zebrafish as a model organism, which due to its transparency, relatively simple body plan and availability of genetic tools makes it ideal for non-invasive experiments to uncover how the brain generates behaviour. The zebrafish brain also contains many ana

NON-TECHNICAL SUMMARY

13. Biobehavioural basis of vulnerability to impulsive/compulsive spectrum disorders - Optimisation and service protocols

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Rats	neonate, juvenile, adult, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To optimise procedures and produce GA rats for use on other project licences held by the group.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To use the optimisation protocols in pilot studies to optimise procedures and combinations of procedures to ensure they are as refined as possible while retaining scientific validity.

What outputs do you think you will see at the end of this project?

The expected outputs will be refinements to procedures and experimental designs and demand matched production of genetically altered rats.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The data obtained from the optimisation protocols will be used to inform experiments conducted by members of the research group using the other project licences held by this group. Therefore data produced from the use of these protocols will primarily be used by members of our research group. However where appropriate refinements will be published and shared with the scientific community in accordance with the principles of the 3Rs.

How will you maximise the outputs of your work?

Refinements to procedures and experimental design will be published and discussed at national and international meetings.

Species and numbers of animals expected to be used

- Rats: 1300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Rats in this project will either be bred and maintained in order to be used in the two other protocols on this licence or on our other licences.

Rats (including GA animals with no adverse phenotype) used for optimisation procedures will be subjected to intracerebral manipulations under terminal anaesthesia, with no recovery or will receive 1 intracranial procedure, and up to three surgeries overall (including the implantation of an indwelling catheter), in order to optimise manipulations or measurements of brain mechanisms while the animal is performing behavioural tasks, including drug self-administration.

Rats (no more than 60%) may be exposed to behavioural procedures aiming at measuring their motivation, impulse control or other cognitive functions, for which they sometimes need to be single housed and/or food deprived.

No more than 20% of the rats may receive administration of substances to induce dependent states. These may also be administered with substances that couteract these dependent states.

No more than 15 rats overall may experience experimentally-induced Parkinson's disease.

The investigation of specific cellular mechanisms requires the decapitation of the rats in a conscious state.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

For the majority of our animals on this project (75%), we anticipate no more than transient discomfort and no lasting harm.

The genetically modified rats lines that we will breed have no adverse phenotype.

The two optimisation protocols are designed to enable us to minimise the impact of intracerebral procedures in subsequent experiments, by optimising and refining the said procedures first in a non-recovery protocol, and then in behaving rats, always using as few animals as possible (2 to 5).

When rats undergo surgical procedures, then tend to recover very rapidly and they are provided with post-operative care, including the use of analgesics.

When rats are trained to self-administer drugs, some (up to 25%) may develop several behavioural characteristics similar to those presented by human beings suffering from a drug addiction, including lack of interest in other sources of reinforcement and associated weight loss, decrease in self-care (their fur becomes dirtier). A very small number of animals we see them self-harm in the same way that drug addicts do when they are when given extended access to heroin. This is because high levels of heroin intake can cause changes to the way nerves in the face and mouth behave: heroin is an analgesic (i.e. it affects feeling and pain perception). When rats can no longer feel the pain some start to nibble their toe nails and toes can inflict damage to their paws.

When rats have become dependent on a drug, such as heroin, upon induction of withdrawal they display typical signs of physical withdrawal, including wet dog shakes, or piloerection, but as in humans, these signs wear off rapidly (within 24 to 48 hours).

In the case of the induction of Parkinson's Disease, rats tend to present a transient lack of motivation that is associated with the neurodegenerative process of the dopamine neurons, hence they need to be supplemented by highly palatable food or feed (including by oral gavage) until they recover (between 3 and 12 days overall).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Non-recovery rat protocol – 100%

Mild rat protocol – 100%

Moderate rat protocol – 100%

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not yet possible to achieve our objectives without using animals, and, especially, rats. Our research, which investigates the inter-individual differences in the vulnerability to develop impulsive/compulsive spectrum disorders, which result from an alteration of many complex, intricate, brain mechanisms and associated cognitive (understanding and perception) and emotional processes which we do not yet understand, even remotely, enough to be able to contemplate modelling them using algorithms or Artificial Intelligence.

The nature of our research therefore requires we use a species whose brain, cognition and behaviour are similar enough to humans to offer insights into the psychobiological basis of human neuropsychiatric conditions. The rat is by far the best species to establish the neural and neurochemical mechanisms underlying inter-individual differences in behaviour, cognition and neuropsychiatric disorders which cannot be investigated in humans.

The rat is so far the only species in which individuals have been shown to have representation of the relationship between their actions and their consequences, to establish coping strategies, to differ in impulse control and in their propensity to take drugs, even to develop maladaptive habits and compulsivity.

Most of our animals undergo long duration behavioural experiments (which last up to 14 months) in which they perform tasks for food or drug reward, and experience procedures that, provided they are fully optimised, produce only transient discomfort and no lasting harm. It is therefore fundamental to optimise these invasive procedures, and that is precisely the goal of the present project licence.

What was your strategy for searching for non-animal alternatives?

We use alternative strategies some of which involve humans, some are computer-based models and some use Artificial Intelligence. In addition, we use cell culture (i.e. cells grown in a dish in the laboratory) and ex vivo organoids (i.e. cells that grow in a dish and form into organ like structures).

Why were they not suitable?

As our objectives, which will be achieved through the use of other complementary project licences, require complex behavioural tasks allowing for the identification of individual vulnerability to compulsive disorders, we cannot rely on in vitro (non-animal) models because these cannot reproduce the integrative function of the brain that is the focus of this research.

Since these experimental procedures are designed to optimise the intracerebral and pharmacological procedures we need to use in order to achieve our research goals in rats, the purpose of the present project licence, must be carried out in the same species.

Human studies cannot allow for a lifetime longitudinal study addressing causal mechanisms of neuropsychiatric disorders, they yield only correlative data and rely very often (if not exclusively) on retrospective analyses which prevent the identification of factors of vulnerability measured prior to the development of the disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

1000 rats will be used for breeding and maintenance of genetically modified/selected strains and wild-type controls. This will enable us to use up to 2500 such transgenic animals in the two experimental

project licences which, alongside the present one, support our programme of research.

150 rats will be used in each optimisation protocol, with groups of 2 to 5 per optimisation, that will enable us to carry out up to 20-25 optimisations over the next 5 years.

The identification of these numbers is informed by our expertise, REDACTED.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

This project licence is designed to enable us to reduce the number of animals being used in subsequent experiments under our other project licences.

Here, for each optimisation strategy, wherever possible, we implement experimental designs that minimise noise in our behavioural or biological measurements and that are always combined with state of the art statistical analyses.

What other measures apart from good experimental design will you use to minimise numbers?

We will use efficient breeding and use both male and female offspring in subsequent experiments carried out under the authority of our other project licences. We will rely on computer modelling or in vitro assays prior to optimising procedures in a non-recovery setting. We will eventually rely on very small samples (approx. 2 to 5 animals per group) to further optimise the procedures in behaving rats.

Together the incremental strategy designed for this breeding and optimisation licence will enable us substantially to optimise the number of animals we plan to use in our overall programme of research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In this project we will use several animal models and methods, the combination of which will enable us to identify the factors of vulnerability to develop compulsive disorders across a wide range of conditions and their biological basis in the brain.

Our methods mostly rely on awake, freely moving animals performing complex behavioural tasks for rewards (e.g. food, or drugs of abuse) and subject to invasive recordings or manipulations of the brain while performing these tasks.

We are fully committed to minimise the cumulative severity of all our procedures as much as possible and have been constantly refining all our procedures in order to minimise the distress to which our animals are subjected.

We will use models of inter-differences in impulse control (high impulsivity trait), Obsessive Compulsive Disorder, drug (alcohol, cocaine, heroin….) addiction and Parkinson's Disease.

We have, over the years, refined our models so that we can study the psychological and biological basis of profoundly debilitating and distressing disorders in humans such as OCD or addiction, with minimal adverse consequences in our rats.

In the case of OCD for instance, rats tend to display compulsive behaviours for no longer than 1 hour per day, and these have overall no other negative consequences. To study Obsessive Compulsive Disorder, we primarily rely on a procedure that requires rats be food deprived to 80% of their free feeding body weight. These rats are absolutely fine and display no behavioural or physiological signs of distress.

For drug addiction, we implemented procedures that enable us to measure the compulsive nature of drug seeking and taking that characterises addiction (in other words the drug is used despite disastrous negative consequences for the user and their relatives/carers) without overall harm to the animal. To study drug addiction, rats initially trained to self-administer drugs through an indwelling catheter implanted into their jugular vein. We have refined this procedure so that it lasts no more than 10 minutes and rats recover very rapidly with no signs of distress. All our surgeries are performed under aseptic conditions and rats are given appropriate analgesia prior to, during, and after the surgery.

For Parkinson's Disease, the procedures we use enable the rats quickly to recover from the initial motivational effects of the sudden development of the condition and ensure they do not develop too profound a motor deficit.

We use a wide array of methods in our research. One is the testing of rats in behavioural tasks in which they are given the opportunity to solve puzzles, work (press levers) to obtain food rewards. These tasks, that are designed to investigate specific psychological or behavioural mechanisms, are not regulated, meaning they do not cause any distress or harm to the animal. However, it can be the case that rats have to be slightly food restricted to engage with the task. In that case food is delivered every day following the behavioural session. Food is given in quantities large enough to maintain the animal body weight between 90 and 100% of their free-feeding weight. It is also better for the animal's health as there is strong evidence that as in humans, free-feeding in rats results in decreased longevity.

We will use systemic administration of drugs either through experimenter-delivered injections, or via previously implanted subcutaneous minipumps or slow release formulations (like some forms of pills in humans). In this case, each drug will be prepared with double distilled water or sterile vehicle, in autoclaved glassware and subsequently filtered prior to use. Dosing procedures will be undertaken using a combination of volumes, routes and frequencies that themselves will results in no more than transient discomfort and no lasting harm and is the minimum consistent with the scientific objectives. We have implemented specific methods to deliver intraperitoneal injections to rats without restraining and stressing them and only highly trained researchers perform these injections.

We will use blood sampling procedures. In that case no more than 10% of total blood volume in 24hrs and 15% of total blood volume in any 28-day period will be taken.

We will use methods designed to measure or manipulate the activity of specific brain areas while rats are behaving, and/or expressing OCD, drug addiction, impulsivity. For this, we need to insert probes, electrodes inside the brain that can be connected to external devices that enable the measurement of brain function. We also rely on pharmacological manipulations of brain functions and for this cannula are lowered into the brain and we use injectors to infuse tiny amounts of drugs that interfere with a specific brain mechanism inside the brain. We will also use the technology of virus-mediated expression of genes in the brain to measure of control brain function. For all these methods, the surgical procedures are all carried out under aseptic techniques and the rats are habituated to be connected to external devices and are always free to move when connected. We use the least invasive methods drawing in fast evolving state of the art techniques and systematically ensure to procedures are optimised and refined (which is the very purpose of this project licence) before using them on larger cohorts.

When rats are food restricted, they often need to be single housed as the dominant would otherwise experience no food restriction and the expense of the subordinate. Similarly, when rats have received intrajugular and/or intracranial implants, they often need to the single housed in order to prevent them from playing with, and damaging each other's implant.

Isolated animals tend to gain more weight than controls; they are more responsive to stimuli predicting reward (in specific behavioural tests) and are hyperactive as measured by specific behavioural tasks. Additionally, we have shown that rats raised in an enriched environment are more vulnerable to develop compulsive disorders.

Overall, we are geared towards optimal refinement, from our choice of animals, to our methods, procedures and skills. First, and foremost, the present licence will enable us to optimise and refine on small groups of rats the intracerebral and pharmacological procedures that will subsequently be used on large experimental groups. The present project licence is therefore testament to our commitment to refinement.

Additionally, I make sure that we maintain our high standards in order to ensure all our refinements are actually implemented. Thus, I review all procedures and skills of the licenced researchers working in my laboratory, under my supervision, regularly and discuss project licence-related matters at each of my weekly lab meetings.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rats are the least sentient organism that enable the measure of inter-individual differences in the behaviours of interest with some individual displaying behavioural manifestations that have high heuristic value with regards to the Impulsive/Compulsive Spectrum disorders we are investigating.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

When rats have to be singly housed for the purpose of protracted self-administration or behavioural training, not only are they handled at least twice a day, during behavioural training, at least 5 days a week (in average), but they are also brought to test boxes several hours per day, at least five days a week.

We have experimental evidence that these housing conditions, as opposed to so-called enriched environments, do actually protect rats from developing disabling compulsive disorders such as addiction to cocaine. Thus, our recent work on environmental enrichment has actually shed new light on the rather anthropomorphic view of the benefit of enriched environments for rodents, as it is likely more difficult to define what is an enriched environment for rats than it is for humans, for whom the definition is very much specific to each individual. Indeed, we have, in a very challenging environment, demonstrated that rats raised in a highly enriched environment are less likely to engage in high levels of cocaine self-administration than rats raised in standard conditions, but instead demonstrated higher vulnerability to switch from controlled cocaine intake to addiction. Thus, of all the 48 rats (24 from a standard condition, 24 from an enriched environment) trained to self-administer cocaine for over 80 days in this experiment, 6 became addicted to cocaine, and they were all from the enriched environment.

For repeated intraperitoneal injections we ensure that the smallest needles and volumes of pH-neutral injections are used and use procedures we have developed and refined, and validated by our Named Veterinary Surgeon, whereby stress is minimised delivering these injections without restraining the animal.

Each of the rats on the optimisation protocols on this licence will undergo neural manipulations (brain surgery) and/or implantation of intravenous catheters for long-term self-administration of drugs of abuse. We take great care to minimise suffering following surgical procedures and minimise the risk of infection and/or catheter damage by using the most elaborate techniques (the present licence is actually designed further to optimise each bespoke intracranial manipulation to further decrease its potential impact on the animals) that have been developed and constantly refined in collaboration with the Named Veterinary Surgeon.

We routinely administer peri-operative analgesia (i.e. pain killers after surgery) and use scoring sheets to monitor animal welfare for a minimum of three days post-surgery. The specific analgesics used varies between different types of experiment and the strategies we have now in place to ensure continuous analgesia through the perioperative period have been designed with the Named Veterinary Surgeon.

We have been investing a lot of time and efforts in refining our skills, techniques, procedures and equipment, and we will continue to do so over the next five years. Over the past years, we have developed and refined, together with our Named Veterinary Surgeon, a scale to enable the daily monitoring (using an electronic reporting system we have also implanted and refined) of the status of the back mounted cannulae ports in rats trained to self-administer drugs. We have also substantially improved our aseptic techniques adopted from the principles of the Laboratory Animal Science Association (LASA) guidelines, to comply with our high throughput requirements.

We have progressively engineered a better catheter for self-administration experiments. Relying on a stepwise, iterative empirical strategy, we have decreased the size of the mesh that is inserted under the skin to secure the port, in order to decrease the surface it occupies under the skin, hence the risk of irritation and physical damage to the surrounding tissue. Having verified, in collaboration with the

Named Veterinary Surgeon that this change yielded positive outcomes in terms of damage to the skin around the port, we then increased the rigidity of that mesh to stop it being grabbed and stretched by the rats, which on some occasions resulted in local irritation. Having observed another improvement, we then decreased the diameter of the port cannula (tube) which reduced the overall size of the device.

We predominantly use Sprague Dawley rats, and not the Lister-Hooded strain which were historically used, as the former demonstrate fewer skin lesions, and tolerate the effects of long-term drug exposure better than the latter. The very low incidence (actually the absence) of adverse effects around ports in 200 rats that had the new monitoring procedure illustrates the improvements made by my laboratory and we will endeavour to further the refinement of this, as well as all the other procedures used in my laboratory. All improvements will be disseminated as widely as possible.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

REDACTED

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I have several lines of information that enable me to stay informed about advances in the 3Rs in order to implement them effectively.

First, I have registered to the NC3Rs newsletter and follow them on Twitter.

Secondly, as all the project licence holders at our establishment, I receive tremendous support from the staff at the establishment, and I receive regular critical updates from the Named Information and Compliance Officer to which I pay the utmost attention and that I share with all the members of my lab.

I hold project licence-related workshops at least twice a year with all the members of my laboratory to discuss the changes in procedures.

I have an excellent working relationship with the animal care staff in my animal facility, which facilitates the implementation of advances in the 3Rs.

Explain the choice ofspecies and the related life stages

The majority of individuals in the world are exposed to stress, or use drugs recreationally, may it be alcohol, tobacco…, sometimes itself as a means to deal with stress, a so-called coping strategy, we are not equally capable of developing adaptive coping strategies or to maintain a recreational, controlled use of drugs. The individual vulnerability to lose control over coping strategies or drug use, which results in Compulsive Disorders such as Obsessive Compulsive Disorder o drug addiction, remains poorly understood. This prevents the development of novel, more effective therapeutic or preventive strategies for these debilitating disorders that affects millions of individuals worldwide. Our research, which relies on two complementary experimental project licences alongside this one, interests itself with the environmental, psychological, neural and cellular factors that contribute to this individual vulnerability to develop Impulsive/compulsive Spectrum Disorders.

This research is only possible with the use of animals because human studies (e.g. brain imaging studies) are useful but can only provide correlative data that do not address causation and short fall of identifying the detailed mechanisms in the brain that support the vulnerability to develop Impulsive/Compulsive Spectrum Disorders. Furthermore, it is not ethically possible to study the genetic and/or environmental factors that underlie predisposition to, and the development of, neuropsychiatric disorders in humans.

Similarly, it would not be possible to develop new treatments for brain disorders without testing them in animal models first. In vitro models (e.g. rat brain slice preparations) or computer simulations cannot be used because the modelling of behaviour in these systems is not sufficiently advanced.

Thus, we use rats because they are the least sentient species which allows researchers to investigate marked inter-individual differences in sophisticated behaviours that capture core features of these neuropsychiatric disorders. Additionally, the brain circuitry implicated in many neuropsychiatric disorders is highly conserved between rats and humans.

In order to uncover the biobehavioural basis of the vulnerability vs resilience to ICSDs across the lifespan, we will carry out investigations, deploying large array of intracerebral measurements and manipulations on juvenile and adult wild-type and genetically modified rats. It is therefore important that such procedures, which are invasive, are optimised prior to being deployed on large experimental cohorts of rats. The purpose of the present project is therefore the breeding and maintenance of genetically modified rats as well as the optimisation of intracerebral techniques and pharmacological manipulations.

The identified need for optimising our procedures stems from our commitment to animal welfare. Indeed, most of our animals run in long-lasting behavioural experiments in which they perform tasks for food or drug reward, and experience procedures, when fully optimised, that produce only transient discomfort and no lasting harm, achieved by a constant refinement of administration techniques by well-trained personnel.

Any adverse effects are discussed with the Named Veterinary Surgeon. If these cannot be quickly ameliorated then animals are killed to prevent suffering.

NON-TECHNICAL SUMMARY

14. Biomechanics and development of cranial sutures in lagomorphs

Project duration

1 years 9 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rabbits	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to advance knowledge of the biomechanical role of cranial sutures (soft connective tissue joints between the skull bones) in overall skull function and development, by investigating how the patterns of cranial strain are influenced by the patency of sutures and suture-like joints.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Craniofacial sutures are unique joints found in the skull and are important sites for bone growth during development, and for absorption of mechanical stress. The primary benefit of this research is the generation of new knowledge on how cranial sutures transmit biomechanical forces (mechanobiology) within the vertebrate skull, and is fundamentally important to improve our understanding of how craniofacial sutures and skeletal muscles influence each other in developing skulls.

The major goal of this study is to measure and compare forces exerted on a skull to the strain imposed by these forces on cranial sutures across the development of young rabbits with normal skull morphology, and those with sutures which fuse prematurely. In the short-term, this will improve our understanding of the evolution and function of cranial sutures. This will be broadly useful to researchers studying evolution, biomechanics, and bone and muscle physiology and function.

The proposed research is also expected have long-term benefits for healthcare. Expected outcomes of this project include expanding our knowledge of suture development, and refining and improving techniques for biomechanical modelling of cranial sutures. This will provide benefits to the academic community through technological advances, and to clinicians who use orthopaedic devices to modulate sutural growth in patients with conditions such as craniosynostosis that affect suture development and patency.

What outputs do you think you will see at the end of this project?

The primary outputs of this research is the generation of new knowledge on the mechanobiology and development of cranial sutures, and suture-like joints. This will be disseminated through peer-reviewed publications (e.g. in broad multi-disciplinary journals like Royal Society Proceeding B) and at national and international conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

In the short-term, peer-reviewed publications and conference presentations will be used to disseminate the outcomes of this research. This will improve our understanding of the evolution and function of cranial sutures, and will be broadly useful to researchers studying evolution, biomechanics, and bone and muscle physiology and function.

The proposed research is also expected have long-term benefits for healthcare. Expected outcomes include expanding our knowledge of suture development, and refining and improving techniques for biomechanical modelling of cranial sutures. This will provide benefits to the academic community through technological advances, and to clinicians who use orthopaedic devices to modulate sutural growth in patients with conditions such as craniosynostosis that affect suture development and patency.

How will you maximise the outputs of your work?

This research involves collaborations with academics and clinicians (plastic surgeons) from both the UK and US. The research will be disseminated both locally and globally through publications and conferences, as well as reaching a broader network through social media, such as Twitter and blogs. These methods will enhance the reach of the publications as demonstrated with Altmetric and traditional metrics.

Species and numbers of animals expected to be used

- Rabbits: 40

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Rabbits will undergo minor surgery to implant rosette strain gauges across cranial sutures, and small radio-opaque beads implanted in the skull bones to measure the movement of bones (kinematics) during x-ray biplanar videography. After recovery from surgery, strain, muscle activity and kinematics, will be recorded during normal behaviours such as feeding during the course of one day. At the conclusion of this study, rabbits will be humanly killed with a schedule 1 method. These rabbits will then be used to collect muscles properties data through dissections, and CT scans to build finite element models.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The most likely source of adverse effects is stress after surgery, or during transportation to, and filming in, the biplanar x-ray facility. Complications and infection after surgical implantation of the gauges is possible, but not likely, due to the sterile setting of the surgical room, and the after-care drugs including analgesia and antibiotics (e.g., Baytril, ketofen, famataide and normal saline, or as advised by veterinary personnel). Rabbits will be habituated to the box that they go in for the x-ray bi-planar imaging to reduce the likelyhood of stress during transportation and data collection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Moderate severity will be expected for all rabbits because minor surgery is involved.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Replacement of animal models is not possible, as a major goal of this study is to determine bone strain and motion during natural behaviours. *Ex vivo* and *in silico* simulations of cadaver specimens can only indicate the range of motions that are physically possible based on joint shape, not the motions actually employed by a living animal, and can only estimate the physical strains experienced during simulated motions. Because humans suffer from craniosynostosis, it is essential to study organisms that have a similar etiology and phenotype. Studies of these rabbits with craniosynostosis could lead to preventing craniofacial growth disturbances and decrease postoperative morbidity in infants with premature suture fusion.

What was your strategy for searching for non-animal alternatives?

Non-animal models are not available.

Why were they not suitable?

The technology of virtual biomechanical models are not sophisticated enough to replace *in vivo* data, and cannot measure real motion or strain experienced by an animal during natural behaviours. These data require direct measurements taken from live animals. These data will be integrated with imaging and *in silico* biomechanical modelling for validation, as described in the project plan.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

No preliminary or prior data are available to
determine the number of animals required to
complete the study
. Judging sample size is difficult because this study does not test a statistical hypothesis, and only needs sufficient sample sizes to assess intraspecific variation in morphology and function.

It is unlikely that three (3) individuals will be sufficient to distinguish between intraspecific and interspecific variation in morphology between a group that varies so much due to the condition of craniosynostosis. Therefore, we have estimated that 10 animals from each group (Juveniles with craniosynostosis; juveniles without craniosynostosis; adults with craniosynostosis; adults without craniosynostosis) will be required to collect high quality data. This number also accounts for up to 20% potential losses of rabbits across the duration of this study. We will carry out a pilot study after three (3) rabbits are tested to see if the minimum number of animals can
be reduced, and again conduct an interim analysis after six (6) rabbits.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

No preliminary or prior data are available to
determine the number of animals required to
complete the study
. Data collection for multiple outputs (strain, muscle activation, bite force and kinematics) can be collected for each animal during the same experiment. This will reduce the number of animals we need, and make the subject specific biomechanical models more accurate with input data from the same individual. We will carry out an interim analysis after six (6) rabbits are tested to see if the minimum number of animals can
be reduced.

What other measures apart from good experimental design will you use to minimise numbers?

We will conduct a pilot study to measure strain, bite force and muscle activation in 3 adult rabbits.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Strain gauges are the only method to collect *in vivo* strain during function, and can also be used to validate the finite element models that will be used for future hypothesis testing without the use of animals. However, to know if these models accurately represent reality, the *in vivo* data is essential for validation. The x-ray based methods are currently the most precise and accurate techniques for measuring 3D, *in vivo* bone motion. The required surgery for these methods will be done using general anaesthesia and analgesia to minimise any pain or suffering.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rabbits experience naturally occurring familial craniosynostosis, where the cranial sutures fuse too early during development. Suture defects must be artificially created to investigate this question in any other species of mammal. Therefore, these rabbits are a better model for modelling the biomechanical effects of suture fusion than an animal with an artificially fused suture, and are the most similar non-human model to naturally occurring craniosynostosis in humans and require less surgical manipulation.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be monitored after surgery for post-operative care and pain management. If irritation is caused by the strain gauge wires, shorter, more insulated, and/or more flexible wires will be considered. Veterinary advice will be sought for any rabbit giving cause for concern and additional analgesia may be given if appropriate.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

No experimental data using these procedures on these species have been published. Similar data only exists in studies on rats. Therefore, these publications have been used for best practice guidance.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will continue to be involved in training programs and attend seminars. I will also enrol any PhD students and postdoctoral staff in the Personal Licence training who join the project, and supervise their

training in the protocols.

Explain the choice ofspecies and the related life stages

Craniosynostotic rabbits are the only existing colony (of any species) affected by familial craniosynostosis in the world. Suture defects must be artificially created to investigate this question in any other species of mammal. Therefore, rabbits are the most similar non-human model to naturally occurring craniosynostosis in other mammals and require less surgical manipulation. Because humans suffer from craniosynostosis, it is essential to study organisms (like these rabbits) that have a similar etiology and phenotype. Non-animal models are not available. Similar data only exists in studies on rats. Rabbits are much larger than rats and the biomechanics of their skull is likely more similar to a humans due to non-allometric characteristics of larger skulls and muscles. To measure the effects of suture fusion, we will collect strain over sutures during growth, as juveniles, and as adults when the skull has matured and the sutures have fused.

NON-TECHNICAL SUMMARY

15. Blocking senescence in ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, neonate, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To assess the importance of senescence in ageing phenotypes and to test the biological effects of preventing senescent cell accumulation on ageing amelioration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project is important to understand how and why ageing develops and what is the importance of the accumulation of old (senescent) cells in age-related pathologies (such as Alzheimer's, sarcopenia, heart failure or cancer). Also, we will study new therapeutic approaches to ameliorate ageing, based on the results obtained REDACTED, which identified several potential anti-senescent strategies.

We will use existing mouse models that recapitulate normal human ageing as well as in premature ageing syndromes, such as progeria. We may also use sublethal whole body irradiation as a known protocol to induce senescence in cells and thus accelerate tissue ageing. This will help understand the mechanisms responsible for normal and pathological ageing and their associated diseases, and could explain why some people age better that others and have longer lifespan. Our experiments will facilitate the design of new tools to study ageing and, eventually, to prolong lifespan/healthspan in humans.

What outputs do you think you will see at the end of this project?

We expect to determine whether nanoparticles can be used in vivo to eliminate senescent cells and thus ameliorate age-related pathologies. Also, we want to determine whether these nanoparticles could be used as diagnostic/prognostic tools in ageing. On the other hand, we expect to obtain information on other chemical compounds that can stop senescent cell accumulation in tissues and have an effect of mammalian lifespan/healthspan. This will lead to new publications and, potentially, provide the basis for clinical trials.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Studies of ageing in mouse models are indispensable and complementary to other research experiments. These models are important to understand how and why ageing develops in an organism and which is the impact of old cells in the development of age-related pathologies such as cancer. We

would like to use existing mouse models that will recapitulate what is observed during normal human ageing, as well as in premature ageing syndromes such as progeria. This will help us to understand the mechanisms responsible for normal and pathological ageing and their associated diseases and may help us to explain why some people develop age better that others and have longer lifespan.

The short-term benefits of our research will impact the community of scientists studying senescence ageing and age-related diseases, including the generation of new tools for senescence research. Also, the researchers working on this project will benefit by being trained in state of the art techniques and protocols by leading experts. A mid-term benefit will be that companies in the commercial private sector could engage in testing the approaches suggested by our research. This could foster the economic competitiveness of national enterprises and attract R&D investments from global business. In the long term, our experiments will facilitate the design of new therapeutic tools to improve ageing and/or prolong lifespan in humans. Thus, they would benefit geriatric patients suffering age-related diseases such as cataracts, diabetes, Alzheimer's, cancer, etc., as well as those having premature ageing syndromes. Many of the diseases have no cure and could greatly benefit from anti-senescent strategies. The therapeutic tools derived from the knowledge generated in this project could have an impact on globally enhancing quality of life in the future.

How will you maximise the outputs of your work?

We have several collaborations with scientists working on the field of senescence and ageing, as well as biotechnology companies. We will use their expertise to take our results forward and test any compounds in other models, in order to accelerate any translational applications. We will also focus on the public dissemination of our results, with publication of articles in specialist journals, presenting results in conferences, networking with focused groups and engaging a wider audience through activities aimed at the public dissemination of sience (such as open days and lecture series).

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be given drugs (by oral gavage, tail vein injection or other methods) and changes in lifespan/healthspan will be recorded by measuring a frailty index over their whole lifespan. Functional tests will be performed on some them to assess amelioration of specific age-related symptoms (e.g. Barnes maze to test spatial memory, Kondziella test to measure muscle strength, functional imaging for heart function, etc.) and blood samples may also be obtained.

Animals will be dosed starting after 2 months of life and kept in the protocol until the endpoints are achieved. A single animal will not be subjected to all the optional steps described above. Involvement of each animal in one or more optional steps will be carefully determined to minimize stress. Animals are likely to be involved in 2-3 of these steps maximum for most of the experiments.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

In most of the steps, no adverse effects are expected, except those associated with ageing. Many compounds and interventions to be used have already been tested in mice and shown to produce minimal side effects. Some agents may cause discomfort (e.g. local injection site reaction) when given repeatedly. The likelihood of such an event is extremely low. We are not anticipating the increased appearance of tumours in the mice used in these experiments due to their shortened average lifespans. Mice may develop reduced mobility as they age, accompanied of a general reduction in organ function (which can lead to dental disease, cornal opacity, dermatitis, lameness, seizures and other age-related symptoms) .

Although unlikely with the types of drugs used for the experiments described here, adverse effects (including death) should always be expected when using therapeutic approaches that have not been reported before. Thus, these new compounds will be tested in a small scale pilot study to determine toxicity and potential side effects before being used in the adequate steps.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild/moderate for all animals (likely to be 70% mild, 30% moderate).

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cell cultures cannot recapitulate the response of a full organism when it comes to ageing. We did preliminary tests on flies but, although genetically similar to humans in many aspects, they are evolutively too distant for experiments done on them to be conclusive in terms of human applications. Non-mammalian models, such as fish or C. elegans, have limited interest for advanced studies due to the huge differences in the ageing processes between these species and human. Thus, this is why

experiments in a mammalian model such are mice are necessary in order to bring these compounds to potential clinical trials.

What was your strategy for searching for non-animal alternatives?

All preliminary experiments to test the biological effects of the compounds to be tested in mice were done in mammalian cell cultures.

Why were they not suitable?

The relevance of cell culture models to assess organismal ageing is very limited.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We based this estimate on the mice used during the five years of the previous licence and the power calculations performed specifically for this project. In our previous work, we tested different drug concentrations of an anti-senescent drug and we will now use the dose that showed less side effects, thus reducing the number of animals needed for preliminary tests. We have used online tools (see below) to estimate the number of animals needed to achieve significance using ANOVA tests.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We used the advice of in-house experts and the following online tools:

https://www.statisticshowto.datasciencecentral.com/

http://www.quantitativeskills.com/sisa/calculations/samsize.htm

NC3Rs' Experimental Design Assistant

What other measures apart from good experimental design will you use to minimise numbers?

Breeding will be carefully controlled to avoid surplus animals. Data from previous studies will be used to determine the best drug concentrations and dosage schedules. When using new anti-ageing drugs, pilot studies will be performed first to determine the best doses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use normal and fast ageing mice. Fast ageing mice allow us to reduce the time the animals are kept in the study, but they do not represent physiological ageing. We will assess the lifespan/healthspan changes in the animals using a frailty score, such as the one described elswhere in this document. The animals will suffer no harm or distress, other than that associated with normal ageing (preliminary experiments show that the side effects of the compounds used are minimal) or potential unknown side effects when using new anti-ageing drugs (risk of suffering will be minimized by testing these drugs first in a small pilot study).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Although useful for preliminary studies (for instance, we first tested some of our drugs in flies), non-mammalian models are not adequate for pre-clinical studies of interventions in humans since they do not fully recapitulate human ageing phenotypes.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The animals will be checked constantly for distress as part of the frailty assessment (a test where we measure age-related parameters such as locomotion, hydration, muscle tone, etc.). Given the fact that distress signs are an essential part of the ageing phenotype, we will already be monitoring very carefully their apperance during the course of the study, due to the intrinsic experimental value of the data. Interventions will be immediate if any threshold is reached, thus minimizing the harm to the animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use the PREPARE and ARRIVE guidelines for planning and reporting experiments, as well as the LASA dosing and blood sampling guidance.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will be assisted by the staff of the animal facility, who will inform us of any changes. We will liaise with the REDACTED's NC3Rs Programme Manager during the project. Morever, the NIO circulates a Newsletter that incorporates up to date information from the NC3Rs website. Throughout the duration of the project, we will always look at advancing the 3Rs that we learn from the information received.

Explain the choice ofspecies and the related life stages

Mice are the most adequate and efficient model for the study of mammalian ageing. Mice will be studied over their whole lifespan.

Home Office

NON-TECHNICAL SUMMARY

16. Bone loss: why it occurs and ways to reverse it

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Bone loss frequently accompanies increasing age and disease states such as arthritis, diabetes and certain cancers. This project aims to prevent bone loss in these conditions and to identify new ways to replace bone once it has been lost.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Musculoskeletal diseases, involving muscles, bones, joints, tendons and ligaments, represent one of the greatest long term health care burdens worldwide. Osteoporosis causes more than 8.9 million fractures annually and 1 in 3 women over the age of 50 will experience osteoporotic fractures, as will 1 in 5 men aged over 50. Bone loss also occurs in arthritis, diabetes and in bone marrow cancers such as multiple myeloma. In these disorders, bone loss occurs faster than it can be accrued leading to complications of a weakened immune system, bone pain, deformity and susceptibility to fracture.

This project centers on ways to prevent bone loss and/or replace bone once it has been lost. There is a significant unmet clinical need for bone forming agents. We aim to understand how bone loss and growth is triggered with a view to applying this knowledge to develop new therapeutic strategies to treat some of the biggest issues for musculoskeletal health such as osteoporotic bone loss.

What outputs do you think you will see at the end of this project?

Autoimmune disorders affect up to 1% of the population and present an ongoing burden on clinical resources with joint destruction presenting the need for costly revision surgery in advanced cases. Anyklosing spondylitis has the added complication of developing inappropriate new bone formation as well as joint destruction and gut inflammation. Of even greater prevalence is osteoporosis and whilst therapies such as bisphosphonates have revolutionised its treatment, there remains the need to find ways to replace bone once it has been lost. Cancer-induced bone diseases such as multiple myeloma and metastasis to bone
have a very poor clinical prognosis and ways to increase lifespan and therapeutic interventions are vital.

This project has the potential to address a number of unmet clinical needs that despite recent advances continue to elude therapeutic intervention. Additionally the discovery of novel bone forming agents and how the body normally produces them, has the ability to provide the next generation of treatment for osteoporosis – one of the largest bone disorders affecting our ever ageing population. The

earlier we can treat patients with autoimmune and cancer associated bone diseases - the better the long term prognosis will be for the individual in terms of disability and mortality.

Work into a novel osteoclast inhibitor is underway and involves the repurposing of an existing drug. This speeds the time to clinic as it has existing safety profiles making the translation pre-clinical models to human trials much faster. It is envisaged that this will take 2-3 years.

Work into ways to alter the bone marrow microenvironment and to alter stem cell fate in favour of osteoblasts is similarly underway and we have candidate molecules that control the process. We need to determine what other factors interact and to design therapeutic agents to alter the process. This part of the project is likely to require the next 3-5 years.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short to medium term, this work will benefit scientists and clinicians in the musculoskeletal field by providing new insights into the mechanisms of action in inflammatory bone diseases and cancer-induced bone changes. The multiple myeloma model we are using has previously been used for new drug development as it faithfully recapitulates the clinical features of this disease. This is an important benefit as we move towards the prevention and/or early intervention in disease in the human population from the earliest signs of symptoms – this can only be achieved if we know the initiating events. All work will be published in peer reviewed articles, online commentary and via social media to ensure the broadest dissemination of results. There are implications for pharmaceutical and biotech companies for the re-purposing of drugs as new therapeutic options as well as the potential development of new in-house therapeutics.

The longer term implications of this work are an impact on clinical practise and potential therapeutic options. In western countries, autoimmune disorders have prevalence rates of 1% for RA and 0.25% for ankylosing spondylitis whilst the life-time risk of developing cancer is 1 in 3. These diseases are all long-term and cause early mortality. Many patients are unable to work, so the socioeconomic impact is high. One of the first line therapies to reduce inflammation is the administration of glucocorticoids yet depending on time and dose these may also be detrimental to bone.

Fragility fractures resulting from low bone mass in osteoporosis increase morbidity and mortality in adult populations worldwide. According to the National Osteoporosis Society more than 3 million people in the UK are estimated to have osteoporosis with 50 % of women and 20 % of men being affected over the age of 50. With estimated costs of £2.3 billion per annum in the UK alone osteoporosis represents an enormous burden to the health care system. With an ageing population in Europe and North America the incidence of osteoporosis and fragility fractures will increase rapidly in the future. By modulating the interplay of immune cells with bone forming cells, we aim to counteract bone destruction in osteoporosis.

Humans present with different bone related cancers that are exceptionally difficult to treat due to the location of the disease and the importance of protecting haematopoiesis. Our animal models that mimic bone cancer and cancer metastases to bone will reveal the underlying disease mechanisms and ultimately improve cancer therapy options.

How will you maximise the outputs of your work?

Via collaboration we will share our expertise in these in vivo models and their anaylsis of bone phenotype with the wider scientific community. Any new protocols or refinements will be published in the relevant Methods journal or within our scientific publications.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of mice will undergo injections with a small percentage of mice having a surgical procedure. The aim of this project is to investigate changes in bone and as bone is slow to change, this means that the duration of experiments ranges from days up to 20 weeks after the initiation of disease.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Adverse effects such as pain, weight loss, inflammation and bone marrow tumours will occur in this project. Transient pain will occur post surgery (for induction of osteoporosis) for 24-48 hours and will be treated with analgesia. Swelling and redness of joints will occur in the arthritis models and will be monitored to ensure that this does not result in altered behaviour (i.e. change in walking or climbing pattern, ability to feed). Any weight loss will be monitored twice weekly in the inflammatory arthritis model and in the bone cancers; the durations of these models are 1-6 weeks. The development of bone marrow tumours is a 3 week model that causes little observable impact on the daily activities of the mice however during the final 2-3 days the mice need to be observed daily for signs of problems with mobility.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity of all protocols is set at moderate however actual severity will be mild or sub-threshold in 50% of the mice.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project application has been compiled with due consideration of the 3R's: Reduction, Replacement and Refinement.
In the inflammation models
, the steps leading to the development of the state of chronic inflammation are poorly understood and it is likely that multiple physiological processes are involved, including proliferation of precursor cells, activation of lymphocytes and recruitment of inflammatory cells to the site of inflammation. Inflammation-induced bone disorders are not static diseases confined to a single tissue or time point and hence modelling the effects of new therapies inevitably involves the use of whole organisms and, in particular, the use of mouse models of inflammation. However, where possible, cells from patients will be used to address questions relating to the mechanisms of action of therapeutic targets.
For osteoporosis the high incidence of bone loss leading to fractures can be better simulated in vertebrate animals rather than tissue culture as bone represents a highly complex tissue in close contact with other tissues such as blood and mesenchyme. These associated tissues have been shown to strongly influence processes of bone homeostasis and repair thus the need to employ mouse models of osteoporosis. However, as we have shown previously, co-cultures of bone forming cells with immune cells are informative in terms of bone formation signals and we use such assays whenever possible.

For the cancer models
, there is no valid in vitro system for replacing the complex interactions between the immune system, cancer cells and bone in transplantation biology. Animal models for cancer development in bone constitute a major prerequisite for rapid bench-to-bedside translation of investigational anticancer therapies. Bone destruction following cancer cell invasion is induced by interaction of the cancer cells with bone and immune cells and is correlated with many complex processes such as angiogenesis, fibroblast migration and osteoclast activation which concertedly cannot be reproduced in vitro.
Likewise diabetes is a multi-organ, multi-cellular disease that is not able to be modelled in vitro especially given that certain aspects such as modifications in bone mineral density develop only in the later stages of the disease.

What was your strategy for searching for non-animal alternatives?

For the majority of our work we use in vitro tissue culture techniques to provide information about molecular and cellular mechanism(s) involved in the pathogenesis of disease or therapeutic effects. These cell culture assays will be used to assess potential therapeutic molecules in functional assays such as expression, activation, proliferation and cytotoxicity. Molecules shown to be inactive in these assays will not be examined further in vivo. This utilisation of in vitro assays is an important replacement of in vivo experiments.

Why were they not suitable?

There are limitations to the cellular complexity that can be achieved in in vitro cultures and hence the need to use in vivo models to investigate complex multi-organ disease states that vary in their presentation and cellular composition over time.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mouse numbers have been determined using power calculations to ascertain the minimum number of mice needed to obtain statistically significant results thus reducing the number of repeats and failed experiments.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

During design the number of animals has been determined by a combination of power calculations and knowledge of the disease penetrance in a given model. When establishing a new model or treatment pilot experiments are run to ensure that the disease is suitably mimicked and that disease severity limits are adhered to.

What other measures apart from good experimental design will you use to minimise numbers?

For the ankylosing spondylitis model, the penetrance is 80-90% in female mice and 50-60% in males – hence female mice will be used preferentially to reduce animal numbers.

Whenever possible the same mouse will be used as experimental and also as control individual. For example the LPS mediated calvarial local bone resorption model allows the use of the right calvarial parietal bone as control when subcutaneously injected with PBS, while the left parietal bone of the same calvaria when injected with low doses of LPS (<10mg/kg) can be used as experimental bone. Whenever possible, untreated control groups will be shared between treatment groups. In addition, untreated control groups will be used as a source of tissues for analysis of expression of pro-inflammatory mediators.

In the cancer model, animal numbers will be minimized by performing multiple assessments on the same animal and transplanting mice with in vivo visible cancer cells (i.e. luciferase) to evaluate the same animal at different time points rather than using several mice for different end points. Whenever possible the same mouse will be used as experimental and also as control individual. For example

unilateral intra-tibial transplantation of multiple myeloma cells allows following up the cancer-induced bone disease in the transplanted leg while the other leg may be sham transplanted with PBS and used as control. Further reduction in animal numbers can be achieved with dietary manipulation to ensure that all of the test animals develop disease.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Before introducing new drugs, chemicals or substances in the treatment regimen or experimental protocol we will conduct dose-response assessment and toxicology testing pilot experiments. Pilot experiments on a reduced number of mice are regularly employed by our group and, in our experience, proved to be crucial when choosing the source (accredited supplier/company) of new diet interventions (e.g. when testing high and low fat diets from different accredited suppliers we observed that one of low fat diet produced the unwanted side effect of weight loss).
For some protocols (e.g. ankylosing spondylitis (AS), bone cancers) where some pain may be experienced by the experimental animals, we plan to run a pilot experiment in order to establish the nature, dose and frequency of analgesic administration. In the first instance, Gabapentin will be administered in the drinking water to diseased and symptomatic mice at different concentrations (3, 10, 30 mg/kg). To date, Gabapentin is considered to be one of the best analgesics for neuropathic pain.

We have introduced a number of protocols aimed at testing specific disease features in an isolated site (airpouch, calvarial bone changes, phenotyping and ageing, dose and toxicity in naive mice; protocols 2, 3, 5 and 6) thus reducing the use of multiple interventions in diseased mice (AS, bone cancer, osteoporosis, diabetes) hence reducing the suffering of and lasting harm to the mice. By only using the disease models at an optimised dose/time, we will reduce the numbers of animals used and the degree of distress suffered.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Bone diseases primarily effect adult stages of life and the way that bone grows during embryogenesis and throughout adolescence is very different to that of the adult therefore this is the lifestage that needs to be investigated. To model human bone disease it is vital to have a vertebrate organism. Some bone work has been done in zebrafish however their immune system is not complementary and they do not develop inflammatory arthritis or osteoporosis. Additionally zebrafish exhibit properties of bone that humans do not share i.e. bone regrowth following amputation.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Experiments will, where possible be refined through the use of imaging technologies so that maximum information can be obtained from each animal used in a study.
In all protocols we will aim to utilise approaches that minimise the animal's potential suffering, i.e. effective analgesia, improved surgical technique and alternating drug dosing regime to reduce volume and frequency of administration. Analgesia will be provided following surgery in all cases.
In case of intra-tibial transplantation we will make every effort to minimise the length of the procedure to minimise anaesthesia time as well as giving analgesics to minimise pain. Analgesia pilots for disease pain are included in Protocols 4 and 8 (AS and bone cancer). If there is no response within 24 hours to the administration of analgesia, the animal will be sacrificed via a Schedule 1 method

.

For the administration of substances we will investigate less invasive ways to deliver these other than via a form of injection. For example, for the delivery of glycosphingolipid inhibitors in the cancer models we have previously investigated using the drinking water (with and without sucrose) as well as the addition of the compound to the food however both proved unreliable as a mode of delivery due to the bitter taste. As this compound requires daily delivery over an extended period (4-6 weeks), we run a pilot study to investigate delivery via mini-pump. We have previously used these pumps successfully for the delivery of PTH in mice. For the delivery of compounds via the intra-nasal (IN) route, we will perform pilot studies (3-4 mice) to ascertain any effects on the nasal passage. We will administer saline or glycosphingolipid inhibitor in a volume of 10ul daily for 1 week in the first instance and mice will be monitored daily for signs of irritation (i.e. pawing, sneezing, redness or discharge) prior to performing larger scale experiments.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Using the 3Rs website (www.nc3rs.org.uk) we will consult with the ARRIVE guidelines and other guidelines such as Responsibility in the use of animals in bioscience research.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will keep up with 3Rs advances by consultation with the NACWO and NVS, through regular visits to the 3Rs website and by receiving emails and newsletters. I will ensure that any advances or new strategies are communicated and discussed with my team via meetings, emails and provide details of recommended online resources.

Explain the choice of species and the related life stages

Mice are being used to model human disease; how it starts and ways to treat it. Mice will primarily be used as adults other than those mice in the breeding protocol. The aim is to find ways to reduce disease incidence and/or severity.

Home Office

NON-TECHNICAL SUMMARY

17. Brain plasticity with experience and recovery

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Plasticity, Learning, Stroke, Exercise, Experience

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand how experience can change brain structure and function. We will measure brain changes using brain scans (MRI), brain recordings and post-mortem microscopic measures. We will use the approaches to answer the following questions:

1. How does the brain change with experience?

The types of experience we will study include learning (e.g., learning a new movement skill), physical exercise, sleep and environmental enrichment. In addition, we will mimic changes in experience by directly stimulating brain activity using electrical or optical stimulation. We will test how these types of experience alter brain structure and function.

In some experiments we will test the role of specific genes in these brain changes by modulating genes in rodents. In some experiments we will test whether drugs can modulate the brain changes. These studies allow us to find out which biological mechanisms are responsible for the changes we observe.

The brain's capacity to change varies through the lifespan. Most of our experiments will be in juvenile and adult rodents but we will also study changes in early brain development, where the brain is particularly susceptible to change. We will not study ageing.

2. How does the brain change with recovery from injury?

Following brain damage, such as stroke, the undamaged parts of the brain adapt to enable some degree of recovery to take place. We will create an experimental stroke in rodents by applying a drug that constricts blood vessels in the brain and mimics some of the effects of stroke. We will measure changes in brain structure and function as rodents recover after this damage.

In some experiments we will test the role of specific genes in these brain changes by modulating genes in rodents. In some experiments we will test whether drugs, brain stimulation, or behavioural training can modulate the brain changes or improve recovery. These studies allow us to find out which biological mechanisms are responsible for the changes we observe and allow us to identify potential therapeutic approaches using combinations of drugs, brain stimuation or training. In our studies in humans we can test these approaches, where feasible, in people who have had a stroke.

3. What are we measuring with MR scans?

Brain scans are commonly used to study brain change in humans, but it is not possible to know which microscopic changes are causing any observed change in brain scan measures. By acquiring brain scan data, brain recordings, and microscopic information in the same animals, our project will allow us to test which microscopic changes underlie observed changes in brain scans. The results of this project will be used to inform studies in human volunteers. Specifically, the animal work will allow us to develop human MRI methods that provide information on microscopic changes that underlie the changes we can detect using MRI scans.

A retrospective assessment of these aims will be due by 17 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The major expected benefit is new scientific knowledge. We aim to answer these questions:

1. How does the brain change with experience?

In years 1-3 we will provide evidence on how learning, 'lifestyle' (eg sleep, physical activity), and stimulation alters brain structure and function. In years 3-5 we will find out how genetic and pharmacological manipulations modulate these effects and how these effects vary over the lifespan.

2. How does the brain change with recovery from injury?

In years 1-2 we will provide evidence on how the brain changes with recovery from damage. In years 3-5 we will test how this can be modulated by behavioural or drug manipulations. Answering these questions has potential clinical benefits as these discoveries can be translated into human trial after stroke. Some approaches (e.g., behavioural training or drugs that are already safely used in humans) could be translated into human trials within 5 years. Others (e.g. types of brain stimulation) would require time to translate into equivalent approaches for use in humans and would therefore develop over the next 10 years.

3. What is the biological basis of brain MRI signals?

Brain scans are commonly used to study people with brain disorders. However, brain scans typically give us indirect measures of microscopic features of the brain tissue. For example, they might tell us about water content, rather than the number of cells in a brain area. Our work will help to interpret brain scan information in terms of the underlying biology. During the 5 years of the project we will develop new methods for MRI scanning and analysis that will allow us to derive measures that relate more closely to the underlying biology.

The underlying biology is relevant to understanding clinically important questions such as how people recover after stroke. We therefore hope that the work will help to identify measures from brain scans that could be useful clinically, for example in guiding rehabilitation after stroke.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use up to 4250 rats and up to 7500 mice over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Behavioural testing

Some of the behavioural tests that we use require rodents to work for food rewards. For these test to work well the animals need to be hungry. We therefore limit their access to food prior to testing. This risks weight loss. We monitor weight carefully and supplement food if needed. If a rodents' weight remains low for a sustained period the the rodent is killed.

Some tests involve brief periods of swimming. This risks hypothermia and stress. We control water temperature and limit the time rodents are in the tank to minimise this. Each swimming period is limited to a maximum of 2 minutes for rats and 90 seconds for mice and animals are dried or provided with a heat source on being removed from the water. These steps normally minimise any adverse effects but we monitor recovery and if signs of hypothermia or stress persist for more than 2 hours after the test then the rodent is killed.

Some tests involve electric shocks being delivered to the rodents feet in order to test how well the animal can learn to avoid the shock. It can take a few days for the animal to learn how to avoid the shock (for example by pressing a particular lever) and during that initial learning period the animal experiences shocks that it cannot avoid.

Substance administration

Some rodents will recieve substances such as drugs. We use appropriate delivery methods to minimise this.

If injections are repeated this risks pain, distress and increased sensitivity. To minimise these we limit number and frequency and vary injection site. Animals exhibiting prolonged signs of suffering would be killed.

Gavage can lead to weight loss. We monitor weight carefully and supplement food if needed. If a rodents' weight remains low for a sustained period the the rodent is killed.

Use of minipumps very occasionally leads to inflammation around the pump. We will monitor carefully and intervene as required. Any rodent with persistent weight loss and malaise would be killed.

Some specific substances we use can cause adverse effects which will be carefully monitored. If rodents experience prolonged weight loss, persistent malaise, or prolonged unexpected change in behaviour they would be killed.

Surgery, recording and intracranial substance administration

Any surgery risks infection and pain. Analgesics and appropriate surgical procedures will be used to minimise this risk. Any rodent not fully recovered within 24 hours will be killed.

Brain surgery and/or use of implants carries small risks of haemorrhage, swelling, or infection during or after surgery. We will monitor closely and treat as required. If rodents have persistent weight loss or if interventions are not effective then they will be killed.

Sensory/optical/electrical stimulation and pharmacogenetic manipulations

These carry a small risk of seizures. Rodents will be monitored and stimulation or dose adjusted if needed and anticonvulsants given if needed. If seizure activity persists the rodent will be killed.

MRI scanning

Most MRI scans will be carired out under general anesthesia which carries small risk of anesthetic death. This risk will be minimised through monitoring and appropriate surgical procedures. If a rodent does not recover as expected and does not respond to interventions then it will be killed.

Some MRI scans require a contrast agent to be injected prior to the scan. This risks pain which will be minimised via analgesics and appropriate dosing. If a rodent shows persistent weight loss or does not respond to remedial interventions it will be killed.

Some MRI scans will be conducted with the rodent awake and performing a task. Typically, we would use liquid rewards to motivate the rodent to perform the task. This requires the rodent's access to water to be restricted prior to the test. This risk dehydration. We will use minimal water restriction required to motivate performance, will monitor the animals and will provide free access to water if a rodent shows persistent signs of dehydration beyond that needed for the task. If the rodent does not put on weight and recover in response then it would be killed.

Blood sampling

Occasionally we need to take a blood sample which risks blood loss. We limit volume taken and limit number and frequency of blood draws. If excessive blood loss cannot be controlled the rodent would be killed.

Stroke model

We will use inject a vasoconstrictor into the brain to mimic some of the effects of stroke. This will be expected to lead to behavioural impairments which will vary depending on the site of the lesion. For example, if we target the motor cortex we expet to see movement problems. Partial recovery is expected but many animals will have permanent deficits as a result of the lesion. We expect animals to recover suffiicently to be able to feed and groom themselves. If rodents experience persistent weight loss or fail to respond to interventions and are unable to look after themselves then they would be killed.

There is a small risk of unexpected cerebral swelling or bleeding. If a rodent shows persistent signs of this it would be killed.

There is a small risk of seizures immediately after surgery which would be treated appropriately. If seizures persist and do not respond to treatment then the rodent would be killed.

The general risks for surgery given above are also relevant here.

Experiments with pups

Some of our experiments aim to study the developing brain and so we will investigate rodents from birth. Studying the first days to weeks after birth is important as this allows us to understand how the brain develops. There is a risk that pups that have been taken away from their mother (e.g. for an experimental procedure to be performed) will be rejected by the dam when returned to the home cage. To minimise this risk we ensure that experimenters handing pups first rub their gloved hands in used nesting material to ensure that the pups continue to smell like the home cage. Also we ensure that pups are active and have returned to their normal colour before being returned to the dam. In our previous experience this approach significantly reduces the risk that the dam will reject the pup.

Use of neuromuscular blockers

Functional MRI (FMRI) scans are very sensitive to movement of the animal being scanned. If the animal moves then data may not be usable. Therefore, to minimise movement we use neuromuscular blockers in some experiments using FMRI. Experimenters using this approach will have been specially trained in the use of neuromuscular blockers. Animals undergoing this procedure will be very carefully monitored and anaesthetic will be delivered along with the neuromuscular blocker.

Enforced fluid and food restriction

Animals that undergo enforced fluid or food restriction may experience weight loss. Any animal who drops below 85% of their lean starting body weight for a period of 24 hours will be given additional food or water. If weight gain does not occur within 72 hours, the rodent will be killed. Any animal dropping below 80% of their lean starting body weight will be killed.

A retrospective assessment of these predicted harms will be due by 17 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The majority of our research is conducted in human volunteers, including individuals who have had a stroke. We use brain scans to study how the brain changes with learning, experience, or recovery from stroke. However, in order to test how brain structure changes at a microscopic level, and to relate this to brain imaging measures, it is it necessary to do experiments in which brain scans can be taken in animals that can then be killed to perform histological measurements. This is not ethical (or practical) in humans. Computer simulations of the brain actually rely on the information that we will provide and so cannot replace the work that we do.

A retrospective assessment of replacement will be due by 17 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

We seek to reduce the number of animals use through:

1. MRI scanning

Our primary focus is brain change, which requires us to measure how the brain changes over time. MRI can be used to scan the same live rodent over time. This uses far fewer animals that would be required for methods that are performed post mortem.

MRI also provides measures from across the whole brain at once, whereas many other techniques focus on a single brain region and so if multiple regions are to be studied this requires many more animals.

MRI provides measures of both brain structure and brain funciton which can be easily acquired from the same rodent in a single scanning session. Most other methods either assess funciton (e.g., electrophysiology) or structure (e.g,. histology).

2. Sensitive behavioural tests

We use very carefully designed and sensitive tests that can pick up subtle changes in behaviour. This reduces the number of animals needed to find a meaningful effect.

3. Training

Our researchers are highly trained to perform tests accurately and consistently in order that they can produce reliable measurements which again reduces the number of animals needed to detect an effect.

4. Pilot studies

We first use pilot studies with small numbers of animals to refine interventions, validate measures, trial drug doses so that minimal doses can be used, and pilot surgeries (eg under terminal anesthesia). This means that our approaches are as refined as possible, and are more likely to work, when we embark on full scale studies.

5. Efficient breeding

We use experienced staff to ensure our breeding strategies are optimal in minimising animal numbers.

6. Experimental design and statistics

We use appropriate experimental design methods, such as randomisation and blinding, to ensure our conclusions will be robust. We use control groups so that we can rule out alternative explanations for our effects (eg the brain might change over time due to development rather than due to our experimental intervention). We perform power calculations so we can ensure we use enough animals so that our results will be meaningful.

A retrospective assessment of reduction will be due by 17 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We work on rats and mice because they are the lowest vertebrate group which reasonably resembles humans.

We use strict limits on what each animal can experience, limiting the number and duration of test and imposing minimal rest time between tests for example.

Many of our experiments use MRI brain scans. MRI is a non-invasive method that is also used in humans. In most of our experiments rodents will be scanned under general anesthesia and will be carefully monitored to ensure appropriate levels of anesthetic are provided. For some MRI experiments we will scan animals while they are awake and in some studies the animals will peform a behavioural task while they are in the scanner. The animals are extensively trained beforehand so that they gradually get used to the experience of being in the scanner.

Many of our expeirments involve behavioural tests. Where possible we use spontaneous behaviours that the animals would perform naturally, such as exploring a new environment. Some tests involve the animals working to receive a food or water reward. In order for these tests to be useful the animals have to be slighly hungry or thirsty so that they are motivated to work. We carefully monitor the animals to ensure that the right level of diet restriction is used.

Some of our tests involve experiences that can be stressful to the animals, such as swimming or experiencing a brief shock to the foot. These tests are only used when there is no suitable alternative to assess the cognitive process of interest. For swimming tests we limit the amount of time the animal does the test and monitor water temperature to reduce discomfort. For footshocks we limit the amount and frequency of shocks and monitor carefully. Some of our tests involve exercise. Rodents can be made to run on a treadmill using shocks. We will use other methods of encouraging running by using obstacles. If animals are experiencing any aversive tests then we will limit the other tests that they undergo.

Some of our studies involve sleep deprivation. We will achieve this by observing animals and providing novel objects or sounds when they start to sleep.

Where possible, animals will be housed in groups. Some studies require us to house animals individually - for example so that we can monitor the activity, sleep or diet of an individual. Methods are being developed that allow for individual monitoring using technology such as remote tagging. We will aim to use these methods wherever possible.

Operations on the brain are done very carefully using aseptic techniques and in state-of-the-art surgical theatres, and the animals are given pain killers after the operations until they have fully recovered. Soon after most of the operations you would not be able to tell the difference between treated animals and controls as they behave in their home cages. It is only on the sophisticated tests of learning and memory that you can begin to tell themapart.

Some experiments involve mimicing the effects of stroke. There are many different ways in which stroke can be mimiced in animals. We will use a method in which we inject a substance into the brain that contricts blood vessels in the injected area. This typically causes less extensive damage than other approaches and can be more carefully controlled. It allows us to test effect of focal damage. Depending on where the injection is made, some symptoms would be expected. For example, if the injection is made in the motor cortex then we expect to see movement difficulties with limbs on the opposite side of the body. These deficits are expected to partially recover over time but in some animals they will not return to normal. We expect all animals to recover sufficiently well to feed and groom themselves and if they do not then they would be culled.

Some experiments involve delivery of a drug. There are different ways to deliver drugs (eg via injection or in food). We would chose the most appropriate method to minimise discomfort. Sometimes substances are delivered directly into the brain. Methods for doing this will be carefully controlled to minimise adverse effects.

A retrospective assessment of refinement will be due by 17 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

18. Breeding and Cryopreserving Genetically Altered Mice

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project will use assisted reproduction techniques that are has been designed to provide an efficient service for freezing germ cells (oocytes/embryos/sperm/ovarian tissue) and the recovery of genetically altered strains of mice. The recovery services will extend to rescuing colonies that fail to breed, in vitro allele conversion and re-establishing inbred strains as part of a genetic stability breeding programme. Following recovery, the mice will be transferred to other projects that have been set up to investigate various aspects of mammalian biology.

The majority of the mouse strains will be archived by freezing oocytes, embryos or sperm and following a specific request, embryo transfer techniques, usually in conjunction with IVF will be used to recover live mice.

Occasionally ovarian tissue will be frozen down in order to preserve a unique mouse strain. This will be limited to those occasions when it is not possible to freeze oocytes, embryos or sperm because only a small number of females exist that carry the genetic modification of interest and further breeding is not possible. On these occasions it will only be possible to recover the mouse strain using ovary transfer techniques.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By providing a central service we are able to invest in the most up to date equipment/techniques which can be used to freeze/recover mouse strains on behalf of the wider scientific community. By employing highly trained staff who can maintain their proficiency in cryopreservation and recovery techniques we are able to provide an efficient service. In doing so we will help reduce animal numbers and ensure only the most refined procedures are used, thus minimising the animal welfare implications of the type of work we do.

Access to central freezing services enables investigators to preserve the unique REDACTED they have generated for future generations of scientists. This in turn facilitates resources sharing and eliminates the need to remake mouse models that have been frozen down.

What outputs do you think you will see at the end of this project?

This project will facilitate sharing unique mouse models of human disease throughout the scientific community, as well as, freezing down their embryos and sperm for future generations of scientists. We will expand and maintain a large archive of mouse strains to safeguard lines for the future. The sharing of quality controlled genetic models should increase the reproducibility of studies as initial mouse stocks will be identical.

Through this sharing process will enable scientific collaborations to be established around the world in the pursuit of better understanding of gene function and the causes of human disease.

We will publish reports in the scientific literature, where we have developed new techniques or a better procedures for exchanging mice or frozen materials. Working on a previous licences we have developed techniques that facilitate the exchange of unfrozen embryos and sperm, as well as, the exchange of frozen sperm on dry ice. Each of these techniques offers a viable alternative to exchanging live mice. In addition, we have improved IVF and sperm freezing procedures making these techniques more efficient and robust which has reduced the number of animals used in these procedures. These improvements have been publish in the scientific literature, presented on open websites e.g. www.infrafrontier.eu and taught on training courses that we host.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

By sharing these unique mouse models we will eliminate the need to recreate the same mouse strain. In doing so, we will eliminate the additional animal and laboratory costs associated with re-making genetically altered mice.

For those REDACTED we have generated, we have applied robust molecular methods to fully validate the modified alleles and to control the background strains. Therefore, we can disseminate validated models and the recipients can be confident in the knowledge that they are working on the correct genetics. For those strains we recruit into the public archive from other establishments we gather as much of this information as possible and share it with the community.

By sharing gold standard mouse strains from a well managed and securely funded embryo bank we ensure that collaborating scientists work on identical mice. This in turn aids the comparison of results between laboratories and helps to improve the reproducibility of biomedical data.

Researchers around the globe will have access to high quality REDACTED allowing study of diseases and/or furthering biological and medical knowledge.

By archiving REDACTED that are no longer part of ongoing research projects we can reduce the number of mice being bred. We also eliminate the need to recreate mice that can be quickly withdrawn from the archive.

How will you maximise the outputs of your work?

To maximise the impact of what we do, all the mouse strains that we freeze down on behalf of the scientific community will be presented on our institutional website and a public website (www.infrafrontier.eu) managed by the European Mouse Mutant Archive (EMMA). We also promote our services as widely as possible through information leaflets, workshops, presentations and conference proceedings. The EMMA website is also used to present details of the techniques we use so the other institutions can take advantage of our leading practice.

Working in conjunction with colleagues within the EMMA consortium, we also make a significant contribution to a programme of technical development and publish our findings in technical papers and as standard operating procedures on the EMMA website.

Species and numbers of animals expected to be used

- Mice: 118,250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Some animals used on in this project may be bred in order to establish colonies of animals for further work. Other mice will be injected with hormones to induced superovulation for egg or embryo harvesting. Yet other mice may undergo an operation to allow embryos to be transferred into recipient females who will give birth. These progeny will be given to the investigator who has requested a particular strain of mice.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals may be group housed or paired, mated and subject to such other non-painful procedures required for conventional breeding. Female mice may be examined for the presence of a copulation plug and culled at a specific time point in embryo development.

There are a variety of possible impacts due to the genetic modifications carried by the mice bred under this licence. Moreover, in a number of cases we will be breeding the genetically altered mice for the first time and we may not be able to predict these effects.

When tissue is required for DNA genotyping, the mildest appropriate method of sampling will be used for obtaining the tissue e.g. ear notching. Rarely due to a technical problem in analysis or the need to genotype at other genetic loci, a second sample may be taken.

Complications due to surgery are rare although wounds may need re-closing. If this is required it will be done under general anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity of the protocols used under this licence will vary between **Mild** and **Moderate.** It is expected that less than 20% of the mice used on this licence will be put on a protocol with a moderate severity limit.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This is a service licence specifically designed to cryopreserve the germ cells (embryos/sperm/ovaries) of genetically altered mouse strains generated by the scientific community so they are preserved for future generations or shared between laboratories without transporting live mice.

What was your strategy for searching for non-animal alternatives?

Because this is a service licence specifically designed to cryopreserve genetically altered mouse strains generated by the scientific community there are no alternatives to the use of mice for this project.

Why were they not suitable?

Because this is a service licence specifically designed to cryopreserve genetically altered mouse strains generated by the scientific community there are no alternatives to the use of mice for this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This application is for a licence renewal and the numbers applied for in this licence reflect the number of mice used over the previous 4.5 years along with estimates of the work we anticipate completing during the life time of this project. These figures can only be estimates based on the expected demand for the services provided under this licence. However, due to the changes in the scope of this licence the number are substantially reduced.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We use a limited suite of proven techniques to achieve the objectives of this licence. Our service has been established in order to cryopreserve mouse strains for the long term and ensure we are in a position to distribute the stocks to multiple users. This dictates that we use 4 to 5 males for sperm freezing; 2 to 8 female mice when transferring embryos (depending on the experimental need); 3 to 6 females for an IVF sperm quality control test and 6 to 15 females for an IVF recovery (depending on the experimental need).

Estimated recovery numbers are calculated based on the number of pups needed for the next stage of the project, taking into account Mendelian inheritance.

The procedural work we conduct under this project licence is conducted as a service to other scientific investigators, rather than defined experimental work in its own right and as such it is not appropriate to follow randomisation and blinding protocols.

What other measures apart from good experimental design will you use to minimise numbers?

We ensure we use the minimum number of mice compatible with the work we are doing by ensuring all reagents are vigorously quality control tested and the laboratory staff are highly trained.

We only use the most advanced techniques compatible with our work and continually review our procedures in accordance with developments in the field. In addition, where it is appropriate to do so, we use the embryo recipient females as sentinel animals in our health screening programme rather than breed additional mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project uses the mouse as an experimental model for every aspect it covers. The mouse is used exclusively because this project has been set up to freeze down and store male and female germ cells from animals that carry unique variations in their genes. The mouse is used for this work because it is the lowest order of mammal that can have its genes manipulated with the precision and complexity available using modern molecular biology tools like CRISPR/Cas9.

The methods used in this project are all well establish and well understood laboratory techniques. We will inject mice with similar hormones to those used in human IVF clinics to induce superovulation. The eggs we harvest will be used for in vitro fertilisation sessions that have been set up to generate fertile

embryos for transfers into recipient females or for freezing down. The embryo transfer techniques we use are, again, very similar to those found in human IVF clinics and are performed to the LASA guidelines for aseptic procedures (LASA 2017 - Guiding Principles for Preparing for and Undertaking Aseptic Surgery). When surgery is performed the operation is conducted under general anaesthesia and pain relief is given via injectable analgesics.

Sperm will also be frozen down for use by future generation of scientists.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The licence has been prepared specifically to freeze down and recover genetically altered mouse strains for future generations of scientists. The mouse strains will have been generated as part of research into the function of genes or the causes of disease. Consequently there is no alternative to using mice for this project.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

This project uses a limited number of well established procedures. Breeding is strictly controlled so we do not produce any more mice than is necessary the work we want to perform.

We use known information to assess the potential welfare costs of the mice that we breed and the welfare of individual mice is followed on daily assessment sheets when it is appropriate i.e. sick animals.

Hormones are administered by injection which is considered to only cause momentary discomfort. To minimise discomfort during injections, we have a single use needle policy which means the needles will remain sharp. To minimise bruising, we also alternate the injection site when giving multiple injections.

We are hoping to develop a technique that will make the hormone preparations more efficient. This will lead to a reduction in the number of mice we need for our work.

We have developed an improved non-surgical embryo transfer technique that can entirely replace the need for abdominal surgery when handling late stage embryos. To complement this work, we are hoping to improve the embryo culture environment to allow earlier stage embryos to be transferred using the same procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

To ensure our work is conducted to the highest standards and can be reproduced by other scientists we follow, and act on the PREPARE and ARRIVE guidelines. We also have access to statisticians who can advise on the appropriate experimental design and analysis techniques.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed by reviewing the literature, attending scientific meetings and talking with colleagues in the field.

We have introduced several procedural changes that have been taken up by others in the field e.g. improved sperm freezing and IVF techniques. As keen supporters of the 3Rs we have successfully submitted two grant proposals to the NC3Rs. The first proposal looked at improvements to the standard embryo culture conditions that we hope will improve efficiency and reduce the number of mice needed to generate the embryos we need. The second proposal was designed to improve the efficiency of the superovulation injections we give. Again, the aim was to reduce the number of mice we need for our work.

Explain the choice ofspecies and the related life stages

This is a service licence designed to rederive and freeze down and distribute genetically altered mice generated by the scientific community. As such it is not possible to use any other species than the mouse for this work. To freeze down mouse strains for future generations of scientists it is necessary to harvest embryos and sperm from adult animals so the embryos and sperm we obtain are able to survive the freezing process.

NON-TECHNICAL SUMMARY

19. Breeding and Maintenance of Gal-deficient Swine

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Animal tissue commonly produces high levels of a carbohydrate antigen called Gal (galactose alpha 1,3 galactose) which is not present in humans. Since humans do not make this carbohydrate they produce anti-Gal antibody, much like occurs in the case of blood group antigens. The research group has shown that Gal is present in commercial porcine and bovine derived biological heart valves (BHVs) and that human antibody binding to Gal accelerates tissue calcification. Antibody induced calcification does not occur using Gal-free tissue from GT-knockout pigs (GTKO). This project is designed to maintain a breeding colony of GTKO pigs to produce tissues for *in vitro* research which aims to establish the basic physical and biological equivalence of GTKO compared to commercial porcine and bovine derived tissue. This will lead to a more fundamental understanding of the process of tissue calcification and the role of antibody in that process. The Gal-deficient GTKO pigs represent a unique resource which forms the core technology needed for the development of Gal-free bioprosthetic devices.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The primary benefit of this PPL is that it provides tissues and materials to researchers developing new therapies for cardiovascular disease. These new technologies are trying to improve the performance of replacement biological heart valves (BHVs), especially in patients under 60 years of age. This is experimental work but if successful the new valves will broaden the available therapies to treat younger patients, giving them a durable device which will not require lifetime anticoagulation medication and thereby avoids the serious thrombo-embolic risks associated with anticoagulation. This would have a major impact in developing nations with endemic levels of rheumatic fever a major cause of heart valve dysfunction, where the resources to manage patients on anticoagulation are limited and therefore the treatment of young patients may not be optimal or in many cases is not available at all.

What outputs do you think you will see at the end of this project?

This project will supply us with GTKO pericardial tissue to support the production of GTKO pericardial biological heart valves for use in ongoing and future *in vivo* studies in juvenile sheep. These studies are designed to compare the biological equivalence of GTKO pericardial biological heart valves to pericardial biological heart valves made with normal (wild-type) tissue. This is necessary to demonstrate to that the mutation in the alpha-galactosyltransferase gene does not compromise the GTKO pericardium in some unexpected way.

This project will also supply tissue for *in vitro* durability testing of our GTKO pericardial biological heart valves and future *in vivo* comparison in juvenile sheep of our GTKO pericardial biological heart valve with commercially available biological heart valves.

If all of these tests are successful, we will be poised to begin producing our GTKO pericardial heart valve under Good Manufacturing Conditions (GMP) with the aim of gaining regulatory approval to start human clinical trials.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This is an experimental program developing a new GTKO heart valve. If the program is successful, showing physical and biological equivalence of wild type and GTKO tissues/valves, high GTKO valve durability (greater than 200 million cycles) and equal in vivo performance compared to existing commercial devices, we will be positioned to begin GMP production of this heart valve which might then be used in a first in man trial.

These valves, because of their lack of the Gal antigen, are expected to resist anti-Gal antibody induced calcification and have improved durability in all age groups but would be most beneficial to younger patients

How will you maximise the outputs of your work?

The results of this work will be published in high quality peer reviewed journals.

Species and numbers of animals expected to be used

- Pigs: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Genetically altered pigs with no expected harmful phenotype will be bred under this project. Each animal will be genotyped following collection of DNA by mouth swabbing or blood sampling. Selected pigs will be maintained to maturity for breeding purposes.

All animals are reared to at least 180 day and humanely killed for tissue harvest.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Pigs bred under this protocol are not expected to show any harmful observable difference in appearance, development, and/or behavior due to their genetic modification.

All pigs will be housed and reared and bred as per standard practices for a normal pig colony.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild 100%

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Tissue samples obtained from Gal-deficient GTKO pigs are required for laboratory purposes to understand the impacts of using Gal-deficient porcine materials in bioprosthetic devices and to support development of a new GTKO pericardial biological heart valves.

What was your strategy for searching for non-animal alternatives?

There are no other alternatives.

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers will be adapted as necessary to satisfy the tissue quantity required for bio-prosthetic heart valve manufacture, and/or biological testing. The estimated animal number is based on the predicted amount of tissue required over the next 5 years.

Typically a breeding colony of 5-6 is maintained, increasing to a maximum of 15 if tissue demand increases.

Animals will only be mated to maintain the health of the line and to satisfy the requirements for provision of basic materials for in vitro analysis.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Animals will only be mated to maintain the health of the breeding stock and to satisfy the requirements for provision of basic materials for in vitro analysis. Care will be taken to ensure the minimum number of animals is produced.

What other measures apart from good experimental design will you use to minimise numbers?

The scale of breeding is matched to the requirements for tissue and maintaining at the minimum breeding stock to maintain the health of the colony (typically 5 animals).

The few excess GTKO animals not used for tissue donation are used to replace breeding stock.

The animals used in this project are used for non-invasive training and teaching purposes and tissues from wild-type animals are available to other groups under our cadaver sharing policy.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Standard porcine husbandry practices are used.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The material demands for producing replacement heart valves (e.g. the necessary size of the tissue) requires us to use an animal of substantial size. This would exclude smaller mammals, mice or rats, with the GGTA-1 mutation. Swine currently are the source of many biomedical materials and are appropriately sized matched for humans. Bovine strains with GGTA-1 mutations have been reported and bovine pericardium is widely used to make bioprosthetic heart valves. Due to their large body size and small litter size cows require far greater resources and time for genetic modification compared to pig and would likely be a more expensive source of GTKO materials for our work. There is no experience using tissues from non-mammalian sources (birds, fish, or reptiles) for making BHVs and these animals, while less sentient, would likely be wild caught, in limited supply and maybe under protected status.

GTKO tissue is typically sourced from pigs over 180 days old to ensure enough tissue is available to produce the bioprosthetic devices.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animal staff monitor pigs throughout the night at farrowing to ensure any complications are detected early and where necessary assistance provided according to standard veterinary practice.

Freedom farrowing crates, which allow the sow a greater degree of movement during farrowing and prior to weaning are being tested as an alternative to standard farrowing crates. Pigs are weaned at 4 weeks to minimise the time that the sow is restricted in movement, whilst ensuring the welfare of the piglets.

Buccal swabs are collected as the most refined way to genotype the pigs, this is a refinement that has been implemented over the REDACTED to replace tail tipping. Blood sampling remains as a back-up as buccal swabbing larger pigs can be stressful as restraint is more difficult. In the REDACTED only buccal swabbing was actually used.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office Code of Practice

DEFRA Welfare Codes for Pigs

How will you ensure you continue to use the most refined methods during the lifetime of this project?

NC3R website will be used as a source of information of advances in 3Rs, as well as review of the regular updates received from the designated establishment. Any advance considered appropriate in this PPL will be incorporated where possible.

Explain the choice of species and the related life stages

Tissue samples obtained from Gal-deficient GTKO pigs are required for laboratory purposes to understand the impact of using Gal-deficient porcine materials in bio-prosthetic devices and to support development of a new GTKO pericardial biological heart valve.

Tissues are harvested post-mortem from pigs, greater than 180 days of age, to provide sufficient pericardial material for valve manufacture.

Adult pigs will be used for breeding purposes to maintain the colony and supply of tissue.

Home Office

NON-TECHNICAL SUMMARY

20. Breeding and maintenance of genetically altered or mutant animals

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To provide and maintain breeding colonies of genetically modified or naturally occuring mutant strains of animals of scientific interest, whose offspring will be used for specific research roles under other project licences or to provide organs/tissues for *ex vivo* research requirements.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The use of genetically modified animals allows for specific gene traits to be studied in a complex physiological environment.

Some naturally occuring mutant strains of animals have incidences of genetic disorders or conditions (e.g. hypertension) for which breeding and maintaining these strains allows their study in a complete physiological environment.

These types of study cannot be achieved by *in vitro* methods alone.

What outputs do you think you will see at the end of this project?

The prime output from this licence will be that animals required for both *in vivo* and *in vitro* research projects will have been provided in the most effective and controlled way achievable for the intended requirements, with good control on reduction and refinement in terms of animals bred and used.

In a wider context outputs of better understanding of complex biological/physiological systems would result from the research these animals have been bred for. Publication and open access to research and new information resulting from the breeding of these animals will be available after the end of this period.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

People and animals with the conditions being investigated in research for which these animals are bred, would potentially benefit from better understanding of the respective conditions, from better diagnosis, earlier and better treatment of such disease conditions. Breeding animals under this licence will provide researchers with good quality animals for their research, enabling better reproducibility.

Controlled breeding under this licence will bring 3R's benefits, in reducing the number of animals produced, identify other research uses and reduce potential wastage. The nature of basic research is that some of the animals bred which then transfer to specific research project licences, will not realise full benefits until after a 5 to 10 year timeframe.

How will you maximise the outputs of your work?

Through sharing and making excess animals bred, or the tissues/organs from them, available for other research purposes, maximum use can be made and animal breeding minimised at the Establishment.

Through information dissemination within the Establishment via research management communications, AWERB, NIO communications, and meetings/seminars involving *in vivo* research groups, researchers are informed of animal resources available and encouraged to use existing bred stock wherever this may be possible. Management group at the Establishment discuss all animal requirements with researchers and attempt to supply requirements from already existing resources, to keep animal production to the minimum possible.

Communications between Registered Establishments, communication via AWERB Regional Hubs, allows sharing of any excess capacity from animal breeding, and provide potential to avoid duplication of breeding some genetically altered lines, that can more efficiently be shared between researchers at more than one Establishment.

Species and numbers of animals expected to be used

- Mice: 5750
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Under this licence animals will only be bred to maintain the mutant or genetically modified status of each line or strain. Offspring from the breeding will be transferred to other project licences for *in vivo* research or to provide suitable tissues/organs required for *in vitro* research projects.

Some but not all animals may have a small 'ear notch' of tissue removed for purposes of genotyping and/or identification purposes.

Some female rats may have vaginal swabs taken to determine the stage of oestrous, where this is important to know for research use of the animals, whether transfer to another project licence authority,

or for Schedule 1 tissue collections.

Some rats may have blood pressure measurements taken using a standard tail cuff (non invasive) method on several occasions each. This may be for selection of future breeding stock or for possible transfer to another project licence authority, or for Schedule 1 tissue collections.

Rats and mice used for breeding will not be maintained after they have reached a maximum age of 15 months or in the case of breeding females will not be allowed to produce more than 6 litters. Animals bred but not transferred for use under another project licence authority will not be allowed to exceed 15 months of age.

All animals will be humanely killed using a schedule 1 method.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The majority of animals to be bred under this licence will expect to be classified as 'sub-threshold' in relation to the adverse effects experienced. Occasionally a strain of animals with a natural mutation or being genetically altered, may develop symptoms of a disease condition, such as heart defect or co-ordination difficulties, as they reach certain ages. Depending upon the condition and experience, such animals are subject to additional health checks by the animal technicians and the Named Veterinary Surgeon (NVS). Should any reach an asesssment of 'moderate' severity threshold which may be reasonably expected to progress further, they are humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Based on previous experience and knowledge of the strains used in these areas of research, more than 97% of all animals to be bred under this licence would be expected to have a severity classification of either sub-threshold or mild. Less than 3% may reach a classification of moderate at which time they are humanely euthanised, should there be concern that they may become either severe severity threshold or being of prolonged duration.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand the effects of a modified gene or gene elements, requires subsequent examination of gene activity in a complex physiological environment, which is not fully possible using just *in vitro* techniques. Therefore observations based on live animals or complete organ systems is necessary.

What was your strategy for searching for non-animal alternatives?

For each research project, ethical review always seeks to identify non animal methods. Where these are not possible and whole body systems are required, then it is necessary to purpose breed such animals in a controlled and managed approach, as is the intention and need for this licence.

Why were they not suitable?

Whole body/organ systems are necessary to understand complex gene interactions. Currently to provide these live animal systems, it is necessary to breed the genetically modified and naturally occuring mutant animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers are based on experience from previous requirements and knowledge of the various research programmes either currently being undertaken by the Establishment, or are being proposed as future research areas within the Establishment.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The animals are closely monitored to ensure that a genetic line can be perpetuated for ongoing research requirements (continuity of research), such that a genetic line is not 'lost' due to poor breeder selection or other issues that prevent subsequent generations from being produced. This has to be closely balanced with avoiding excessive breeding, which would result in significantly larger numbers of animals which may not otherwise be required for research programmes.

For each individual line maintained for a researcher, a 'colony directive' is developed, and regularly assessed by the NACWO with each researcher, to ensure breeding numbers are minimised and periods for which additional breeding to produce research stock are planned for, with specific numbers to be bred.

If a line is known to be no longer required for a period of greater than 12 months, and if not already 'cryopreserved', this option will be investigated. Alternatively if same line is available at another Establishment, the line will no longer be bred at this Establishment but re-acquired if needed in the future from such sources.

What other measures apart from good experimental design will you use to minimise numbers?

Having animal breeding under the control of this 'service breeding licence' and managed by animal technicians within the establishment, is an excellent way of achieving these aims. Consulatation with researchers is an ongoing process, to ascertain numbers of animals required at specific time periods. Breeding directives (detailed breeding colony management documents) are established and routinely monitored to ensure the above situation is maintained.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Genetically modified or naturally occurring mutant lines of mice and rats are proposed as the species to be bred under this licence and which will be used within a range of research projects aimed at understanding various medical conditions. These animals will either be transferred to the jurisdiction of other specific licences for *in vivo* projects, or will be used for tissue and organ supply for *in vitro* projects, following humane euthanasia and tissue/organ collection.

Best husbandry and breeding management along with regular observation by trained animal technicians will ensure pain, suffering or any potential for lasting harm are avoided or minimised, due to strict standard operating procedures.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Because many areas of research require whole body systems in order to understand the complex physiological interactions and affects of individual and multiple gene complexity.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Consultation and regular communication with the Named Veterinary Surgeon (NVS) for the Establishment will help identify if new and better treatments are available and which may be of

relevance.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

PREPARE and ARRIVE guidelines are utilised for research projects that animals bred under this licence would be used for, as are LASA guidelines, IAT and RSPCA recommendations/advice for housing and husbandry.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Membership of organisations such as Laboratory Animal Science Association, Institute of Animal Technology, attendance at related meetings and conferences on the use of animals in research. Subscribing to and monitoring the array of resources available from sources such as NC3R's, RSPCA, FRAME, UAR and others.

Implementation of advances will be achieved by submission to and consideration by the Animal Welfare Ethical Review Body (AWERB) at the Establishment, and also from the AWERB Regional hub, that the Establishment is affiliated to.

Explain the choice of species and the related life stages

These animals are being used to support research into a wide range of medical conditions and diseases. By breeding under a 'service licence', many strains and genetic lines of animals required by various research teams, can be expertly bred and maintained by animal technicians at the facility, who ensure control on numbers bred and therefore preventing wastage.

Home Office

NON-TECHNICAL SUMMARY

21. Breeding and maintenance of wild type and genetically modified mice for the investigation of G protein coupled receptor function in normal physiology and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, pregnant, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Cells in our body communicate with each other by releasing chemical messengers from one cell that then bind to and activate receptor proteins on other cells. One of the largest family of receptor proteins are the G protein coupled receptor (GPCR) family which include well known receptors such as those that bind to adrenaline, serotonin and dopamine. Because these receptors are on the outside of cells and because they are involved in many physiological and disease functions the pharmacological industry have been targeting these receptors with new drugs. In fact GPCRs have been the most successful drug targets known to man. Despite this the full potential of the GPCR family has yet to be realised. The reason for this is that we lack fundamental understanding of the biology of many of these receptors and have little knowledge regarding how to target them in disease. This project licence will enable the breeding and maintenance of wild type and genetically modified mice as well as the harvesting of tissues and transfer of mice to other project licences for the investigation of the biology and therapeutic potential of GPCRs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We lack effective drugs for the treatment of many of the world’s most devastating diseases. This is exemplified by dementia where the treatments for relieving symptoms, such as memory loss, have limited efficacy whilst there are no drugs that stop or slow the disease. Currently, GPCRs offer a huge potential as targets for drugs for the treatment of many human and animal diseases including dementia. However in order to realise this promise we require a better understanding of fundamental aspects of GPCR biology, how receptors operate in disease and how best to design drugs with the correct pharmacological properties to treat disease whilst minimising side effects. Hence the breeding and maintenance of genetically modified mice described here will allow for these key studies to be conducted.

What outputs do you think you will see at the end of this project?

This licence is for breeding and maintenance. The outcomes described below will be from other projects that will receive animals from this licence .

1. In the neuroscience project we aim to establish the role of GPCRs in the regulation of neurological

responses such as learning and memory, anxiety-like behaviours and locomotion. We also expect to determine the impact of GPCRs particularly the muscarinic receptor family in the symptoms and progression of neurodegenerative disease and schizophrenia.

2. In the lung respiratory project we expect to determine the role of GPCRs in the regulation of lung function and if targeting GPCRs can change the course and symptoms of inflammatory airway disease

3. In the gut physiology experiments we expect to determine the role of GPCRs gut physiology and visceral pain.

These discoveries will be disseminated in the following ways;

1. Peer review literature

2. Scientific meetings in the form of talks and poster presentations

3. To the general public in the form of press releases, public seminars and social media

We also expect these discoveries to result in further grant applications and both charitable and government grants.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Academic Community - will benefit from a understanding of fundamental biology of GPCRs and the understanding of the best ways to target GPCRs to regulate pathophysiological responses.

Pharmaceutical/drug discovery community – will benefit from the validation of new GPCR targets in human disease and an appreciation of the pharmacological principles that can be applied to drug design.

General public – will benefit from the prospect that new methods will be developed to apply to drug discovery against some of the currently most intractable diseases including Alzheimer's disease and inflammatory gut disease.

How will you maximise the outputs of your work?

In terms of publications in the scientific literature and presenting in research meetings we are very experienced in these areas with strong relationships with editors of the top journals including Science, Cell and Nature as well as being well connected with organisers of major research meetings. Hence we anticipate that we will continue to have strong outputs through these routes. We have also been developing our outputs via social media with both institutional and personal social media outlets being

developed including Twitter and Facebook. Finally we are improving of public outreach with visits to local prisons, schools and presenting to REDACTED.

Species and numbers of animals expected to be used

- Mice: 35,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically the animals will be mated, litters weaned and off-spring used in subsequent mating.

Alternatively, off spring may be used for tissue or transferred to other project licenses.

Occasionally, tissue samples may be taken for genotyping.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We are expecting no adverse effects of animals bred and maintained in this project.

We do however have a strain where the receptor that controls salivar secretion (the M3-muscarinic receptor) is deleted (knockout). This strain sometimes finds feeding on normal food (chew) difficult. We therefore in a proportion (~2%) of these animals require to feed them on a wet mash chow. Also there is small propensity (~2%) of the female M3-muscarinic receptor knockout mice to show a bladder dysfunction which will similarly be monitored.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All the mice bred under this project will have a mild severity.

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are no available cell culture models to investigate the three primary areas of this project namely; (i) neurological disease, (ii) gut inflammatory disease and (iii) lung inflammatory disease. Although we are using human tissue samples as much as possible we require animal model of these diseases in the background of genetic models expressing mutant forms of our target receptors to investigate the role of GPCRs in the context of normal physiology and disease.

We are employing replacement strategies where possible such as those below;

1. By conducting biochemical experimenrts such as proteomic and transcriptomic experiments we are looking for early markers of disease that can give reliable indications of drug efficacy thereby reducing the number of animals and the time they are exposed to disease. This is particularly the case in the neurodegeneration studies but also in our inflammatory models.

2. We are using human tissue with increasing fequency to reduce the number of mice used.

What was your strategy for searching for non-animal alternatives?

We are using human brain tissue (both normal and disease) obtained from registered human tissue banks for the neuroscience projects described here. We are also working closely with clinicians to obtain human lung tissue (both disease and normal) and human gut tissue. We are therefore making every effort to use human tissue to determine the role of GPCRs in normal physiology and disease as opposed to animal tissue.

Why were they not suitable?

Human tissue is preferable to mouse tissue however it is not possible to employ genetics to validate the receptor targets in human tissue. It is also not possible to trial drugs that target our receptors in humans - rather we can only test the response to our drug treatment in resected tissue or from post mortem samples. Hence we aim to combine the animal studies with human tissue studies to probe the function of GPCRs in human disease. The ultimate aim will be to subsequently develop drugs based on our findings to trail in human clinical studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have ~19 mouse strains of mice at any one time which on average is maintained at 30 animals each strain per month which over a 5 year period equates to 30x12x5 ~35000 miuce

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We are constantly making attempts to reduce the number of animals in the following ways;

1. We are using well described protocols to reduce pilot studies and animals used in training.

2. We have established a strong and robust management system to oversee breeding and maintenance to ensure the most efficient use of animals. This management system involves two dedicated animal technicians that maintain records and inspect the animals on a weekly basis. They are also the point of contact for training and maintaining training records for the group. They are also the "eyes in the lab" reporting on the quality of the workers and complicance with the licence.

What other measures apart from good experimental design will you use to minimise numbers?

We have excellent management systems and data-bases in place to enure efficient breeding and husbandry of the mice.

Where possible we also share tissue amongst users and importantly co-ordinate studies to most efficiently use mice. We also have a large tissue archive which is well indexed and stored.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

GPCR mutant mice

These will be used to directly determine the role of GPCRs in normal physiology and in disease. In particular we have developed mutant receptors that can not be activated by the natural ligands but

instead be activated by drugs. In this way we can not only test the role of the target receptors in normal biology but importantly test the action of drugs that work by activating these receptors. Also we have developed GPCR mutant mice where the receptor is restricted in the number of signalling pathways that can be activated. Such receptor mutants can be used to determine the biochemical and signalling pathways used by receptors to mediate clinically important effects and distinguish these from pathways that lead to adverse responses.

Breeding and maintaining these animals will not lead to any pain, suffering or harm.

Neurodegeneration models

We will breed neurodegenerative models including prion over expressing and prion null mice. There is no suffering or harm associated with the breeding and maintenance of these strains. These strains will be used to determine the impact of GPCRs in the progression of disease and disease symptoms and whether targeting these receptors can modify disease.

Reporter mice for reactive oxygen species

There is no suffering or harm associated with the breeding and maintenance of these strains which will be used to monitor mitochondrial function during neurological disease particularly prion disease and whether targeting GPCRs can impact on mitochondrial activity.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Where possible we will use early life stages (e.g. mouse embryos and neonates) to generate neuronal cultures and terminally anaesthetised animals for histology (e.g. perfusion fixation). However the neuroscience projects require models that most closely resemble human physiology and be models that can be genetically manipulated in this case mice are the most appropriate. Also we wish to test the action of receptors and drugs that might lead to new drugs for human use. The receptors and receptor system need therefore to closely relate to humans and therefore mammalian systems such as mice are the most appropriate.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We are always looking for further refinement of procedures. For example we have been undertaking a study to determine biomarkers of neurodegeneration that can be used to establish early on in disease if targeting our receptors of interest impacts on disease before clinical signs appear. We have also been looking towards methods of evaluating gut inflammation using mild inflammatory models and assessing sensory neuronal activity using terminally anaesthetised animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our primary published source of guidance on 3Rs is via the national centre for replacement, refinement and reduction in animal research (NC3Rs). This organisation publishes regularly on guidance for researchers. The European Medicines Agency also publish excellent practical guidance on 3Rs. We also pay particular attention to the peer reviewed scientific literature for further methids to refine our protocols.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We have regular up-date sessions and training in new approaches run locally and nationally. We also keep abreast of the published literature and share good practice locally. Importantly, we also have expert collaborators that share good practice and we are always looking at new methods to improve our 3Rs.

Explain the choice ofspecies and the related life stages

We are using mice for the followingreasons;

1. Mice are a species where it is possible to change genes in a process often described as genetic engineering. In this way we are able to change specific genes that encode for proteins such as the receptors that are being studied in this project. Hence by genetically engineering mice we can either delete receptor genes or change them so the receptor can be activated by synthetic drugs. This will allow us to probe the function the receptors. Such appraoches are not currently possible with other species.

2. Using embryos and neonates are the optimum life stages to generate primary neuronal cultures using schedule 1 methods

.

Home Office

NON-TECHNICAL SUMMARY

22. Breeding and maintenance of wild type and genetically modified mice to study effects on vascular function

Project duration

0 years 6 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Cardiovascular diseases, or diseases which indirectly affect the cardiovascular system have a huge impact on our health, cause many people to die prematurely and cost the Health Service a huge amount of money. This licence aims to breed and maintain genetically altered mice and their tissues, which will be used in experiments to study effects of genetic mutations on function of the blood vessels.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The project will increase our understanding of how blood vessels change when animals have certain genetic modifications such as a lack of an enzyme of receptor which may affect how their blood vessels function. This is important as it can sometimes help to identify how and why the function changes and maybe identify ways in which new drugs can be developed to target these processes.

What outputs do you think you will see at the end of this project?

This licence will allow us to maintain and breed a colony of genetically modified animals. The colony will provide live mice and their tissues to study the effects of deletion of this particular gene on regulation of blood vessel function. This will, in due course generate significant new data on blood vessel regulation and the importance of the fat which surrounds blood vessels. We intend to publish this data to share our findings and help advance the field.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We will learn more about how blood vessel function and, more importantly, how they stop functioning properly when they become diseased. We will find out more about how the fat which surrounds our blood vessels can change during diseases such that it becomes damaging rather than protective.

All of these experiments are carried out using genetically modified animals but these can give valuable information about what may happen in humans and by understanding a disease better we can identify targets for drugs or other therapies which can then be developed and tested.

How will you maximise the outputs of your work?

We aim to publish our research in scientific journals so that our findings can be shared with other researchers working in this area. We also aim to present our findings at national and international meetings so that ideas and novel techniques can be shared and the best approach to investigating our area of research adopted. We collaborate with others in the area so that new skills can be learnt and supporting skills can be used to optimise the programme of research and maximise the outcomes.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The animals on this licence will simply be used for breeding, their genotype being determined by a small sample removed from their earlobe. This does not have any overt adverse effects on the mice.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Breeding of mice should not cause any ill-effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The single protocol on this licence is mild. Very few if any animals are expected to suffer any more than momentary discomfort during ear notching to determine genotype.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We derive much of our preliminary data from experiments which do not use live animals and this helps us to decide on conditions for studies which do use animals. However, in order to investigate how a particular enzyme or receptor or protein affects vascular function, one of the most effective ways is using animals which are genetically modified so that they lack that enzyme, receptor or protein and that requires mice to bred under licence.

What was your strategy for searching for non-animal alternatives?

We make extensive use of cells from blood vessels grown using a technique known as tissue culture. From these experiments we can derive a huge amount of data which reduces animal numbers and informs the experimental conditions when we do need to use animals. We also make extensive use of historical samples of preserved tissue and tissue fluids/blood which originally came from animals but can be used in multiple experiments.

Why were they not suitable?

They are suitable for certain experiments which form the bulk of our research. However, in certain experiments- such as measuring how an enzyme (such as AMPK) affects blood vessel function, we are able to breed animals which lack this enzyme and investigate how their blood vessels and surrounding tissues are affected.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on past experience of running breeding colonies of mice which are used to produce animals for experimental projects. In the proposed breeding over the 6 month life of this

licence, we expect that up to 1000 mice may be bred and their genotype determined experimentally

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Breeding is tightly controlled so that the colony only generates the numbers of animals required. The colony is closely monitored and animals used promptly so that the size is kept within the limits of this licence. The design of experiments which use these animals under non-licenced procedures follow current guidelines and good practice.

What other measures apart from good experimental design will you use to minimise numbers?

Our breeding programme is tightly controlled so that the colony size is monitored and is of a sufficient size to produce the number of animals needed without significant excess. When a member of my research group uses an animal, tissues are shared between multiple users and across research groups so that maximum use is made of that animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project involves breeding mice with specific genetic modifications which are of interest to us. Such modification- removing the ability of the animal's genome to produce a specific protein or enzyme allows us to investigate what effect that has on the animal in terms of its cardiovascular system and how it's blood vessels function. When required for use these mice are usually killed via a humane method and their tissue and cardiovascular system investigated.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We are investigating the cardiovascular system and so the best models of cardiovascular disease are in mammals and this is why we use normal and genetically modified mice. It is important that our basic scientific research has what is called "transferability"- where the results have relevance to the disease or condition in humans. This is difficult to argue when using some less sentient species in the type of research we do.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The experimental models we use are accepted by the scientific community and we have published a great deal or peer-reviewed data reported our findings with them over the last 10-12 years. Through this period we have refined our techniques to make the breeding successful.

In breeding animals it is necessary to determine their genotype and so a small ear notch is taken which may cause no more than momentary discomfort. Breeding animals may also have their diet modified but, again, this does not have any expected adverse effects.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We design and report all our studies according to the ARRIVE guidelines which are widely accepted and endorsed by the scientific community:

https://www.nc3rs.org.uk/arrive-guidelines

How will you ensure you continue to use the most refined methods during the lifetime of this project?

There are several sources of information available including the NC3Rs website:

https://www.nc3rs.org.uk/

I also regularly correspond with the NACWOs (animal house staff) regarding the best way to maintain our colony of breeding mice and consult with the NVS where any problems arise and to get the most up-to-date information.

Explain the choice of species and the related life stages

For the types of experiments we are performing we need to breed adult animals as their cardiovascular systems are fully developed.

We choose to use mice as this allows us to breed and use mice which are genetically modified (GM), this allows the genome of the animal to be manipulated so that the protein product of a particular gene is not produced (or in some cases the manipulation can be so that more of the protein is produced). This allows us to use animals which are deficient in proteins we are interested in studying- such as an enzyme known as AMPK.

Home Office

NON-TECHNICAL SUMMARY

23. Breeding and production of genetically altered mice

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to support basic and translational research by providing genetically altered mice for research projects - both the creation of novel genetically altered strains and the maintenance by breeding of established genetically altered strains.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work underpins a range of research projects and has directly enabled many significant and high-impact research findings that have increased our understanding of several human disorders ranging from infertility and cardiovascular disease to rare, debilitating, genetic conditions.

What outputs do you think you will see at the end of this project?

This project will underpin a range of scientific studies aimed at understanding genetic diseases such as cardiovascular disease, cystic kidney disease and developmental disorders. Genes implicated in these conditions will be targeted and the relevant tissues and organs studied. In addition to the supply of tissues, animals will be provided for further experimentation in a centrally co-ordinated way to ensure consistency, maximise efficiency and minimise the numbers of animals being used. The scientific insight underpinned by this project will lead to a greater understanding of these diseases and syndromes and help to identify new treatments. This will lead to research publications, greater information for individual patients and patient groups, and provide resources that will be of benefit to the wider scientific community.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

A particular benefit is the maintenance and generation of high quality GA animals using standard protocols to enable researchers at (or moving to) the establishment to continue their research effectively and efficiently. This facilitates international collaborations and interactions that significantly enhance research. Furthermore, having a single licence enables oversight of all breeding and implementation of consistent processes and welfare assessment to minimise the harms to the animals and maintain accurate phenotype information. This licence currently supports scientists working in the fields of cardiovascular disease and childhood kidney disease but due to the nature of this licence, the focus may change depending upon the types of studies being undertaken.

How will you maximise the outputs of your work?

Enabling collaboration is core component of this project. This has been shown to increase overall efficiency and enhance the scientific outputs of research. Furthermore, there is a rigorous selection process during which each individual project is scrutinised to ensure that the most appropriate and refined methods are employed and that the project has the greatest likelihood of achieving the desired goals.

Species and numbers of animals expected to be used

- Mice: 7450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of mice are bred to maintain the genetic modification. Some mice will be used to produce new genetically altered strains and this will entail some mice undergoing surgery, for example, to generate sterile males (vasectomy) needed in the process, or female mice receiving hormone injections to induce ovulation to provide eggs for carrying out the genetic modification.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The vast majority of mice under this licence are not expected to show adverse effects and are only used for breeding to maintain the genetic modification. A proportion of genetically altered mice will show some features of the human diseases they are designed to model, for example, abnormalities of the kidneys, eyes and brain in the case of Joubert syndrome models, however, these are typically only noticeable following microscopic analysis of the affected tissue. A proportion of mice will be used to produce new genetically altered strains and this necessitates (i) hormone injections to induce ovulation and provide eggs for manipulation, (ii) surgery (under anaesthesia) to render males sterile so they can mate and produce "pseudopregnant" female mice that, following surgery (under anaesthesia) to reimplant manipulated eggs, will act as surrogate mothers for the new genetically altered mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

It is estimated that up to 80% of mice under this licence will show no adverse effects and be Mild. Only 25% of animals bred under the Moderate protocol are predicted to exhibit any adverse effects, ie, < 10%

of the total number of mice being bred.

What will happen to the animals at the end of the study?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The investigation of single and multiple gene effects can be undertaken in a variety of in-vitro and non-mammalian systems and the researchers make use of a variety of these systems, but some studies require the use of live animals, in order to investigate gene effects in an intact mammalian organism. Although genetically altered animals need to be bred for research purposes, many of the specific research manipulations can be carried out in vitro, on tissues obtained after the animals have been humanely killed.

What was your strategy for searching for non-animal alternatives?

Cells cultured in the laboratory and computer-generated models are widely used by the research teams supported by this application to complement animal studies, however, these are not as absolute alternatives as it is not possible to model the effects of a disease gene on the whole body by only using cells in culture. Furthermore, many of the animals bred under this PPL will be humanely killed to generate tissues for laboratory analysis, including the culture of cells and the generation of data to improve computer modelling, without suffering more than mildly themselves.

Why were they not suitable?

Genetically altered mice typically complement experiments carried out on cells cultured in the laboratory and other non-animal approaches, so non-animal alternatives are an important component of medical research. For example, kidney cells can be isolated and cultured from the urine of patients with cystic kidney disease and disease mechanisms/novel treatments can be investigated using these cells but genetically altered mice are essential to then put these findings into the context of a complex organ and the effects on the whole body and provide a most rigorous preclinical model for testing new treatments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers are based on previous demand for the maintenance of genetically altered mice and the likely increased demand for the creation of new genetic models due to recent technological developments improving the precision with which genetic alterations can be made.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Holding a single project licence to breed these small colonies enables effective control of the numbers bred. We can also ensure that uniformly high standards of animal care and welfare are applied since the staff involved have extensive experience in this field. We also enable effective sharing of some colonies between different research groups, to allow a reduction in the number of animals produced but not utilised for research procedures.

The centralisation of the production of genetically altered mice provides researchers with access to unrivalled expertise in both design and execution and ensures the highest efficiency thus significantly reducing the number of animals that would be required if individual groups were to attempt to produce their own genetically altered mice. Requests from researchers are scrutinised by a panel that provide expert guidance to ensure the experimental design is optimal and can efficiently deliver the project outcomes making use of the minimum number of mice.

Throughout, the principles of the Assessment Framework for Efficient Breeding of Genetically Altered Animals (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf) are adhered to.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding colonies will be monitored carefully to avoid over-production of animals, and animals of specific genotypes that are produced will be used by more than one research group whenever possible. Breeding colonies that are not required in the short/medium term will be stored as frozen embryos or frozen sperm, to minimise continued production of GA animals. Where specific genotypes are readily available from academic or commercial sources, mice will be acquired for each study, to avoid maintaining a breeding colony.

Furthermore, we actively participate in a number of projects for archiving and sharing of REDACTED and phenotyping information (eg EMMA, MRC Mouse Network) as well as maintaining informal arrangements for sharing lines such as tissue-specific cre lines.

The numbers of animals used on specific projects will be kept to a minimum by requiring those using the animals to provide details of the experimental designs that will be used and adhering to the principles of the Assessment Framework for Efficient Breeding of Genetically Altered Animals (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Genetically altered mice have proven to be a powerful way of understanding human disease and providing insights not possible from other sources.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Whilst less sentient animals such as zebrafish can provide some insights into basic aspects of vertebrate development, and are used by research teams to complement mouse studies, to understand conditions affecting such tissues and organs as the kidney, immune system, lungs and brain, a mammal is needed. Wherever possible, the earliest stage of development (least sentient) will be used, however, for example, embryonic stages are not suitable for the study of conditions such as Joubert syndrome that affect kidneys due to the fact that the laboratory mouse kidney is not fully developed at birth and, whilst some early evidence of cystic kidney disease can be observed in the mouse at birth, the kidney does not reach a stage of development corresponding to the neonatal human kidney until the mouse is approximately ten days old.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The majority of genetically altered animals bred under the authority of this project have no clinically deleterious phenotype, or can be maintained as heterozygote animals, so that clinically significant adverse effects are not apparent. Homozygote animals with a deleterious phenotype are produced only when specifically required for the project, or, if produced during a breeding programme, are humanely killed as soon as possible after a welfare problem is identified.

Deleterious effects in some lines develop only after several weeks, and in these instances, breeding programmes are devised to make use of younger animals, that are then humanely killed before the deleterious phenotype is expressed.

When a new GA line is to be imported for maintenance on this licence, details of the anticipated phenotype will be obtained from the supplier and this will inform the initial decisions in relation to breeding and maintenance of the line. When possible, “mouse passport” data that contains more specific husbandry advice will be sought. During establishment of the initial breeding colony, litter size, number successfully weaned, and any specific adverse effects will be documented by regular (daily) examination of the animals. Husbandry modifications (eg use of soft diet, later weaning dates for smaller juveniles, additional bedding etc) will be adopted as required, as outlined in Wells et al, 2006. If the genetic alteration could lead to immunocompromise, husbandry conditions would be modified appropriately, ranging from more stringent barrier conditions through to maintenance in flexible film isolators.

Genotyping will normally be undertaken using tissue removed when ear-notching for identification purposes. When this is not suitable, and tail-biopsy is required, then a specific justification will be submitted to the AWERB before this method is used. If tail biopsy is required, it will be undertaken under brief general anaesthesia (eg with isoflurane) and analgesia (eg meloxicam) administered.

Any pain associated with procedures such as embryo transfer will be minimised by appropriate use of analgesics. All surgical procedures will be undertaken using aseptic technique, by experienced surgeons, so that the incidence of post-operative complications can be minimized.

Furthermore, we constantly strive to improve the general husbandry of our animals, for example recent developments include widespread implementation of non-aversive handling methods to reduce stress, additional in-cage enrichment, the inclusion of "houses" within the home cage providing a more secure environment for breeding animals to make their nests, and improved bedding that we find reduce neonatal losses.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the guidance provided within the Assessment Framework for the Efficient Breeding of Genetically Altered Animals

https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf

We regularly check the latest developments at the NC3Rs website and have discussions both within AWERB and with the veterinary team to ensure the work carried out under this PPL is conducted in the most refined way.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

As a member of AWERB, I participate in numerous discussions and briefings concerning advances in the 3Rs and regularly look for updates from the NC3Rs website. In terms of the specific techniques being carried out, along with the veterinary team, we constantly look to refine our approaches, in particular those of a surgical nature and implement best practice based upon the latest NC3Rs findings, for example, the widespread use of non-aversive handling techniques for routine animal husbandry.

Explain the choice ofspecies and the related life stages

These mice are genetically altered for use in research - typically in order to better understand human diseases and seek new treatments.

Home Office

NON-TECHNICAL SUMMARY

24. Breeding Genetically Altered rodents and embryo production

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo
Rats	pregnant, adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To provide Genetically Altered rodents and wild type embryo's to the research community in the establishment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are several common use Genetically Altered colonies used in various projects in our establishment and by providing these strains to the various projects we can ensure that the colonies are bred under best practice guidelines. We work within guidelines which are taken from the Genetically Altered breeding initiative from the Home Office in relation to colonies which will be held under this service licence. We regularly review the number of mice to ensure that the demand is met while preventing the overproduction of mice.

Some Genetically Altered colonies will be maintained for the use of tissue collection only. By maintaining the Genetically Altered colonies on the service licence we can ensure that the colonies are bred under best practice guidelines.

The similarities between mouse and human early development enable the Fertility group to use mouse embryos (0.5-2.5 dpc) to carry out feasibility studies and develop techniques before they are applied to the human. For example, the group have been able to test the functional ability of synthetic proteins which have been shown to have an effect on human fertility. This type of infertility affects approximately 1200 couples per year in the UK. The mouse work is a prelude to the work translating to human oocytes.

The use of Genetically Altered embryos will only occur when we are cryopreserving Genetically Altered colonies which are held under this service licence.

What outputs do you think you will see at the end of this project?

We will have animals which are good quality in terms of genetics as we will follow best practice. This involves refreshing the background of strains by mating them out to the genetic background every 5-10 generations.

Strains with either mixed or ambiguous background strain information will undergo genetic monitoring to confirm the background substrain. By carrying out genetic monitoring it will give confidence to the reproducibility of the work.

We also use the breeding data which is generated from Genetically Altered colonies maintained under the service licence in colony sizing calculations. Using sizing calculations will help to make sure that

the colonies are sized to produce the number of animals required for experiments whilst also not overproducing animals which will be culled as surplus.

Data will allow us to calculate mortality rates of individual Genetically Altered colonies, thus removing the need to refer to genetic background strain data.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The research community will benefit as we will produce good quality animals for their research with accurate breeding and phenotyping data. By producing animals which have good genetic integrity the reproducibility of experiments is improved. By using colony calculations we can reduce the number of animals being produced and potentially wasted.

How will you maximise the outputs of your work?

As a large establishment, there may be duplication of Genetically Altered colonies and by offering to breed and maintain the Genetically Altered colonies under one service licence we can reduce the number of mice which are potentially wasted. The use of the service licence will be disseminated through the establishment welfare meetings. At the meetings, the benefits of using the licence will be discussed e.g. reducing the number of animals wasted, genetic integrity and reproducibility etc.

Within my regular reviews of colonies at the establishment we can specifically target groups where we identify an issue with the breeding and promote the use of the service licence as an alternative.

Species and numbers of animals expected to be used

- Mice: 27,000
- Rats: 1,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most animals on the licence will be Bred and Maintained with no welfare issues. Mice will be maintained to a maximum of one-year-old on the breeding and maintenance protocols. Where required animals will be earmarked to obtain a sample for genotyping. The earmarking will generally take place when the animal is around 2 weeks old.

Intraperitoneal injection of hormones 46-48 hours apart to generate either wild type embryos for the fertility group or to generate transgenic embryos for the cryopreservation of lines. The hormone injections are used to increase the number of ova which is obtained from each female. By using this method we are able to use fewer animals to obtain the required number of ova for scientific outputs. The females are then culled by a schedule 1 method to harvest the embryos/oocytes. The cryopreservation of lines is to either remove a non used line from the shelf reducing wastage or to safeguard from a disaster such as fire or flood. Female mice can be left unmated after the hormone injection depending on the researcher's requirement.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are many possible adverse effects due to genetic modification of the genome. Information on expected phenotypes will be collected prior to breeding and will be recorded in a colony passport. Any animals exhibiting any unexpected harmful phenotypes will be culled. In the unlikely event of any animal showing any signs of suffering greater than minor and longer than transient or that compromise normal behaviour in any way, the animal will be terminated by schedule 1.

Any animal which displays an unexpected adverse effect on the moderate breeding and maintenance protocol will be moved to a PPL with the relevant authority as soon as identified.

Ear notching should involve only slight and transient pain and no healing problems. If tail tipping is used then the pain will be controlled using a local anaesthetic, and any bleeding will be controlled by local pressure.

Intraperitoneal injections should involve only slight and transient pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Breeding and maintenance of genetically altered rodents (mild) mice we expect 80% to be sub-threshold and 20% mild of the 20,000.

Breeding and maintenance of genetically altered rodents (mild) rats we expect 80% to be sub-threshold and 20% mild of the 1,000.

Superovulation mice we expect 100% to be mild of the 7,000

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mice and rats are required to supply the needs of end-users Project Licences. In order to fully understand the effects of human genes and their disease-associated mutants, there is no suitable substitute for a mammalian model. The mouse and rat is the model of choice for genetic modification modelling human diseases because of the availability and ease of manipulation of the mouse ES cells. The justification for their use lies with the end-users Project Licence and cell culture assays will be used wherever possible.

Scientists in the REDACTED require live early stage embryos (0.5-2.5 days)

What was your strategy for searching for non-animal alternatives?

The aim of the service licence is to provide end-users with mice and rats for their studies and the consideration of non-animal alternatives will differ depending on the end users' area of research.

Any researcher who wishes to use the service licence will need to provide justification of why they wish to use animals under the service licence and details of any non-animal alternatives they have considered.

On the request to house animals on the service licence the end-users will need to detail which searches and search engines they have used to find non-animal alternatives.

Why were they not suitable?

The aim of the service licence is to provide end users with mice and rats for their studies and will only be done when non animal alternatives have been considered and rejected. The reasons for this will differ between projects but typically the reasons for this are that a whole organism is required for systems biology or behavioural research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The majority of this licence concerns the breeding of mice and rats. We have extensive experience of calculating animal numbers on a previous licence and we plan to carry on with this practice. We work with end- users to calculate the minimum number required to reach their scientific goals. This involves

estimating the final number of animals required and then calculating the number of breeding animals required using existing best practice guidance. This includes ensuring the appropriate age of animals used for breeding, replacement of breeding animals before productivity declines and the use of production efficiency index calculations to size the colony. All colonies on the service licence undergo a three weekly review where the productivity of each breeding pair/trio is assessed and any which fall outside of our guidance ais removed.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The size of colonies held on this licence will initially be calculated on the need of the end-users. They will be expected to provide a rationale for the number of animals required to meet their scientific goal and we will calculate the number of breeding animals required using known breeding data.

Genetically Altered colonies held on the service licence will be subject to regular reviews of the breeding performance. The actual breeding performance will be assessed during these regular reviews using data held on a database. It is these data which is used to calculate colony sizes and identify breeding pairs/trios which fall outside of our guidance.

Where usage of a line has fallen to a point where it is no longer possible to breed efficiently, for example, a line being kept on 'tick-over' and not currently being used for experimental work, we will suggest to the users that we will cryopreserve the line. This reduces the number of animals being produced unnecessarily.

What other measures apart from good experimental design will you use to minimise numbers?

The primary purpose of this service licence is the efficient breeding of Genetically Altered animals.

All strains which are maintained on the service licence will be overseen by experienced animal technicians to ensure that the breeding programmes devised for the colonies are followed. This will help to minimise any potential wastage from overbreeding. Where appropriate lines will be cryopreserved to prevent animals from being produced unnecessarily.

This service licence also provides the opportunity to consolidate the breeding of models used by several end users. This would prevent the wasteful maintenance of several smaller separate colonies to provide each of the end-users with these animals. An example of this would be commonly used cre lines.

Animals are promptly sampled for genotyping so that any animals which are of the incorrect genotype are not kept within the colony. End users must demonstrate that the genotyping protocol is validated and robust before a newly generated model is allowed onto the licence.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The aim of this project is to provide end-users with mice and rats. This will include models relevant to neuroscience (such as the TARDBP*M337V/Ypet Tlbt line which is used as a model of motor neurone disease), cardiology (such as the TMEM16A line which has altered blood vessel function) and other areas of biomedical science (such as the STIM1 line which has altered calcium signalling, important in the immune response). By consolidating the breeding of these lines and monitoring it with dedicated staff we can ensure that breeding and maintenance is done in the most refined manner. This includes efficient breeding practices and the calculations used to size the colonies. We also routinely refresh inbred lines to ensure the genetic integrity of the lines and prevent potentially harmful genetic drift.

Where a line is no longer being actively used this would be cryopreserved which involves superovulation. This is performed using a very established procedure and is considered to be the most refined. In brief, this involves two timed intraperitoneal injections prior to breeding.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The aim of this project is to provide end-users with mice and rats, the justification for which will depend on their individual scientific goals. Typically, the justification for using rodents is that lower-order organisms do not exhibit the required features. For example, an adaptive immune system which is absent from species such as flies. Adult rodents are required for work involving behavioural testing or investigations into ageing diseases. This makes the use of embryos impractical for these scientific areas of interest. Increasingly, rats are being used for more complex cognitive tasks which mice are unable to learn, so there will be instances where end-users use rats over mice or other species. End users will be required to provide justification to use models on this service licence.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

By using efficient breeding and colony management we can reduce the number of animals being produced which are being culled as surplus. By using the efficient colony management guidelines we have in place we can ensure that breeding animals are retired from breeding by 8 months of age which reduces any potential for breeding related complications.

Where substances are administered by injection the minimum effective dose and the most refined route will be chosen.

When tissue is required for genotyping ear punch is the default position.

Whilst this service licence includes the option for producing animals for cryopreservation by embryo we will always recommend sperm freezing, as the most refined method of cryopreservation, before we

agree to carry out embryo cryopreservation.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office efficient breeding of Genetically Altered animals

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We have in place guidelines for breeding colonies which ensure effective breeding of rodent colonies in line with the principles of the 3R's. These are applied to the breeding on the service licence but also distributed through the establishment to other licence holders who maintain breeding colonies. These guidelines will be regularly reviewed based on any advancements made in this area. These advancements will be identified through regular attendance of conferences (LASA, IAT Congress, NC3R's tech symposium, etc.) and comparisons to other large breeding institutions, such as MRC Harwell and Jackson Laboratories. We receive frequent updates from both MRC Harwell and Jackson Laboratories as well as information from the NC3R's, Norecopa and our internal 3R's subcommittee. The 3R's subcommittee collects advancements from across the establishment and disseminates this information. This enables the wider implementation of the advancements made by individual groups.

Explain the choice ofspecies and the related life stages

In order to fully understand the effects of human genes and their disease-associated mutants, there is no suitable substitute for a mammalian model for certain disease models. Due to the complex interactions which take place between different cells, tissues and organs this can only be replicated in a living organism.

Scientists in the Fertility Unit use early-stage mouse embryos (0.5-2.5 dpc) to carry out fertility studies before applying the technique to human embryos. The mouse ova enables them to test

For cryopreservation, we will use females between the age of 3-4 weeks old as it has been shown that females in this age bracket produce a higher yield of ova and a higher percentage of females which are mated produce fertilised ova.

Home Office

NON-TECHNICAL SUMMARY

25. Breeding split gene-drive mice spreading female infertility

Project duration

2 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to test the efficacy of a safeguarded genetic system known as a split gene-drive to spread a genetic alteration through a laboratory-contained mouse population. If successful, gene-drive may find future application as a breeding tool for reducing the cost, time and number of animals required to generate populations of genetically altered research animal. If applied to spread female infertility, gene drive could also find application as a pest management tool.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Genetically altered animals remain an essential tool for biomedical research; however, the cost, time and requirement for a large number of animals to obtain a few individuals of the desired genotype is prohibitive for many complex models of human diseases, such as arthritis and cancer. A cross between mice that are heterozygous for three unlinked genes must produce 146 offspring for a 90% probability that one will be a homozygous for all three genes. Gene drive has the potential to ensure specific genetic alterations are passed on to offspring and, therefore, could substantially reduce the cost, time and number of animals required to generate populations of animal models harbouring a desired genotype.

Gene drives also have potential as a management tool for control of invasive pest populations. In agriculture and wildlife, invasive pests are well known: rabbits in Australia, REDACTED ls in the UK, and the omnipresent infestation of rodents around the globe. Invasive vertebrate pests impact the environment, economy and society. Current control methods include shooting, poisoning and trapping, which are costly and largely inadequate, and they often lead to unwanted suffering in target and non-target species. A gene drive spreading female infertility may offer a humane, species-specific and cost-effective alternative to current control methods.

What outputs do you think you will see at the end of this project?

The outputs of this project will help assess the feasibility of using gene drive as a research breeding tool for efficiently generating study populations of genetically altered animals. This study will also provide preliminary data to inform the debate on gene drive as a tool for managing invasive mammalian pest populations. The findings will assist with technical development of gene drive technology as a breeding tool and a humane alternative to current pest management tools. Dissemination of the project through mainstream media will encourage public and political discussion on genetic pest control approaches.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Gene drive as a research animal breeding tool

The application of gene drive as a research breeding tool could significantly reduce the time, cost and number of animals required for generating genetically altered animals for biomedical research. Gene drive technology has the potential to guarantee the inheritance of one or more specific genetic alterations. In this way, gene drive could substantial reduce the number of animals used, as well as the time and cost of research involving genetically altered animals. Ultimately, gene drive technology could reduce the resources required for scientific research and fast track the development of treatments and cures for disease. If successful, publication and dissemination of our findings could see gene drive technology being widely applied as a research animal breeding tool in the next 3 years.

Gene drive as a pest management tool

Invasive mammalian pests are a global concern that impact the environment, economy and society. Current control methods include shooting, poisoning and trapping, which are costly and largely inadequate, and they often lead to unwanted suffering in target and non-target species. Therefore, the outputs from this project have the potential to benefit environmental conservation efforts, support native predated species, the economy and those within our society that are impacted by mammalian pest, such as farmers and foresters. The outputs also have the potential to reduce suffering in pest species and non-pest species that are affected by currently deployed control methods. The beneficial outputs would likely not be seen for 10 years or more as this technology would require subsequent scientific investigation, including advanced ecological modelling, and a political and public consensus reached before deployment.

How will you maximise the outputs of your work?

This project contributes to collaborative research efforts to assess the feasibility of genetic pest control tools in vertebrate species. The outputs of this work will play a key role in this growing pool of knowledge and many within this collaborative research community are eagerly awaiting the results from this project. We will disseminate outputs through the research community via personal communication, invited talks, workshops, conference presentations and scientific publication. Outputs will be disseminated through mainstream media channels to encourage public and political discussion on the potential use of genetic pest control approaches.

Species and numbers of animals expected to be used

- Mice: 128

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The gene drive mice used in this project will be mated to generate 16 litters of pups. Within those litters, the percentage of offspring that inherit the gene drive will be quantified. Once the female offspring reach sexual maturity, we will check the fertility status in a select number of female offspring that inherited the split gene-drive system.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

This study is expected to have no impact or adverse effects on animal health other than infertility of the female offspring that inherit the split gene-drive system.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Infertility of some female offspring is expected to be of mild severity. Loss of pregnancy will occur shortly after conception, at the 2-cell embryo stage. We anticipate no other impact from this study on animal health or wellbeing.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Gene drives transmit through sexually reproduction, therefore, the only way to investigate the potential of the safeguarded split gene drives in this project is in sexually mature animals. This project will use the mouse to study the potential of gene drive in mammalian animals.

What was your strategy for searching for non-animal alternatives?

No non-animal systems were considered, as gene drives transmit through sexual reproduction the assessment of these genetic systems is only possible in animal systems.

Why were they not suitable?

Gene drives can't be tested in non-animal alternatives as they transmit through sexual reproduction. At present, there are no non-animal systems for studying the complex biological processes involved in sexual reproduction for the transmission of gene drives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The only previously reported study on gene drive in mice used a different genetic strategy and, therefore, we can not predict the efficiency of the split gene-drive approach in this study based on their findings. The previous study reported up to 5 successful born litters for the gene drive systems tested.

This study aims to generate 8 litters of pups for each of the two gene drive systems tested.

If we estimate an average litter size of 6 pups, we will generate a total of 96 pups whilst screening offspring. To generate these litters, the project will require approximately 8 split gene-drive breeding males (4 of each genetic system) and the 16 wild type female breeding partners. An additional 8 males will be required to confirm the fertile status of the split gene-drive female offspring once they reach sexual maturity. In total, we estimate this study will use 128 mice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

For a gene drive to be successful as a research breeding tool or pest management tool it will be required to propagate at a rate much greater than 50% (at least 75%). At this rate of transmission, we will be able to see this effect in the selected sample size. If successful in this initial underpowered

study, we will consider the value of undertaking an additional study to statistically validate the most efficient of the two split gene-drive systems tested.

What other measures apart from good experimental design will you use to minimise numbers?

We have chosen to perform a small-scale study before considering a larger-scale study that would offer statistical validation of the most efficient strategy. In this way, we are reducing the number of animals being used and whilst gaining valuable data on the biological potential of mammalian gene drive technology, both as breeding tool and pest management tool. By testing two systems at small-scale we will gain insight into the best strategy to further investigate or develop.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project will breed and maintain lines of genetically altered mice. Breeding of animals is a natural behaviour and this is anticipated to have no negative impact of animal health or wellbeing. Females may inherit a female infertility trait, which is expected to have minimal impact of animal wellbeing as loss of pregnancy will occur very shortly after conception.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

This project examines the potential of gene drive technology in mammalian pest species. The is the most accessible, genetically sophisticated and cost-effective mammalian model. As gene drives propagate through sexual reproduction it is necessary that sexually mature adult animals are used in this study.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We anticipate minimal animal suffering during this project. Animals are checked regularly checked (typically daily) and any animal identified to be suffering at a level greater than anticipated will be managed accordingly by experienced staff.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will design and carry out our experiments in accordance with the PREPARE and the ARRIVE guidelines. If required, we will consult the Experimental Design Assistant of the NC3Rs (https://www.nc3rs.org.uk/experimental-design-assistant-eda).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

REDACTED. The researchers involved in this project are active participants in 3Rs research and stay informed on the latest advances through scientific publications, social media channels and discussion amongst colleagues and peers. The Institute is a state-of-the-art facility with the expertise to implement advances in the 3Rs as they evolve.

Explain the choice ofspecies and the related life stages

The mouse is the preferred mammalian model for genetic research. Mice are cost effective because they are relatively cheap and easy to care for. The mouse also benefits from a fast generation interval and is small in size, so convenient to house. It is relatively easy to manipulate the mouse genome compared to other mammalian species. As the mouse is the preferred and most widely used mammalian model for genetic research, gene drive is likely to have the greatest impact as a research breeding tool in this mammalian species. For these reasons, the mouse is the species selected to study gene drive technology in this project.

As gene drives transmit through sexual reproduction, the mice used in this project will be sexually mature adults

Home Office

NON-TECHNICAL SUMMARY

26. Breeding, Archiving and Rederivation of Genetically Altered or Natural Mutant Animals

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To provide a demand-matched supply of genetically altered rodents of high health status and defined genetic quality.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Demand for genetically altered animals continues to increase as the knowledge of the genomic sequence becomes increasingly understood. New emergent technologies including genome-editing tools will see an increase in more sophisticated models become available. This PPL will provide a means to breed and maintain these lines to transfer to other licences for experimental purposes. In addition, sperm and embryos may be frozen to keep genetically altered lines for future work.

What outputs do you think you will see at the end of this project?

A mouse passport is generated for all mouse strains. This includes information about background, breeding and phenotypic effects.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

Researchers and their programmes of work at our establishment.

How will you maximise the outputs of your work?

Animals will be issued as requested and pairs set up to replace the issued animals. If larger numbers were to be requested then the breeding would be increased accordingly. This method is designed to keep stocks to a minimum. Wherever possible standing orders will be encouraged so supply can be accurately controlled and stocks kept to a minimum. All strains entering or leaving the unit are accompanied with a mouse passport which gives in depth detail about the strain and identifies any phenotypic effects the gene modification may have.

Species and numbers of animals expected to be used

- Mice: 7000
- Rats: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of the animals will be used for the breeding and maintenance of genetically altered or non-harmful mutant animals.

Some animals may undergo surgical procedures to either render the animal sterile or to be able to implant embryo's

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals bred and maintained under this protocol are not expected to exhibit a phenotype that will exceed mild severity. However, it is difficult to predict the nature and severity of any potential defect and for all types of animals there will be careful monitoring for possible side effects/phenotypes:

- Alteration in food/drink intake
- Any change in behaviour, social interaction, vocalisations etc.

However, genetic manipulation can occasionally result in unplanned and unexpected effects on mouse physiology and development which may impact on overall life expectancy. The vast majority of genetically altered animals bred and used in this protocol are expected to have a lifetime experience equivalent to that of their wild-type background strains.

Animals that have undergone a surgical procedure may suffer some pain and inflammation at the wound site. Analgesic agents will be administered routinely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All of the GAA animals bred and maintained on this PPL will experience only mild or in the majority of cases, less than mild pain, suffering distress or lasting harm.

Animals that have undergone a surgical procedure are not expected to experience pain greater than moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because of the nature of the licence there are no alternatives other than to use live animals to generate more live animals.

Use of live animals for archiving embryos and subsequently rederiving them is a well tried and tested way of obtaining specific pathogen free animals and securing the colony for the long term.

What was your strategy for searching for non-animal alternatives?

N/A

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on previous Home Office returns

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Breeding programmes can be tightly controlled in accordance with the needs of the end user. Setting pre-determined targets minimises over production of animals which would otherwise be surplus to requirements.

Good working knowledge of the lines being actively bred allows optimum use of those animals in research programmes allows future requirements to be anticipated and minimises duplicate requests.

What other measures apart from good experimental design will you use to minimise numbers?

The ability to freeze down and transfer embryos will reduce animal use by removing the need to keep redundant colonies. It will also insure against loss of lines and allow rederivation of lines if required.

Rederivation will allow access to animals of high health status minimising experimental variation caused by disease. This will give more consistent results and therefore less animal wastage.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice and Rats will be used under this PPL

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

This PPL is based on researcher requirements. Mature animals are required to produce further animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The techniques are established and the limitations and potential problems are known.

The animals will be cared for by dedicated animal technologists who have the expertise and skills required in the breeding of the animals.

Experienced animal technicians are able to assess any welfare problems that may occur at an early stage and are able to determine appropriate end points in consultation with the NACWO and NVS.

The transgenic colonies will be maintained to the same high standards as all other animals in the unit, with health screening to FELASA standards.

No animals with genetic disabilities exceeding mild severity will be bred on this licence.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office

Breeding of Genetically Altered Animals Assessment Framework

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Consultation with a regional NC3R's representative who's role is to inform researchers and technicians of 3R's initiatives and funding opportunities. They also share best practice amongst facilities in the UK and encourage technician and researcher involvement in 3R's activities around the country.

Our local AWERB also has a 3R's sub-committee where the 3R's are discussed and new approaches disseminated to researchers in-house.

Explain the choice ofspecies and the related life stages

Age appropriate animals are required for the project.

Home Office

NON-TECHNICAL SUMMARY

27. Cancer Pathways in Metabolic Disease

Project duration

1 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this proposal is to finish off projects in which we have been studying cancer-associated pathways (and in particular the Mdm2/p53 pathway) in regulating metabolic disease *in vivo.* This has allowed us to understand how p53 controls diseases such as diabetes and obesity and how metabolic stress can activate the p53 signalling pathway.

Another gene of interest we have been studying is the REDACTED, which is important for cell death as well as fat regulation; and how deletion of this gene manifests global metabolic changes in the context of the whole animal. Cohorts for this project are ongoing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have successfully delivered on the aims of our previous project licence (12 papers published thus far) but there are one or two outstanding experiments which we will complete in the next 6 months (slightly beyond the expiry date of the current licence). It will be important to take these experiments to conclusion in order to complete our studies, publish our results and deliver on the large grant which funded these works exploring how the REDACTED pathway contributes to metabolic disorders.

A manuscript outlining the functionality of the REDACTED gene is in preparation and will lead on to a body of work specifically interrogating REDACTED in REDACTED which will be covered by a focused project licence (in preparation). This licence will permit us to maintain these colonies until the new licence is in place.

What outputs do you think you will see at the end of this project?

New Information: These studies offer the potential to better understand the signalling pathways and biological processes controlling cellular metabolism and will give insight into how cellular wiring goes awry in these diseases in a physiologically relevant system.

Publications: Work arising from these studies will be published in peer review journals and presented at national and international meetings to disseminate knowledge (to scientists and clinicians). We will also publicise our results to the public at open evenings, social media, and on our website.

Products: There may be therapies which have been developed to treat cancer (eg p53-centred therapeutics) which could be used to treat other metabolic diseases and vice versa where drugs such as metformin used to treat diabetes may be identified as novel cancer treatments. The REDACTED knockout mouse model is the first such murine model of REDACTED and has been disseminated to many labs throughout the world.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The knowledge gained from these studies will be of interest to the scientific community (short term) which will lay foundations for future scientific endeavours which could ultimately lead to new therapeutic approaches (long term) benefiting cancer patients and patients who suffer from metabolic disorders such as diabetes and REDACTED.

How will you maximise the outputs of your work?

We will continue to collaborate with colleagues who are experts in this field and disseminate this work through publication and social media at the earliest opportunity. Many international collaborations have been established through sharing of the REDACTED-KO mouse line.

Species and numbers of animals expected to be used

- Mice: No more than 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Genetically altered animals will be bred together to achieve specific cohorts of interest which will be aged and tissue harvested to ascertain the effects of these genetic alterations in the whole animal. Animals may be put on a special high fat diet to modify their metabolism and test how these specific genetic changes adapt to these metabolic conditions. To better understand these changes we may administer labelling reagents prior to humanely culling animals which aids our analysis of the tissue. Animals will be maximally aged to 12 months of age.

A particular cohort of genetically altered animals will be given a high fat diet to induce metabolic changes and predispose to the development of liver cancer. Animals typically develop liver cancer between 4-6 months of age.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Normal animals placed on high fat diet may gain weight but are healthy otherwise. Males with a REDACTED-KO mutation have a slightly reduced body weight but this does not cause welfare concerns and the mice are otherwise healthy. In a small cohort (<40) we expect animals to develop liver cancer which will result in abdominal distension. Any animal displaying discomfort or abnormal signs will be monitored daily and humanely culled if abdominal distension reduces mobility, or the animal also shows signs of subdued behaviour and/or abnormal breathing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals on this project will have a subthreshold severity meaning they will show no harm. A small proportion (<20%) will be placed on a high fat diet and/or undergo non-invasive imaging which maximally will be a moderate severity due to repeated anaesthesia. Less than 40 animals will develop liver disease or cancer and will exhibit moderate clinical symptoms.

What will happen to the animals at the end of the study?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studying metabolism in the lab has obvious limitations and the true effect on energy metabolism as a result of dietary changes can best be achieved in a living organism. Long term consequence of altered metabolism (e.g. diabetes) is also best recapitulated in the living animal. Furthermore, tissues are made up of different cell types which can all contribute to cues influencing the reaction to metabolic stresses which is often difficult to recapitulate in non-animal alternatives.

What was your strategy for searching for non-animal alternatives?

Our *in vivo* mouse experiments are an extension of solid *in vitro* observations and only progress using mice when sufficient rationale is obtained based on *in vitro* cell culture, including embryonic stem cells and where possible 3D organoids.

Why were they not suitable?

In vitro models do not allow the overall effects of systemic metabolic disease to be fully modelled in different tissues or the circulating blood system of a physiological animal. In addition the long term

effects of sustained metabolic changes (such as fat deposition) is difficult to recapitulate in a tissue culture dish or 3D models as these changes elicit systemic alterations within the whole animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of the animals will be used in a breeding programme to attain the relevant genetic alterations of interest. We request 800 breeding animals because of the complex genetics in the resulting cohort animals. These cohort animals will be transferred to an end-use protocol for ageing and further assessment (not expected to be more than 120). This will allow us to carry out additional timepoints with a reporter mouse to subsidise a timecourse study that is currently near to completion. Experimental cohorts for one or two key studies have already been generated on a transferring licence, for example we anticipate transferring a cohort of no more than 50 animals to be completed under protocol 3 and 30 animals to protocol 2.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Numbers are calculated based on our own experience, using pilot studies in the first instance, to inform on the numbers we require with advice from our in-house statisticians. We try to scale up experiments and stop recruiting into cohorts when we achieve a statistically significant result.

What other measures apart from good experimental design will you use to minimise numbers?

We use inbred strains of mice which are nearly identical to other in genotype resulting in less variability between animals and allow us to use fewer animals to achieve a statistically significant result. We routinely perform pilot experiments using only a few animals, before scaling up to the appropriate numbers for a full study. We maximise the breeding programme to generate the most effective breeders to create the genetics of interest.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use widely applied techniques to study metabolism, primarily using changes to diet (eg high fat diet) which requires less handling of animals. Regular monitoring of weight/welfare will allow us to complete studies at the earliest endpoint in which we observe a significant result to prevent unnecessary suffering by extending the study period.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The mouse is a mammal and warm-blooded which shares many features of human metabolism not found in other cold-blooded species such as flies and worms. Furthermore with the ease of manipulating the genetics of the mouse, this makes the mouse the lowest and best model organism to understand the genetic changes observed in metabolic diseases.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All animals are health checked daily in addition to the routine monitoring by the researcher. Where any animal shows abnormal behaviour this animal is placed on enhanced inspection. Study animals are often weighed at regular intervals to detect early clinical signs.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We adhere to the Workman Guidelines for the welfare and use of animals in cancer research and regularly review the NC3Rs website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We continually review our processes and take advice from the Named Veterinary Surgeons, Home Office Inspectors and the NC3Rs website. Our technical staff are very proactive in adopting 3Rs advancements such as non-aversion handling and single-use needles.

Explain the choice of species and the related life stages

Genetically altered animals (GAA) allow us to assess the relevance of a particular signalling pathway in the normal physiological and disease settings using the complete animal. This is particularly relevant when studying metabolic disorders. We are using GAA animals to model how a particular gene alteration associated with a genetic disorder called REDACTED manifests the clinical symptoms in these patients.

Metabolic syndrome is an enormous health burden and is closely linked to the formation of liver cancer. We are also studying the commonly altered p53-MDM2 signalling pathway in a metabolic syndrome that predisposes to liver cancer.

Home Office

NON-TECHNICAL SUMMARY

28. Cardiovascular and Metabolic Effects of Uraemia

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Kidney disease, Heart failure, Hypertension, Diabetes, Stroke

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The increased incidence of artery disease is a significant global health issue. Kidney failure is a major trigger for artery disease and around 50% of patients with kidney disease die of the consequences of artery disease eg: strokes, heart attacks. In patients suffering with both kidney disease and diabetes (25–40% of patients with kidney failure are diabetic), the chance of a cardiovascular caused death is even higher. We believe that this combination of diabetes with kidney failure creates an entirely unique disease scenario requiring treatments distinctive from those given to diabetics or kidney disease patients alone, however much more work needs to be done to further our knowledge of the causes of kidney disease and its pathology if we are to improve its treatment.

Our project has two objectives. Firstly to increase our understanding of kidney disease and its effect on the heart and blood vessels.

Our second aim is to work towards identifying new treatment approaches for these conditions in collaboration with the pharmaceutical industry. We do this on a contractual basis using the same protocols that we use in our own research specifically to test drugs developed for kidney disease.

Much research is being done to develop new drugs for treating kidney disease, diabetes and the associated symptoms eg: high blood pressure, however the fact that the kidney is a major site of drug metabolism means that a diseased kidney may not be able to metabolise many drugs rendering them ineffective. To overcome this, an immense diversity of drugs need to be developed and tested.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

In the long term these investigations are expected to benefit medicine, particularly in the fields of kidney and heart disease and diabetes. The possibility that new disease targets may be identified, for which new drugs could be developed will ultimately provide a major benefit to public health.

Collaboration with the pharmaceutical industry also has benefits in terms of animal welfare. If we did not offer our expertise to industry our clients would have to set up their own animal facilities which would be costly, time consuming, would mean greater animal usage and would involve other groups working through the process of training and model introduction in order to build up the necessary skills. Alternatively they would seek out other research establishments willing to collaborate with them perhaps in places which apply less monitoring of animal well-being. In both these cases the overall result would be greater animal suffering.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use a maximum of 5500 mice and 3500 rats over the 5 year course of the licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

In our research we induce kidney disease in the animals either through surgery on their kidneys or by administering a substance that causes the disease. We then treat the animals with a test agent and monitor its effect against the disease. We compare healthy and diseased animals. Diseased animals begin to display symptoms of kidney failure and these symptoms gradually worsen over the course of the experiment. Although some of our disease models have the potential to make the animals profoundly ill, we limit the time of the duration of the disease so that the experiment is finished before the animals reach that severely ill state. During the course of the experiment we perform tests on the animals that may cause minor distress such as taking blood while the animal is conscious held within a restrainer or echocardiography measurements while the animal is anaesthetised. At the end of the experiments animals are placed under deep anaesthesia so that concluding tests/ measurements can be performed. Animals may be killed under anaesthetic or by other humane methods. Blood/organs are extracted for analysis in the laboratory.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The bulk of our work is carried out using kidney and heart cells grown in our laboratory. These experiments combined with computer based studies enable us to test our ideas regarding disease pathways and possible cures. When we eventually find a reliable promising treatment we carry it forward to be tested in a more complex and therefore realistic disease situation, that is, in an animal with kidney disease. We have to perform these final experiments because the response to a particular therapy observed in a single group of cells growing on a plate may turn out to be very different in a complex living organism where there is the possibility of interaction between many different cell types. Mice and rats share many similarities to humans in terms of body responses to disease so they are our preferred animal choice. However we are aware of recent advancements in our field of interest using lower classed animal species eg: fish larvae, and we intend to explore these alternative possibilities in the future.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Over the last 5 years we have reduced our rat usage by 50% by switching to using mice. This has allowed us to use mice which have been genetically modified. Genetic modifications are changes made to the animal's DNA which remove or upregulate a particular characteristic (protein) in that animal which we think may be causing the disease. When we induce kidney disease in that animal we may find that it is protected from the disease compared to normal animals because of that DNA change. In this way our our experiments are more efficient than when using normal animals resulting in a smaller number of experiments required and less animals needed per experiment resulting in a reduced number of animals overall.

We have also improved our methods of inducing kidney disease in mice by changing from a surgical method to one using a modified diet. This has the advantage of being easier to replicate (as surgery is subject to variability depending on the surgeon). Again this results in fewer animals needed for each experiment and has the added advantage of being much less traumatic to the animals. We still use surgical methods in rats because our diet induced disease is not yet compatible in rats however we are continually developing this method with the intention of using it in rats in future. We have further decreased our animal usage by designing experiments in which (where possible) we can use historical data for the ‘sham’ (operated on but not treated with drugs) animals.

Where surgical methods are unavoidable we ensure that the surgery is performed by a small number of highly experienced staff which limits variability between individual surgeons again meaning fewer animals per experiment.

We employ the ‘3rs – Reduction’ statistical package when planning our experiments. This package is designed to help researchers achieve the experimental outcomes they want using the minimum numbers of animals.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Over the course of the last project licence we have increased our usage of genetically modified mice allowing us to target our experiments better, using smaller and fewer experiments and consequently resulting in fewer animals used overall. We have introduced some additional procedures which are designed specifically at refinement. The major change is the replacement of surgery induced kidney disease with diet induced kidney disease in mice. This method is expected to produce similar results but without subjecting animals to the trauma or operator variability that surgery inevitably causes. Although we have already been employing this diet we have further decreased its harmful effects by reducing the amount of adenine in the diet and also by allowing interchange between adenine diet and normal diet during the experimental term. Our intention is to continue refining this method specifically by:

1. Adding other components to the adenine diet to improve its taste making it more palatable with the mice so that they gain weight at the same rate as animals receiving normal diet.

2. Developing the diet for rats so that it too can replace surgery as a means of inducing kidney disease in rats.

Recently (following a ‘Refinement’ publication by another group) we have begun adding softened food onto the cage floor enabling animals (particularly those recovering from traumatic procedures (eg: surgery to induce kidney disease / streptozotocin injection to induce diabetes) to access the food more easily thus improving recovery. We have also reduced the time animals spend singly housed in urine specimen collection cages from previous 48 hours to a current maximum of 24 hours. In our ‘streptozotocin (STZ) induced diabetic nephropathy’ protocol, we have reduced overall harm by changing the method of STZ administration from one large dose to 5 consecutive low doses spread over 5 days since small doses of STZ are better tolerated by the animals.

Less evolved species eg: fish, are proving to be more and more effective in kidney and heart studies and our long term intention is to devise renal disease models in fish and by so doing reduce our mouse usage.

Home Office

NON-TECHNICAL SUMMARY

29. Cell death, inflammation and cancer in the GI tract

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged, juvenile
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The regulation of cell death and inflammation by both genetic and environmental factors is fundamentally important for the maintenance of homeostasis in the gastrointestinal tract. If these factors are not regulated appropriately, they may contribute to the development of gastrointestinal diseases such as inflammatory bowel disease or cancer and may additionally lead to systemic diseases such as sepsis.

We aim to:

1. define the regulation of cell death, cell shedding and inflammation in the gastrointestinal tract at the molecular level at baseline and throughout the stages of development of gastrointestinal inflammation, chemotherapy-induced mucositis and gastrointestinal cancer.

2. investigate how genetic and environmental (eg diet and microbiome) factors contribute to the development of gastrointestinal and systemic disease

3. identify new therapeutic approaches to treat gastrointestinal inflammation and cancer

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The gastrointestinal tract plays a very vital and unique role in that it is exquisitely controlled to regulate the absorption of substances across an epithelial cell layer that is only one cell thick, yet prevents the passage of the intestinal microbiome and mycobiome into the body that can cause systemic inflammation. However, the regulation of homeostasis in the gastrointestinal tract and how this is perturbed during the development of gastrointestinal disease is currently not fully understood. Furthering our knowledge of how genetic and environmental factors contribute towards regulating the gastrointestinal mucosa will identify new molecular targets, for which new pharmaceutical products may be developed and may also lead to the development of new diagnostic tests and techniques for gastrointestinal disease.

What outputs do you think you will see at the end of this project?

This project will produce a wide range of data that will provide extra knowledge about how the normal gastrointestinal tract functions and how this is perturbed during several gastrointestinal inflammatory

diseases and cancer. We aim to publish these findings in high quality publications in high quality peer reviewed journals. Several are anticipated along the themes of NFkB signalling within the gastrointestinal epithelium, mechanisms of chemotherapy and tyrosine kinase-induced gastrointestinal toxicity, intestinal cell shedding mechanisms and their inhibition, genetic and environmental changes to the intestinal barrier (eg by dietary emulsifiers) and intestinal microbiome changes in response to diet or infection. Data will also be presented at national and international conferences such as the Digestive Disease Week conference in the US and the British Society of Gastroenterology meeting in the UK. We aim to contribute to both scientific and societal impact and will engage with public engagement opportunities to present our work to a wider audience locally and nationally.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Short term

Our studies are mainly mechanistic in nature and therefore will benefit the scientific community in the short term. We will identify mechanisms that may then be targeted to prevent gastrointestinal inflammation and cancer. These studies will where possible be informed by human patient data (from literature and locally from clinical trials and strong links with local hospitals) and will also inform the collection of new data from patients.

Long term

We aim to improve patient quality of life by translating our findings into the clinic. Our mechanistic insight will contribute to novel treatment strategies and drug development for IBD and gastrointestinal cancer.

How will you maximise the outputs of your work?

We have numerous collaborations that will help disseminate new knowledge rapidly. Our interactions extend from Universities worldwide to SMEs and large pharmaceutical companies worldwide. We aim to publish unsuccessful approaches alongside our successful approaches in peer reviewed journals.

One particular internal collaboration makes us well placed to try and achieve our long term aims of translating our mechanistic findings into the clinic. We will continue and further our collaboration with the Department of Pharmacology to cross reference how our mechanistic data fits with current understanding of drug interactions, PK/PD modelling, current treatment approaches, clinical trials, human tissue biobanks. Additional support is available from mathematical and computational modellers based worldwide and accessible through a large consortium project with the aim of shortening the time of drug development through clinical trials and reducing the amount of *in vivo* experimentation necessary in drug development.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

We aim to cause the least suffering possible to animals that allows us to answer appropriate scientific questions about gut health and disease. The diseases and mechanisms under investigation are all associated with the gastrointestinal tract and include inflammatory bowel disease, gastric and colorectal cancer and mechanisms of diarrhoea and cell death in response to various drugs. In order to investigate how to prevent or cure these diseases, we need to conduct animal experimentation, normally in mice but in rare cases, rats may be a more appropriate model organism. Typically, we will either inject a substance or administer a substance in the drinking water or diet and then kill animals to investigate their gastrointestinal tract from 0-1 week. A smaller number of other studies are of longer duration up to 6 months to 1 year (such as during the investigation of *Helicobacter* colonisation or the production of tumours) which takes longer to cause the changes in the gastrointestinal tract. In such long term studies, there is not normally any further intervention during the development of the disease and animals are closely monitored. A small number of surgical studies are used to implant tumours into the intestine as this is the correct anatomical location for the disease we study, in such cases, animals all receive appropriate anaesthesia and pain relief. Other surgical studies are conducted under terminal anaesthetic and mice are not allowed to recover so do not feel any pain or discomfort. At the end of all experiments, animals are humanely killed and tissues are taken for further quantitative analysis in the laboratory.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We aim to end some studies before the animals feel any effects of the intervention. This is particularly relevant when we are investigating how the disease is initiated. However, this is not possible in all cases as animals need to develop the disease/condition in order for us to investigate how to prevent or treat it. In such cases, we typically kill animals as soon as they develop the disease and before they have any long term lasting effects. The diseases relevant to these studies are related to the adverse effects of weight loss and diarrhoea and we aim to minimise these effects as much as possible. Animals are monitored and their data recorded on a regular basis and they are killed promptly if they lose more than 20% of their original weight and if they show other signs of ill health such as hunching and reduced movement in order to prevent any further suffering. The vast majority of animals will be killed at the intended experimental end point and show more mild clinical signs of the disease.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of mice (and potentially a much smaller number of rats) under investigation will experience 'mild' severity during our protocols. Some techniques that require the development of disease will lead to 'moderate' severity banding in these animals.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst standard *in vitro* tissue culture techniques are informative, they are not able to recapitulate the complex environment found in the gastrointestinal tract. The interactions of multiple cell populations such as epithelial cells that form the inside layer of the gut, with cells of the immune system and surrounding stromal cells are needed to address all of our research questions, and interactions such as this are currently unable to be accurately generated in cell culture experiments.

What was your strategy for searching for non-animal alternatives?

We continue to undertake cell death and proliferation assays in cultured cell lines, primary cells and long lived organoid lines (gastroid, enteroid and colonoid) extracted from human and mouse tissue as well as in mice *in vivo*. While cell death assays in isolated cells or cell culture can be informative, they do not precisely reproduce cell death mechanisms *in vivo*. This is because the surrounding environment including neighbouring cells and extracellular matrix, growth factors and circulating hormones profoundly influence cell death, proliferation and inflammation processes. We have made progress in developing co-culture assays between bone marrow-derived dendritic cells and intestinal organoids, however, immune cells are widely recognised to change phenotype as soon as they are cultured. It is not currently clear as to how many cells are required to mimic the environment in the intestinal mucosa and other cellular compartments such as different immune cells, gut-specific immune cells, myofibroblasts and neurons, blood supply, oxygen supply, currently unknown signalling components are also not considered. Therefore, the complexity of this *in vivo* environment cannot currently be accurately reproduced *in vitro*. *In vitro/ex vivo* experiments will always be performed if possible and will also be used to inform doses and time-points for *in vivo* investigation.

Why were they not suitable?

Whilst the majority of cell lines are cancer derived, the growth and induction of tumours is heavily dependent on the complex environment and cell types only found *in vivo*. For this reason we shall employ either the standard nude mouse model or syngeneic models to study the effect of agents on tumour growth and administration of carcinogens for the induction of carcinogenesis.

Colitis is a complex inflammatory reaction in the intestinal wall involving multiple cell types acting sequentially. This again cannot currently be reproduced *in vitro*. However useful information can be gained by studying biopsies obtained from human patients with colitis. Wherever possible we shall use human biopsy samples in our studies.

Colonisation of the stomach with *Helicobacter species* or distal gut with other bacterial species causes a complex inflammatory and atrophic reaction in the gastointestinal mucosa. This cannot be reproduced *in vitro*. However, it is possible and valid to study the effects of *Helicobacter species* and other bacterial species on individual signalling pathways in cultured cells. We shall maximise this latter approach as much as possible.

The intestinal microbiome is complex and many bacterial species cannot be cultured *ex vivo*. To address the complexity of the intestinal microbiome, this requires *in vivo* experimentation. Human faecal and urine samples are used in preference, however, it is impossible to control genetics and dietary components in the human population. The use of inbred mice that have the same diet can control for both genetic and environmental effects.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Where possible, we will use tissue culture techniques and human tissue biopsies to address our research questions. We have previously established that a minimum of 4 mice per experimental group are required for reliable data generation in radiation and mucositis studies, 6 mice are required per group for *Helicobacter* infection studies and that there is a greater degree of variation during experimental colitis studies resulting in the requirement for minimum group sizes of 10 mice. We will therefore estimate numbers of animals based on our previous studies and from other published data. When necessary, we will seek statistical advice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The exact number of animals required will vary with each particular experimental design but we will aim to use data from every animal to its full potential. We will first utilise data from our own studies and the literature to inform any new studies. Online tools such as the NC3R's Experimental Design Assistant will then be used to further inform our studies as these will help to build a visual representation of each experimental plan and provide feedback about experimental design, sample size and statistical analysis methods. We will ensure that appropriate statistical power is achieved for each study and will seek statistical advice for complex multifactorial studies. Potential sources of bias will be considered,

for instance, the allocation of mice to groups at the start of each experiment will be considered (eg random, weight-matched, sex-matched).

Factors that will determine sample size will include natural animal to animal genetic variability, variability in response to a drug/treatment and the administration route, variations in intestinal microbiota and other environmental conditions within the animal unit. By considering these factors and addressing as best as possible the sources of bias, we will produce reliable and reproducible data from the smallest number of animals possible.

What other measures apart from good experimental design will you use to minimise numbers?

For each and every experiment, as part of good laboratory practice, we will write an experimental protocol which includes:

1. a statement of the objective(s)

2. a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group) and the experimental material

3. an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated).

Pilot studies will always be conducted with two mice if we have no prior experience of the experimental approach, time-course or dose and this will be informed by extensive literature searching.

We aim to provide tissues of interest to other researchers interested in different organ systems where possible both at the REDACTED of Liverpool and at other institutions.

I am actively involved with a project (TransQST) that is aiming to reduce the number of necessary *in vivo* studies by replacing them where possible with computational and mathematical models. Models include how intestinal epithelial cells respond to damage inducing stimuli in terms of their dynamics, proliferative activity and their resistance to cell death. Models may inform how may animals are necessary to ensure a reliable result from computational modelling of further doses and time-points that look at the tragectory of disease.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The structure and function of the gastrointestinal tract of mice is similar to that of the human and there are many genetically manipulated strains of mice are available that are suitable for the proposed studies. Therefore, the majority of our studies will be conducted in mice. We will also occasionally perform experiments in rats particularly to assess whether there are any species differences between rats and mice. Data from our previous and future experiments will be used to determine the minimum doses of substances required to exert biological effects in order to avoid doses that induce significant toxicity. Where possible, time-points will be analysed when there are early signs of disease but no clinical ill health.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Zebra fish and drosophila are being used increasingly for the study of biological systems and these organisms are both suitable for genetic manipulation. The structure of drosophila intestine is however substantially different from that of mammals and would be unsuitable for most of our studies; however, the zebra fish intestine does display structural similarity. Little is currently known about the dynamics of zebra fish intestine, however we will monitor the field of investigation closely and will include zebra fish in our experimental plans when information about the intestinal epithelia becomes sufficient to enable us to design appropriate experiments.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Data from previous and future experiments will be analysed in order to use the minimum doses of substances required to exert biological effects, rather than doses that induce significant toxicity. In addition, where possible and certainly in all initial experiments, we will analyse time-points when there are early signs of disease but no clinical manifestations (e.g. where possible we will analyse development of aberrant crypt foci in the colon rather than actual tumours).

Wherever necessary we shall use local and general anaesthesia to minimise animal suffering. In anaesthetic with recovery protocols, mice will be administered with pain releif. In grafting experiments we shall kill the mice if the tumours grow to more than 12.5mm in diameter. In all long term experiments, animals will be killed if they lose more than 20% of their initial body weight and if they show any other signs of ill health such as hunching, lack of group behaviour or breathing difficulties.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the ARRIVE guidelines as recommended by the NC3Rs

For tumour studies, recommendations by Workman *et al*, British Journal of Cancer, 2010 will be adhered to, for instance to implement a maximal allowable tumour size.

Laboratory Animal Science Association (LASA) best practice guidelines will be adhered to for blood sampling.

The Grimace scale of facial expressions will be used to inform on animal pain condition in mice.

The Experimental Design Hub will be consulted when establishing a new experimental protocol and is available through the NC3Rs website.

There is a wealthy resource of guidance for best practice training and protocols available through the NC3Rs website, for example, handling and restraint, euthanasia, humane endpoints, welfare assessment, microsampling, anaesthesia, analgesia. PIL holders who are required to undertake any of these activities will be signposted to this website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I and personal licencees will be encouraged to attend all relevant NC3R-related seminars organised by our REDACTED. I encourage all PIL users who operate under authority of this licence to view the 3Rs training video on the NC3Rs website (https://www.nc3rs.org.uk/contemporary-training-3rs) and read the documentation on 'Responsibility in the use of animals in bioscience research'. REDACTED to develop organoid co-culture systems to reduce and replace some *in vivo* experimentation. There is a trainers email that is regularly supplied to project licencees and trainers, a newsletter and a local SharePoint site for all animal users that documents any advances in the 3Rs that is maintained by our REDACTED and 3Rs champions. I aim to implement any advice given and will be actively involved with ensuring that all PIL holders are compliant with any recommended advances. We will discuss 3Rs policies and principles regularly at lab meetings and also discuss any advances in this area we have made (particularly in the development of 3D organoid co-culture) with colleagues locally and in posters/oral presentations at meetings.

Explain the choice ofspecies and the related life stages

Mice are the least sentient animal for the proposed studies. All studies have the requirement for a gastrointestinal tract that functions as a human gut functions. Less sentient animals show great differences in how their gut functions compared to humans. The diseases under investigation are normally associated with juvenile to adult and ageing adult human populations and therefore, this is the choice of life stage in our studies.

Home Office

NON-TECHNICAL SUMMARY

30. Cell signalling in neural and cardiovascular development and regeneration

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project seeks to define molecular and cellular mechanisms that help establish functional neuronal and vascular networks and to determine whether these mechanisms contribute to organ regeneration and repair in diseases of the nervous and cardiovascular systems.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The knowledge gained from work carried out under this licence will help us understand the genetic and anatomic basis of birth defects. This knowledge will also provide vital information on pathways relevant for the design of therapeutic strategies aimed at repairing neural and vascular networks in damaged organs.

What outputs do you think you will see at the end of this project?

To date, our basic research programme has yielded several seminal contributions to the fields of neuronal and vascular biology that significantly increased the current knowledge base. Thus, we have provided insight into the mechanisms of blood vessel growth and remodelling during normal development, the guidance cues used by neurons and neural crest cells to correctly position themselves in the developing body, and the regulation of blood vessel leakage in the adult organisms. Moreover, we have uncovered roles for some of these pathways in adult nervous system repair.

Our current project will continue to advance knowledge of developmental processes to understand how functional cardiovasculature and neural structures form. We will strive for this work to be published in high impact journals with broad readership across fundamental biomedicine and in an open access format. Thereby, this knowledge will benefit national and international researchers in the areas of cardiovascular development, neurodevelopment and molecular genetics.

Much of our work will also have a translational element by advancing knowledge of fundamental pathophysiological processes that are perturbed in human disease. The application of this new knowledge will, in the long term, provide vital new information to achieve clinical goals. For example, our work on signalling pathways and progenitor populations that control the pathophysiology and regeneration of neurovascular tissues may catalyse novel treatments of acquired conditions with vascular or neuronal involvement, such as nerve injury of the limb or cornea. As another example, learning how to grow functional new blood vessels in ischemic diseases or prevent pathological vascular remodelling in eye disease or the asthmatic lung will lay the foundations for therapeutic correction of these processes to alleviate disease severity. To ensure that such outputs are achieved, we will submit suitable findings to journals at the interface of fundamental and translational research that offer an open access format.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This project will significantly enhance our knowledge of the developmental processes that establish functional cardiovasculature and nervous system wiring patterns.

Knowledge of the developmental processes that underlie and promote cardiovascular health and neurodevelopment is key to understanding how we function as adult human beings. An immediate impact of this project is its opportunity to raise awareness and understanding of science and research through public dissemination of novel findings and explaining their significance.

In the medium term, this research will benefit translational researchers aiming to design new clinical tests for inherited diseases and those working on chronic inflammation or in regenerative medicine. For example, our work will identify novel functions for signalling pathways implicated in congenital and acquired disease that may serve as biomarkers and describe novel types or progenitor cells for vascular growth that may be used for preclinical work in the area of organ regeneration.

In the long term, the academic knowledge generated will thereby benefit clinical medicine to impact positively on public health via novel diagnostics and new pharmacological treatments for patients with cardiovascular and neurological disorders.

In summary, the knowledge we will generate will benefit basic and translational scientists, clinicians and commercial sector researchers in the areas of cardiovascular development and disease, neurodevelopment, neural repair and molecular genetics.

How will you maximise the outputs of your work?

To disseminate knowledge widely within the research community, the team will:

- Publish data in relevant peer-reviewed international journals, most of them in open access format. They will strive to publish both successful and unsuccessful approaches, as they have done in the past.
- Present findings at national and international meetings.
- Engage with media teams at our establishment's press office and funding agencies to communicate key findings to the lay public.
- Where appropriate, incorporate novel information also into lectures for undergraduate and graduate students enrolled in programmes at our establishment.

To raise awareness and understanding of biomedical research, the team will engage with the public:

- To maximise the availability of our research, results from this project will be published in high-impact journals with open access-compliant policies.
- The team will promote the findings of our studies on our establishment's web pages.

- The team will liaise with our establishment's and the funding agencies' media services to disseminate findings through public websites and national media.

To enable potential clinical exploitation, the team will:

- Publish results in a timely manner in journals read by scientists and clinicians and present at national and international conferences attended by scientists and clinicians.
- Seek collaborations with clinicians to advance new strategies for translation. Key to achieving this objective is the team's location in an environment of academic - health sciences partnerships between our establishment and NHS hospital trusts, such as, but not restricted to, the REDACTED.

Species and numbers of animals expected to be used

- Mice: 16000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most animals in this project will be genotyped and then used as tissue donors after a humane form of killing (Schedule 1 method). A subset of animals will receive injections that do not cause more than mild and transient discomfort. Some animals will be injured non-invasively, for example with a laser or by modulating environmental oxygen, whilst other will undergo superficial or invasive surgery. Some animals will be exposed to mild allergens. Each animal will only undergo one type of surgical procedure only, and only experience this procedure once. Most experiments involving surgery are completed within two weeks.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

A small subset of animals may experience some pain, in particular after surgery. The period of pain is expected to be relatively short for most protocols, i.e. 24 – 48 hours, although it may last longer in the hindlimb and myocardial ischemia protocols. Pain will be controlled with methods advised by the veterinarian. For protocols with a maximum severity classification of mild or moderate, animals will be culled if they lose 10 or 15% of their pre-treatment weight, as this would indicate that pain or other adverse effects stop them from feeding sufficiently. Some animals will receive eye injuries that may

impair vision for up to two weeks, but this is not expected to impact on their behaviour, because mice rely heavily on their sense of smell and touch instead of vision. Some animals will receive a leg injury, but this is not expected to impair their movement or feeding behaviour, because mice can move well on three legs; moreover, these injuries typically heal extremely well within 2 weeks. Some neonatal animals will receive a heart injury, but this also heals extremely well within 2 weeks in the majority of cases. Some animals will be exposed to mild allergens, which usually cause only mild symptoms such as sneezing or scratching. Should animals display abnormal behaviour such as a hunched posture, eye scratching autotomy, laboured breathing or lack of movement or weight loss, then they will be killed by an approved method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity experienced by animals will vary from sub-threshold for the vast majority to mild for 20% and moderate for around 10%. Unexpected phenotypes due to a novel treatment or genotype will likely be rare, as most substances and genotypes to be used have been previously studied. Nevertheless, mice will be monitored closely to ensure that progression to severe clinical signs is prevented.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The principal aim of this project is to understand the molecular and cellular mechanisms that control the growth and behaviour of the vascular and neural cells that give rise to the nervous or cardiovascular systems. Specifically, the project seeks to understand the normal and abnormal development of cells in the context of whole organs, and to investigate how such developmental pathways may be exploited to promote organ repair in congenital and acquired diseases. There is currently no experimental approach that can completely replace the use of animals for such whole body fundamental and preclinical studies.
To achieve aims of the proposed research, the project will therefore use wild type and genetically altered mice.

What was your strategy for searching for non-animal alternatives?

Experimental studies utilising bioinformatics and tissue culture models have previously identified candidate molecules and cellular pathways that may prevent excessive injury or aid tissue repair and

regeneration in vascular or neuronal disease. This project will continue to use such methods to identify further candidates and identify regulatory relationships between molecules and signalling pathways, reducing the number of animals required.

Why were they not suitable?

REDACTED signalling pathways that may control the behaviour of vascular and neural cells in vivo. However, they have not established the precise function of these candidate pathways in vivo. For example, we found that a signalling pathway identified in cultured endothelial cells is not essential for blood vessel growth, as was predicted from in vitro work, but instead controlled neuronal behaviour in vivo. The experiments in this project are therefore designed to test predictions derived from in vitro models in the context of real tissues, which are composed of multiple cell types and in which several different signalling pathways operate in parallel to orchestrate physiological responses.

A second limitation of in vitro work is the inability to provide physiological evidence that a pathway identified in vitro controls the co-patterning of vessels and neurons in vivo, as no suitable in vitro models are presently available to study this interaction properly. For example, blood vessel networks change in response to perfusion and local oxygen demand, but neither parameter can be controlled appropriately in vitro models. Moreover, during organ repair, both neural and vascular networks are influenced by immune cells, which are recruited to sites of injury and release a wide variety of cytokines that can affect the behaviour of vascular and neural cells in ways that are poorly understood and can still not be modelled appropriately in vitro.

The above limitations will be overcome by manipulating candidate pathways through genetic or biochemical means in the context of a living animal and the subsequent analysis of organs with cell biological, histological and biochemical methods.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will breed approximately 40 different mouse strains with genetic modifications to maintain these modifications or to cross-breed them to each other in novel combinations, and then use the offspring to propagate the colony or for experiments. On average, this breeding programme will generate around 2400 mice per year. Around half of the offspring will be used for further colony maintenance or for experiments. The other half is expected to be of unwanted genotype or sex. Mice of unwanted genotype will be born due to the principles of Mendelian genetics, whereby a carrier trait will only be passed to half of the offspring, and the other half will be wild type. Mice of unwanted sex will be generated,

because we need many females for the breeding programme to carry litters and feed their offspring, but we will only need a few stud males carrying specific traits for breeding.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Mouse colonies will be maintained at the minimum size required to generate sufficient animals of appropriate genotypes and to allow repeats of experiments for statistical comparisons.

The breeding scheme used will minimise the generation of harmful mutants and involves mating asymptomatic carriers of harmful genetic modifications to wild type mice to maintain the colony or to each other or to asymptomatic carriers from other stains carrying different mutations. To minimize harm to individual animals, it is therefore unavoidable that we will generate many mice of unwanted genotypes. They will be culled without having undergone any specific procedure or used as controls in experiments to reduce breeding of wildtype animals or import from commercial breeders.

The mouse number used at each age and in each experiment will be kept to the minimum required to achieve reproducible and statistically significant data. Based on past experience, we need at least 5 and at most 10 adult animals or embryos for each genotype, developmental stage or experimental condition to achieve such significance.

Where possible, we will reduce the amount of in vivo work with in vitro models, in particular to identify new candidate pathways, by explanting tissues and generating stem cell lines. The animal number will therefore be kept to the minimum required to achieve the goals of this project.

What other measures apart from good experimental design will you use to minimise numbers?

Where possible, we will perform retinal imaging in longitudinal studies of live animals rather than cohort studies to examine how genetic changes or treatments affect eye health, as this will substantially reduce the number of animals required.

For experiments requiring the production of tissues, we will harvest multiple organs and share them out amongst team members to advance several research projects simultaneously, rather than allowing each team member to produce and use their own animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

To generate information relevant to humans, a mammalian model is important. Mice are the lowest mammalian species suitable for our studies and also provide the most refined model. Firstly, the planned programme of work builds on prior knowledge and experience in ours and many other laboratories on neurovascular development in mice. Secondly, mouse models are available with mutations in the molecules of interest. Thirdly, standardised assays are available that can evaluate vessel growth and neuronal behaviour in mouse tissues ex vivo to minimise the animal number used decrease severity.

Caesarean delivery will be used to prevent females from suffering when they develop complications during labour that could harm the safe delivery of their offspring. Caesarean delivery will also be used when there is reason to believe that pups may develop adverse side effects at birth due to congenital defects caused by their genetic make-up.

Oxygen-induced retinopathy and laser-induced choroidal neovascularisation will be used as non-invasive models of human eye disease. The former involves placing pups with their mothers into a high oxygen environment, similar to what is experienced by premature babies and causing similar pathology. The latter model recapitulates neurovascular changes in age-related macular degeneration and is also suitable for longitudinal studies, reducing the number of mice required at different time points compared to conventional methods that involve killing groups of mice at various time points for histological analysis. Despite retinal injury, mice do not show abnormal behaviour, presumably because the retina does not have sensory nerves and because mice do not rely on good vision but mostly on their keen sense ofsmell.

To investigate human eye diseases with severe visual impairment due to corneal disease, some experiments will need to induce corneal neovascularisation or injure corneal nerves. The former involves placing sutures into the cornea, similar to the procedure performed in humans with corneal transplantation. This procedure is very well tolerated, because the corneal epithelium heals fast, but the ensuing neovascularisation obscures vision. The corneal abrasion model causes moderate discomfort, because epithelial loss exposes sensory nerve endings, similar to the experience of having dust in the eye. However, the injury site heals rapidly in otherwise healthy mice, mostly within 24 hours and almost completely by 48 hours, and eye drops can be used to counter irritation and dry eye sensations.

Some experiments will surgically induce hindlimb ischemia in one of the hindlimbs of adult mice, because it is the most refined models to model key events that occur in human ischemic limb disease. Thus, even though surgical intervention will cause some discomfort, post-operative mice rarely show signs of distress and can walk and reach food sources without difficulty, because the three other legs remain fully functional. This model causes symptoms akin to those experienced by patients with diabetic limb disease.

Some experimental investigations will require induction of a myocardial infarct via using coronary artery ligation in neonates. These experiments will use neonatal mice rather than adult mice, because they typically recover well, due to the capacity of the neonatal heart to heal muscle and vascular injury. This model is therefore more refined than using adult mice and also more informative to identify the molecular and cellular mechanisms that actively promote repair and may be used to inform treatment of the human condition.

In some experiments, we will induce an asthmatic phenotype via repeated allergen administration. For these experiments, we will administer allergens that only induce mild asthmatic phenotypes and which do not cause anaphylaxis or other serious symptoms in mice. Specifically, we will use a combination of low dose ovalbumin and house dust mite extract, as these allergens are also relevant to a large number of human patients with asthma.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Data obtained from the research in lower vertebrate species, including fish and amphibians, will inform our experiments, but we cannot ourselves rely on these lower species to meet the objectives of this proposal, for the following reasons: Genetic lineage tracing is not currently possible in any species other than mouse. Moreover, many antibodies are available to identify cell types and specific proteins of interest in mouse, rat and human, but are rarely available for lower vertebrate species, including fish and amphibions. Further, the identity and behaviour of hematopoietic cell lineages and immune processes are significantly different between mammalian and lower vertebrate species, but most of our experiments consider hemato-vascular interactions as key processes that regulate physiology and pathology of the cardiovasculature. Amongst the mammalian systems, mice are the lowest mammalian species suitable for the proposed studies and the only species in which we can do genetic lineage tracing. To decrease severity, most mice will be used at the stages that are least sentient. In particular, embryonic forms will be used to investigate developmental defects wherever possible, as this prevents the birth of mice with severe adverse defects due to genetic defects. Neonates will be used instead of juveniles or adults for neovascularisation models when possible, as neonates are considered less sentient. The eye will be used as the preferred model to examine the mechanisms of neovascular disease, because we can cause diseases through non-invasive methods and because mice are not compromised by a temporary impairment of vision.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Where animals are at risk of developing adverse effects due to their genetic status or a procedure, the level of monitoring will be increased over that performed routinely for healthy animals, typically twice or three times daily. Appropriate post-operative care will be provided, including heating pads, and monitor the operated mice until they have recovered fully from anaesthesia. Post-operative pain will be minimised by providing analgesia, as advised by the veterinarian who oversees this project. Mice will be trained by gentle handling prior to carrying out any procedure and returned to their home cages after the procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The project will refer to published guidance, including:

- https://www.nc3rs.org.uk/3rs-resources

- https://www.lasa.co.uk/current_publications/

- local standard operating procedure approved by AWERB and our veterinarian

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The team working on this project will stay informed about advances in the 3Rs via the NC3R's website, newsletter and local events.

Explain the choice ofspecies and the related life stages

This project will use the mouse as a model organism, because suitable strains of genetically modified mice or natural mutants are already available or can be generated effectively to study the processes under investigation. Moreover, experiments will be able to draw on a large body of existing knowledge for this species to allow rapid progress and a large number of well-established procedures are available to model key aspects of human disease. Importantly, mouse cells have been found to employ signalling pathways and cellular mechanisms similar to human cells to control their behaviour, and it will therefore be possible to study human cells in vitro and mouse cells in vivo in a complementary manner. The project will use all life stages from embryo to adult to understand the origins and impacts of congenital diseases, determine the contribution of the cardiovasculature to the emergence of diseases and investigate neurovascular interactions in development, disease and organ repair.

NON-TECHNICAL SUMMARY

31. Cellular & Molecular Mechanisms of Skin Development and Repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this work is to understand how tissues repair after injury, with a particular emphasis on the mechanisms of scarring. The majority of our work is on skin, where we are working understand anatomical variations in wound healing since different body sites vary in their mechanisms and quality of repair. We also study tissue repair processes in the ovary, where there is damage inflicted by ovulation, because this wound heals remarkably well and has the potential to inform us about mechanisms of scar-free healing. We hope to ultimately extrapolate our findings from the mouse model to develop new treatments for human wound healing, fibrotic conditions, and site-specific skin diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are many human skin diseases and wound-associated pathologies with insufficient treatment options. This work tests a novel hypothesis that the development of the skin (which differs depending on the body site) holds clues for the regional variation in wound repair, scarring and disease manifestation. Also, our investigations on tissue repair in the ovary has the potential to help us understand different problems associated with ovulation, including ovarian cancer.

What outputs do you think you will see at the end of this project?

This project will lead to new information about: 1) skin development; 2) mechanisms of wound healing in the skin; 3) regional manifestation of skin diseases; and 4) mechanisms of tissue repair in the ovary. This information will be disseminated by publication as well as by conference presentations.

A potential longer-term output may include new treatment approaches to wound-associated pathologies and fibrotic conditions, since this work aims to identify novel therapeutic targets.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our short-term outputs (publications and conference presentations) will mostly benefit the relevant academic communities. We anticipate that our findings will have significant impact on scientific approaches to studying and modelling skin and wound healing and the reproductive biology field will also gain important information about the ovulatory process.

If our longer-term goal of discovering novel treatment strategies to improve wound repair and limit scarring/fibrosis is realised, those who could benefit would be patients with wound-associated

pathologies (from chronic wounds to keloid scars), and a range of skin diseases (e.g. lupus, scleroderma). Our investigations on tissue repair in the ovary has the potential to help us understand different problems associated with ovulation, including ovarian cancer.

How will you maximise the outputs of your work?

The outputs of this work will be maximised namely by wide dissemination of the results (including negative findings) via publication and conference presentations. Moreover, we will continue to collaborate with researchers whose work would benefit from our alternative development biology perspective on tissue repair and associated pathologies.

Species and numbers of animals expected to be used

- Mice: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In order to study ovulation in mice, we propose to inject them with hormones to trigger the ovarian cycle. This is a widely-used protocol that does not appear to cause any distress for the mice, as it requires only two injections and simply mimics the natural hormonal cycle of the mice (mild rating). Occasionally these animals may be treated with additional drugs (that are not expected to have adverse effects), or we may use genetically altered mice (causing no obvious health problems) to study the role of specific cells and molecules.

As for the skin wounds, they are usually made to back skin of adult mice, and typically 4mm in diameter (4 may be made on one mouse) or 1cm in length (2 may be made on one mouse) . Occasionally one 8mm wound will be made, or other sites of the body will be wounded to better reflect human diseases. For a small portion of our work, young pups may be wounded since before a certain stage of skin development scarring does not occur and this provides a window of opportunity to better understand the mechanisms of tissue repair. These procedures are performed under anaesthesia with pain relief provided, and are considered of moderate severity.

All animals are humanely culled (Schedule 1) at the end of these experiments.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The mice undergoing procedures on this licence are expected to experience mild or moderate effects, including transient pain and stress due to the skin wounding protocol and treatments by injection. The genetic alteration to mice we will use are not expected to have any (or only mild) ill-effects on health.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of the animals maintained and undergoing procedures will experience only mild or sub-threshold effects (75%). Only 25% of the mice used on this licence will be subjected to the wound protocol, therefore experiencing a procedure of moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complexity of tissue repair cannot be fully modelled in vitro or by using computer modelling because of the diverse cell populations and their intricate interactions. For example, recruitment of inflammatory cells from the circulation, or the importance of circulating hormones add layers of complexity that are impossible to fully recreate in culture or in silico systems.

What was your strategy for searching for non-animal alternatives?

We are able to study certain aspects of wound repair ex vivo, with organ/tissue culture. Our team regularly employs culture experiments (using mouse and human tissue) to investigate how specific molecules affect particular aspects of wound repair. We have spent significant time over the last few years developing in in vitro model of extracellular matrix, which mimics the architecture of scar tissue well, and is amenable to manipulation. Ultimately we aim to extrapolate our findings to human wound repair; accordingly, we use human tissue in culture whenever possible.

Why were they not suitable?

It extremely difficult to have “control” human in vivo wound experiment, or to analyse human ovulation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The maximum number of mice for this work is 4500. This reflects housing up to six genetically altered lines (and the minimum number of animals required for their generation) for approximately 1 year of experimentation each. This will require up to 2500 mice.

For the wound experiments (ovarian and skin) we have performed power calculations based on our experience (6-8 wounds are required per assay per time-point) and have safely estimated the number of mice required to analyse two groups (e.g. control vs treatment/wild-type vs genetically-altered) at numerous time-points. For the skin only, these numbers are then expanded since we will study multiple anatomical sites, at different stages of the life-course. These calculations have led us to predict usage not exceeding 1200 for skin wound studies, and 300 for ovarian wound studies.

Our phenotypic analyses of mouse strains that have novel timing/cell types for their genetic alterations will not exceed 500 mice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Yes. In designing these experiments we have received statistical advice (in particular for gene expression profiling experiments). Also, as much as possible we use histological approaches since numerous wound parameters can be analysed with only one sample. Finally, we have consulted with a number of NVS over the years to balance the size of the wound/number of wounds per mouse, so that we can have the most statistically powerful data possible, as well as maximising the information gained per mouse, without causing additional distress.

What other measures apart from good experimental design will you use to minimise numbers?

One strategy we use to minimise animal numbers is, experiments are designed with a staged approach so that early in vitro findings rationalise and justify follow-up in vivo work. Also, to keep numbers at a minimum, animals used in the wound studies may also provide the starting material for some of the cell culture experiments. Finally, the numbers of genetically altered mice are minimised by adopting efficient breeding strategies (e.g. keeping homozygous mice when practical).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mice to study both ovarian and skin wound healing, with less than 4500 being required over the 5 year project.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The relatively close evolutionary relationship between mouse and human make it an excellent model. Genetic resources in the mouse enable us to manipulate gene expression in different cell types and to genetically label and isolate distinct cell populations. In parallel, we are carrying out studies using human tissue biopsy material that will inform and be informed by, our mouse experiments.

We use the whole animal model in some instances since the complexity of tissue repair including an immune response cannot be accurately modelled in vitro or with computer modelling because of the diverse cell populations and their intricate interactions. Specifically, the proposed research uses a mouse model of wound repair, in which the skin of adult male mice (abdomen, back or cheek) is wounded using a biopsy punch that is 3mm in diameter. These wounds are as small as possible, yet sufficient to elicit a complete wound response and to provide the quantity of tissue required. All wounding procedures are performed under appropriate anaesthesia. During and after all procedures mice will be carefully monitored. In our experience, wounded mice do not show signs of pain or suffering, eating and drinking normally.

In parallel we are also using our animal models to generate source material for in vitro work. The development and use of in vitro methods serves both to reduce the total number of animals used but also offers a refinement to our experimental approaches as it allows us to dissect the influence of individual cell types.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will stay abreast of recommendations in terms of analgesia, and will continue to minimise the wound size/number required for our scientific questions.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office documentation, as well as publications in relevant academic literature will be regularly consulted.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Via the NC3R charity, and through regular communication about best practice with our Biological Services Unit, the NVS and NACWO, and the users group.

Explain the choice ofspecies and the related life stages

The relatively close evolutionary relationship between mouse and human make it an excellent model. Genetic resources in the mouse enable us to manipulate gene expression in different cell types and to genetically label and isolate distinct cell populations. Most of our studies will be conducted in young adults, however occasionally it will be necessary for us to investigate tissue repair in neonates, at a time when the skin is still developing and the cells within the tissue are more flexible in terms of the type of cell that they will become.

NON-TECHNICAL SUMMARY

32. Central nervous system nutrient sensing and microglia in development, health, aging and neurodegenerative disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project will explore how changes in nutrition can impact on brain function throughout life in both health and dementia (neurodegeneration). We will look at how nutrition, and cell sensing of nutrients impacts on cells in the brain, including the brains immune system cells (microglia) and try to understand how these factors may alter brain function.

A retrospective assessment of these aims will be due by 27 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Poor nutrition (either under or over) is a major global concern, affecting over 2 billion adults, and nearly 250 million children. There is a significant body of evidence demonstrating that nutritional availability can have a major impact on brain development and function throughout life, and studies have now identified systems that regulate how our cells respond to different nutrients. Learning more about how nutrition impacts on brain development throughout aging, and the mechanisms that regulate this, will help improve our understanding of the risks of poor nutrition on the brain, which may in turn help us to improve outcomes in people who have suffered from nutritional problems. In addition, nutrition may play a fundamental role in age related neurodegeneration, such as is seen in dementia, and understanding more about the mechanisms that underlie this role will provide new insight into the possible causes of these diseases, and also prospective new routes to therapy development.

What outputs do you think you will see at the end of this project?

Outputs will include new information regarding the impact of nutrition on the brain both in healthy aging and diseases such as Alzheimer's disease. It will lead to several publications that will advance our understanding of how nutrition may be linked to disease and will tell us more about the mechanisms underlying this interaction. It will also improve our understanding of how and why malnutrition during development has a profound and long-lasting impact on brain function as we age, and explore whether any of these impacts can be inherited.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

Initial benefits (obtained throughout the course of the project) will be seen by other researchers in the field of aging and neurodegenerative diseases, as they will provide mechanistic information to improve our understanding of how things may go wrong as we age. Longer term (over the course of the project and beyond), data obtained from this project may provide us with new targets against as yet unidentified proteins or genes, to try to develop therapeutics to treat diseases such as Alzheimer's disease, and may also provide us with simple approaches to reducing disease risk, or improving mental capacity as we age, which will have benefits for all.

How will you maximise the outputs of your work?

All data obtained in this work will be widely shared throughout the academic community, with the goal of publishing all findings, positive or negative, in relevant scientific journals. As new findings are obtained, collaborations with both local colleagues and those further afield will be sought out to further develop our research, and if appropriate, relevant pharmaceutical or therapeutic companies will also be approached with the goal of further progressing potential new treatments. In addition, efforts will be made to engage with the local lay community to share any findings of interest, and in cases of specific interest to patient groups, we will liaise with the appropriate support group to try to disseminate the relevant information widely and accurately.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The work planned in this project falls into four main categories:

1. Normal and genetically modified mice will be aged out typically to around 2 years old, and during their life around half of these animals will undergo behavioural tests to look at how well their brain works. These tests will include tests of memory, and tests for mobility. In most cases, mice will be tested 6 times in their lifetime. They may also undergo an MRI scan up to 6 times in their life.

2. Normal and genetically modified mice will be placed onto an altered diet - either increased fat/cholesterol (12 months max), or reduced calorie/fat/protein (16 weeks max). Around half of these

animals will then be placed on another altered diet for a further 16 weeks/12 months. These animals will be regularly weighed, and aged out to typically 2 years, and around half of them will undergo tests of memory and mobility function, as well as MRI scans, typically a maximum of 6 times throughout their life.

3. Normal and genetically modified mice will receive a dietary supplement or drug related to nutrient control such as statins, usually for their entire lifetime (typically 2 years). Around half of these animals will undergo memory and mobility tests and MRI scans throughout their lifetime (typically 6 sessions for each), with half of these also being placed onto an altered diet, as described above.

4. Healthy normal female mice will be placed onto a reduced nutrient diet for 3 weeks before being used as breeders. These mothers will be maintained on this low nutrition until their pups are weaned. Pups will continue to be maintained on a low nutrient diet until they reach 6 weeks old, at which point, they will be returned to normal food. These pups will then typically be aged out up to a maximum of 2 years old, and around half of these animals will undergo memory and mobility tests and MRI scans throughout their lifetime (typically 6 sessions for each for a 2 year old mouse).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals on this project that are maintained out to old age may develop various age-related issues that are common to mice, such as benign tumours or hair loss, and in some cases arthritis or sore patches on the skin. If these effects are only mild, and cause minimal distress, the animal may be maintained for several months, however, if any of these issues are thought to cause significant pain, discomfort or distress, the animal will be culled.

Animals modelling dementia may have learning and memory problems, that progress throughout their life. However, these are not expected to have any major welfare issues for the affected animals, and animals will be kept for a maximum of two and a half years (usually no more than two) as these memory problems develop.

In a small number of cases, where we are looking at models of motor neurone disease, animals may develop problems with mobility, and a mild tremor. This is not expected to be accompanied by any pain, and in most cases, will not affect the mouse's ability to move around their home cage. These animals be kept for a maximum of two years as these mobility problems develop. In rare cases, animals may experience difficulties moving around their home cage, and this impact will not exceed a maximum 2 week duration. This more severe mobility issue may also be accompanied by weight loss, which again is not anticipated to last longer than 2 weeks, and in most cases, will not exceed 1 week.

Animals on an altered diet may experience weight gain or weight loss. This is not expected to cause anything more than minimal discomfort to the animal, and may last for the lifetime of the animal. Animals receiving a dietary supplement or drug known to alter nutrient availability (e.g. statins) are not expected to experience any adverse effects.

Prospective mothers undergoing malnutrition are expected to show signs of weight loss, and may have reduced litter size, or problems carrying a litter to term. The period of malnourishment for these mothers

will not exceed 10 weeks. Pups from these mothers which are also experiencing early life malnourishment may be smaller than usual, and may grow and develop more slowly. The period of malnourishment for these pups will not exceed 6 weeks after birth, and no significant additional long term adverse effects are expected as a result of this malnourishment for the rest of the lifetime of the mouse, which will not exceed 2 years.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the experimental work planned in this project is not expected to result in more than mild to moderate impacts on the animals to be used. Most work from the first 3 categories described above is expected to result only in mild and/or transient symptoms that are not expected to result in more than minimal discomfort. In some cases, animals may experience some level of motor impairment, or weight loss/gain that results in some difficulties negotiating their home environment. However, none of these symptoms are expected to result in any pain, or lead to any long-term significant distress for the animal. Similarly, many animals on this project will be kept to old age, and these may experience a number of issues related to aging, but this will not exceed the mild to moderate symptoms that aging humans experience. This work accounts for approximately 92.5% of the experimental animals to be used under this licence.

The malnourishment of breeding females and their newborn offspring is anticipated to have a more significant impact on the mice to be studied, and may result in prolonged sensations of hunger lasting several weeks, that leads to a more significant level of short to mid-term discomfort. This work accounts for the remaining 7.5% of experimental animals to be used on this project.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 27 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project is interested in the interaction between nutrition and brain function, which requires us to be able to study the interaction between food intake and the brain. To be able to fully understand how different nutrition can impact on brain function, we need to be able to explore what happens in response to different long term diets, which can only be readily achieved in living animals. Most of the work in this project is focused on how nutritional changes can affect our brains as we age, including understanding more about whether long term diet can contribute to diseases such as Alzheimer's disease. This requires us to be able to study the brain throughout aging. Both the complex circuitry of the brain and the process of aging are challenging to model outside of a living animal, hence using animals is the only way to address these questions. Finally, we are also interested in understanding how any brain changes we see may relate to changes in behaviours such as learning, and these characteristics can only be measured in a living animal.

What was your strategy for searching for non-animal alternatives?

Various cells, including stem cells (grown in a dish).

Brain slice cultures (thin slices of brain that are grown in a dish).

Why were they not suitable?

Where possible, suitable cell or brain cultures will be used to address basic questions about cell function. Basic cell and stem cell cultures can provide information regarding what happens within a single cell, while brain slice cultures can provide information about local cell networks. However, neither of these options can fully mimic the impact of interactions between the millions of cells within the brain, and also how communication with, and the function of other parts of the body can impact on the brain. In addition, neither cells nor brain slices can give us any information on the practical behavioural consequences of any changes we see.

A retrospective assessment of replacement will be due by 27 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers to be used on this project have been estimated based on total numbers planned for the various different experiments to be conducted under the remit of this licence. For initial studies where basic information regarding expected outcomes for disease model or control mice is already available, power analyses have been conducted based on the expected effect size and variability, and total animal numbers per group have been assigned based on these analyses. For small scale pilot studies, where effect size and/or variability are not known, numbers will be kept small, and based on prior experience of similar studies to give the minimum number of animals expected to be needed to generate solid pilot data for further study. In the case of follow-up studies for this work, current number estimates are based on those typically required for similar experiments, but specific power analyses will be conducted for each experiment to confirm optimal numbers before the experiment begins.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

During the design phase of each experiment, where information was available, appropriate searches were done on each mouse line of interest to ensure we had access to all relevant information regarding expected outcomes in these animals, and this knowledge, combined with more general knowledge on the likely response of an animal to the specific modulations being tested was combined to help drive the power analyses that informed our final animal number choice. Extra consideration was made for a number of variables, including sex, age and background strain. The statistical approaches to be used at the end of the study formed a major part of the experimental design process, ensuring that all experimental approaches are robust.

The experimental design was also discussed with other researchers familiar with these kinds of studies, to further validate the design, and to ensure that we had included adequate control groups to each experiment, such that all data obtained will be valid.

What other measures apart from good experimental design will you use to minimise numbers?

As far as possible, all experiments will be conducted longitudinally, to allow us to maximise the data obtained from each animal, and where possible, multiple data types will be obtained from the same animal (e.g. behaviour and imaging). For tissue harvest, all organs of interest will be harvested from each animal, and experiments will be designed to allow multiple follow ups in the tissue from each animal, thus minimising the total number of animals required.

In many cases, small scale pilot studies will be conducted prior to each full scale study, with follow up analyses to ensure both that the objective is a valid one, and also that experimental design can be optimised to use the minimal number of required animals. This will ensure that unnecessary or poorly powered large scale experiments do not take place.

As far as possible, breeding strategies will be designed so that all animals from a mating are used for an experiment, and for general maintenance of a line, animal breeding will be monitored and controlled to ensure that we obtain sufficient mice to maintain the line, while minimizing the birth of mice that are not required.

A retrospective assessment of reduction will be due by 27 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

All the work planned in this project will use mice. These will include healthy control animals, and also models of diseases such as Alzheimer's disease and motor neurone disease. In most cases, these models will not induce any significant suffering to the animal, as they do not impact on the ability of the mouse to feed, drink and move freely about their cage. In the case of models of motor neurone disease, the animals may develop some problems with mobility. This is a known feature of motor neurone disease, and cannot be fully avoided. However, the models used in this project will either be slow progressing models, that do not develop major paralysis, and can hence still readily access their food and water, and move about their cage, or they will be animals bred only to provide cell and tissue for culture at a point prior to the onset of any obvious disease. These models have been selected because they provide a good model for the disease, while minimising the suffering of the animals.

A number of studies in this project will look at the effect of altering nutrition on brain function throughout aging. The dietary changes to be used have all been previously reported, and are not expected to cause any major long term problems for the mice, aside from some mild changes in weight. These diets are all designed to reflect aspects of human diets, and have been selected as they combine a realistic reflection of human nutritional variation with minimal long term welfare implications for the mice.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

This study is interested in the long term impacts of nutrition on the brain, specifically on the cerebral cortex, a brain region that is only found in mammals. Where possible, embryonic or newly born animals will be used to generate specific cell or brain cultures. However, the long term impact of diet on brain function can only be measured by altering the diet of animals throughout their life, and studying the impact this has. This is a long term process, that cannot be conducted under a terminal anaesthesia, and also requires us to be able to look at the brain function of conscious animals, including measuring factors such as memory. Since only mammals have a cerebral cortex, the region most affected by many

diseases such as Alzheimer's disease, the use of conscious adult mice is the only way to address the majority of questions posed in this licence.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals undergoing any kind of nutritional variation will be regularly monitored (a minimum of weekly, and increasing on demand), including being weighed, to ensure that no unexpected welfare issues arise unchecked, and if any dietary modifications are found to cause unexpected distress, they will immediately be modified or terminated to ensure we minimise such welfare costs.

Any animals undergoing regular handling as a part of the experiment will be handled regularly prior to the start of the experiment, to ensure that this process does not induce unnecessary anxiety or stress to the mouse. In addition, all mice will receive appropriate training for all behavioural tasks prior to the onset of experiments, both to minimise anxiety and stress, and also to improve outcomes, which should ensure consistent data from all mice, and hence allow the use of the smallest number of tests and animals.

Any animals undergoing dosing will where possible be given the compound in their food or water. Where this is not possible, dosing regimes will be designed to minimise stress and suffering to the animal. Animals will be handled prior to the onset of the experiment, and in the case of oral dosing, a thin flexible plastic tube will be used, and animals will be acclimatized to this prior to the administration of any substance. Animals receiving any compound will be extra closely monitored during the initial treatment phase, to ensure that no unexpected issues arise.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All work will be conducted following the general principals of the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines developed by the NC3Rs organisation.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will regularly check the NC3Rs website for updates, as well as liaising with both our NTCOs and our local NC3Rs regional programme manager. Any relevant changes will be implemented immediately for all new experiments, and consideration will also be given to implementing changes to ongoing experiments, provided any such change is not expected to have an impact on the animals such that it may alter research outcomes.

Explain the choice ofspecies and the related life stages

This project works with mice from gestation out into old age, as we are interested in how nutrition can influence our brain function and development throughout life. The mouse has been selected for these studies, as they have a similar diet to humans, and also possess a brain region called the cerebral cortex, which is only found in mammals. We are especially interested in how nutrition throughout life might alter our risk of developing dementia and similar diseases, and so many of the mice used in this project will be genetically modified to develop aspects of these diseases as they age. Other mice will have genetic alterations to how their brain cells sense different types of nutrients, which will allow us to look at how these nutrient sensing systems behave as we age, and how they may be involved in the development of dementia and related diseases.

A retrospective assessment of refinement will be due by 27 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

33. Characterizing the biological function of select evolutionary conserved REDACTED proteins

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to learn more about how the oldest members of a family of proteins (named REDACTED proteins, or KZFPs) control which genes are used in different types of cells, and when. We want to understand how they affect how our bodies work and develop, from the beginning of life to adulthood.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

REDACTED proteins are the largest group of DNA binding proteins in the human genome - their function is to compact small portions of DNA, making it temporarily inaccessible to most other proteins. KZFPs have a strong preference for repeated segments of our genomes which can copy or cut-and-paste themselves to different or extra places in the DNA. These pieces of DNA are called 'transposable elements'. Many of those are the remnants of viruses which infected our ancestors thousands of generations ago. Scientists agree that KZFPs are responsible for the control of these transposable elements when they are young, and stop them from spreading amongst our genome.

Recent discoveries show that some of the transposable elements which have been in the DNA of humans for a particularly long time may have been domesticated and do useful work for the cell. REDACTED proteins might be still be controlling them, determining when and where they can work, indirectly deciding which genes are in use at any time, and how intensely they are being used. We want to understand more about this and we think we can find out how much and when this matters. We plan to consider the time before birth, and the life of healthy youngsters and adults. We plan to use mice to do this, because in many ways they are surprisingly similar to humans, and we share many of the same REDACTED proteins with them. However, the family of REDACTED proteins is very large, with hundreds of different members, and we plan to focus on the oldest ones as they are more likely to be important.

Actual genes make up about 2% of our DNA, and most scientists study those as they are the source of proteins. We hope that this work we plan to do over the next five years will lead to a better understanding of some of the rest of the genome, and how it helps in controlling the activity of genes. In the past, most scientists thought that transposable elements don't do much, but we have been discovering in the past few years that they play a big role in the life of the cell. We think our work will help doctors understand the medical importance of changes in the DNA of patients when those changes are not in genes. We hope our research will help to understand how transposable elements and KZFPs work together to decide which genes are 'on' or 'off', which we think will prove to be very useful to prevent and treat illnesses.

What outputs do you think you will see at the end of this project?

The main outputs from this work will take the form of increased knowledge about the REDACTED protein family, which is the largest family of proteins in our genome and is vastly under characterized. We would better understand their role in the control of transposable elements and its implication in the evolution of gene regulatory networks. We will share these outputs by publications in scientific journals, communications through conferences and the press, and before this, privately discuss preliminary results with other senior colleagues in the field to potentially establish collaborative partnerships.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term, the outputs will help the scientists in related fields generate new hypotheses to deepen our knowledge of REDACTED proteins (KZFPs), how they participate in the regulation of transposable elements (ancient retroviral sequences in our genome), and their impact on gene regulation. Some high impact publications would affect the larger scientific community, most probably in the form of dispelling some preconceived misconceptions about the noncoding genome.

More importantly, we hope that our outputs will affect the way we analyze data from the rapidly accumulating databases of full human genome sequences, since we are focusing on KZFPs conserved between human and mouse. There, patients have their genome sequenced to try to identify the cause of rare diseases. Right now, the current state of affairs is that most efforts are still focused on genes, representing 2% of the genome. The rest of the mutations are hard to interpret as we have little knowledge of how transposable elements and other regulatory sequences interact – one of the main goals of this project is to increase our understanding of this study space, and this will undoubtedly help the public in the long term in the form of improved diagnostics.

How will you maximise the outputs of your work?

We will communicate our results in conferences and scientific publications, make sure we publicize major findings in the press, communicate privately with scientists in the field about successes and failures to avoid replicating work unnecessarily and share best approaches and techniques. We plan to publish negative results (absence of phenotype) in open-access journals whenever possible.

Species and numbers of animals expected to be used

- Mice: 3400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The number of animals required to generate our target genetically modified REDACTED will be kept to a minimum and will experience the minimum harm possible – we will use standardized procedures for superovulation, electroporation of fertilized eggs, and implantation.

On genetically modified animals, no procedures other than observational handling are planned – animals will be observed then sacrificed at predetermined life stages to harvest tissues for RNA sequencing and other genome wide assays. The specific time points will be adapted for specific REDACTED proteins, depending on phenotypes observed. For example, in the case of embryonic lethality, embryos would be harvested and a minimal heterozygote colony would be maintained. At the other end of the spectrum, long term monitoring of adult animals will be performed if we cannot detect an observable phenotype in early life, and they would be sacrificed at a pre-determined time (i.e. 3 months, or 1 year adult life) to obtain tissues for analysis (RNA-seq to quantify changes in gene expression, ChIP-seq to determine what proteins are present on the DNA, ATAC-seq to quantify chromatin accessibility, tissue embedding / observation by microscopy). If a phenotype with any effects on the well-being of the animals is detected, we would perform these analyses on a time point before they manifest to avoid any unnecessary impact on animals.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

As described previously, we have little information about potential phenotypes following the knock-out of specific REDACTED proteins. So far, Zfp568 (a REDACTED protein) has been described as embryonic lethal. Zfp57 and Zfp445 (both evolutionary conserved REDACTED proteins) have been implicated in the maintenance of genomic imprinting, and animals exhibit a small size / weight phenotype. We don’t expect dramatic phenotypes outside of embryonic lethality for most REDACTED proteins we target, even if they are the most evolutionary conserved, but this is largely unpredictable.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We will be careful in our selection of which targets to study in-depth after initial phenotypes manifest – we will either select life stages where we can study the effects of the deletion of the gene before any adverse effect manifest for the animal, or focus on the targets that yield mild phenotypes. Should one of our targets unexpectedly develop a moderate or severe phenotype, we will carefully consider and weight potential benefits in relation to the adverse effects the animals would experience and seek the required approvals from the Home Office, possibly leading to a request for an amendment to the current project license to perform any work that would necessitate the use of such animals. It is however not our intention neither our goal – ideally our targets will as we predict cause mild or transient phenotypes.

What will happen to the animals at the end of the study?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Most planned experiments in our lab will be performed in vitro and are expected to yield a wealth of information about the role played by KRAB-ZFPs in the evolution of gene regulatory networks. However, there are clear shortcomings to such experimental systems – this includes the limited number of cell types we can keep in culture on the long term, the lack of tissue microenvironment, the inability to observe effects on the overall organization of tissues, organs and complex biological processes (behavior, metabolism and development). Most importantly, the main reason for the use of animals is to monitor for the apparition of phenotypes which might only manifest after a prolonged period of observation (months) or during development, for example very early during embryogenesis. This aspect is critical to demonstrate the domestication of transposable elements in gene regulatory networks, as the participation in a phenotype which benefits the organism fitness is an essential criteria to demonstrate the highest level of function achievable. We envision that in the future the biotechnological development might partially provide ways to avoid using live animals (with for example in vitro artificial tissue / organ culture) but as of now these are not mature enough.

What was your strategy for searching for non-animal alternatives?

We are using a mix of different cellular models in vitro: cancer cell lines, human primary cells, embryonic stem cells that we can differentiate to specific cell types of interest, and gastruloid systems (in vitro systems that can create embryonic-like structures from stem cells). They are used in parallel with this project to minimize animal usage – however they cannot achieve our goals with the exclusive use of these systems and many aims require the use of animals.

Why were they not suitable?

None of these models can fully recapitulate the developmental process of an organism, and one of our primary aims is to assess the impact of specific evolutionary conserved KZFPs on development. Even differentiation from stem cells to specific cell types is artificial in many ways, with the supplementation of massive doses of cytokines or inhibitors to quickly induce the process – cellular microenvironments and signalling between cell types cannot be reconstituted fully in vitro, and these models are an approximate representation of reality. The gastruloid system generates embryo-like structures, but are somewhat disordered and develop much faster than a real embryo – they also lack important structures, including what would become the head / brain, where many of our targets are highly expressed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have prioritized our list of KZFPs proteins by using multiple parameters and will generate KO mouse models for the top few candidates in search for observable phenotypes. We initially aim to study 5 REDACTED knock-out for specific KZFPs of interest at once, but plan to generate up to 10 REDACTED to find promising candidates. We estimate that each line will necessitate around 300 (initial characterization and achieve all aims) but up to 500 animals (for a possible full long-term phenotypic characterization of 1 or 2 candidates with highly interesting profiles) for its generation and study over the 5-year period covered by this project. Specific experiments that are planned were subjected to a power calculation to ensure that conclusions at predicted thresholds can be made.

Depending on the pattern of expression of specific targets, single or multiple tissues would be tested from the same mouse. Study groups would include wild type animals (littermates) compared with heterozygotes and homozygote deleted for the target. If there is evidence of a sex-specific phenotype (as observed with an imbalance of sexes in pups for example), we would assay age-matched sex-specific groups in parallel. We also plan to assay changes in gene expression patterns potentially induced by loss of a specific gene at various stages of life of the animal (for example, at 3, 6 and 12 months of age).

If the phenotype is related to a block in development leading to embryonic lethality, we would use the same groups and numbers, using embryos at specific developmental stages instead. We plan neither treatments nor experimental perturbation of animals aside from the initial genetic manipulation to knock out a gene of interest. In some cases, we know that multiple KZFPs bind in close proximity on the genome at a subset of their targets, and depending on the viability and fertility of individual mice KO for each KZFP, we will also assay the viability / phenotype in a double KO mice. Our experimental plan is simple and we will have no problem publishing using the ARRIVE guidelines.

Our plan is to study at least 5 different KZFPs broadly (to achieve our 4 aims) and a few (1-2) different KZFPs in details on a long period. Even though we start with the ones most likely to yield a phenotype and for which we have strong hypothesis, we cannot fully predict the observability of the phenotype. Therefore, we plan for a scenario where up to 10 mice line KO for different targets will need to be generated in total over the 5-year period of this proposal, but we aim for the lowest count possible. For example, we would generate a new line against the next target in our priority list to replace one that is technically difficult to obtain, or to replace one target that unexpectedly yielded a phenotype which results in the animal experiencing moderate to severe negative consequences.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Sample sizes required for transcriptomic techniques we plan to use have been subjected to rigorous power analysis. This has been done with the advice of various individuals from different groups knowledgeable in the matter.

We have selected candidate genes with high likelihood of phenotype based on multiple criteria, including but not limited to patterns of expression and functional activity, underlying enhancer potential of transposable elements they bind, evolutionary conservation, and function of genes near binding sites.

Since we plan to create many mouse models of different KZFPs sequentially, we will also improve the experimental design iteratively should we notice possible ameliorations that were overlooked during the initial preparation phase, and will do so using the best planning tools available, such as the NC3R's Experimental Design Assistant.

What other measures apart from good experimental design will you use to minimise numbers?

We are keeping up-to-date with the latest developments in methods to genetically modify embryos (CRISPR technology) to optimize the way we generate the knock-out REDACTED – for example, switching from microinjection to electroporation of embryos greatly enhanced the survival rate, reducing the number of total animals required to generate any particular knock-out line.

We will use publically available pre-existing REDACTED from appropriate repositories whenever possible – we plan that this will be the case for example if we require reporter cell lines for a specific KZFP we need to study more in detail. We will favor this strategy in this case as knock-in of complex cassettes is still much less efficient than producing a knock-out using CRISPR. However, we find that producing knock-out in-house with the current CRISPR technology has very high success rates, making it a preferable alternative to ES-cell based, non-validated REDACTED that are available for a few KZFPs.

Similarly, we plan our colony management based on the expected litter size of specific genetically altered animals, should it become apparent that they are reduced for any given mouse line deleted for a given KZFP.

We also plan to restrict the number of REDACTED generated / studied to the absolute minimum to achieve our objectives. We will work initially with up to 5 different REDACTED KO for specific KZFPs, but the goal is to reduce this number to a few promising candidates we can study in detail. We have plans to perform initial characterization of up to 10 lines, but this will only be the case if problems arise with the initially selected KZFP candidates. For example, we would discontinue a line should a moderate or severe phenotype unexpectedly manifest, and replace it with another candidate.

We carefully selected our targets based on a wide-array of publicly available datasets encompassing expression, conservation, predicted gene essentiality from CRISPR studies in cell lines, etc.

We also plan ahead and plan to re-use multiple tissues from any particular individual to maximize the data output per animal, and share tissues with other teams in our Department should they need any from sacrificed animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Knockout mice models are the most efficient way to answer questions regarding function of any particular gene, especially those suspected to play roles in development and higher order biological functions. We will use the best standard protocols for the generation of transgenic animals, and continue to update them as new information becomes available. We will be able with the same model to determine multiple objectives at once, such as the determination of the overall gene essentiality for normal development, if it triggers any observable phenotype at the organism level, to be able to quantify changes in gene regulatory networks in particular tissues, and quantify epigenetic changes resulting from the absence of any particular KRAB-ZFP. We don't plan any procedures or protocol that could cause pain, suffering or distress on the genetically modified animals after we obtain them – our plan is simply to observe the animals, sacrifice them at a given time point and study changes at every level possible. If any of our targets unexpectedly causes a phenotype associated with pain, suffering or distress, we will evaluate the animals before apparition of those symptoms whenever possible, and favor other genes of the KZFP family not inducing such effects.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

KRAB-ZFPs appeared in tetrapods (frogs, reptiles, birds and mammals) limiting the species available for in vivo studies to higher organisms. The family is evolving extremely rapidly and is highly divergent between older phylogenetic branches – for example, no KRAB-ZFPs are conserved between amphibians and mammals. The mouse is the only suitable candidate as it shares a significant portion of its KRAB-ZFPs with human (80 conserved out of 350), making it a relevant model for human health in our specific case. Mouse models have been successfully generated for a few KRAB-ZFPs and conditional KO of TRIM28 and led to interesting phenotypes. Moreover, there is currently biobanks of embryonic stem cells knockout for most genes in mouse, including multiple KRAB-ZFPs we plan to use – we will maximize the use of these resources to avoid generating transgenic REDACTED ourselves, which would also accelerate our plans and diminish the number of mouse required to achieve our goals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

While we don't know what kind of phenotype could appear, we will monitor animals regularly after generation of a new KO line to assess if any phenotype is visible or quantifiable. Once a phenotype is identified, animals will be continuously monitored to minimize welfare costs on a per-individual basis, as the phenotype might be variable. Our main goal is to prevent any unnecessary suffering or minimize it should it be necessary – we expect our knock-out lines to yield mild or transient phenotypes. Should a moderate or severe phenotype appear unexpectedly, we would stop the use of that line, or perform the planned assays at a time point before the moderate / severe phenotype appears. We will trial the use of non-surgical transfer of CRISPR-treated embryos to decrease the welfare costs on host recipients when we generate the knockout lines.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will stay up to date with publications from the home office, including but not limited to updates to the "Guidance on the Operation of the Animals (Scientific Procedures) Act 1986", updates on the NC3R website on various topics, including on the refinement and usage of genetically altered mice, as well as the PREPARE and ARRIVE guidelines. We keep up to date with the latest guidelines and best practices for the efficient breeding of genetically altered animals (Such as the Assessment Framework document from the Home Office (https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf). We will keep up to date with publications from LASA (Laboratory Animals Science Association), and the database of information / tips / best practices on both the NC3R website and by our local network.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will liaise regularly with our NACWO, have conversations with other users of the facility including other research groups, and visit various online resources available REDACTED other 3R related online resources such as www.nc3rs.org.uk). We also plan to regularly attend meetings on best practices, and we are monitoring the calendar of such events published on the nc3r website regularly for nearby (UK / Europe) opportunities.

Explain the choice ofspecies and the related life stages

Mice are the most rational choice to study evolutionary conserved REDACTED proteins – this protein family appeared at the dawn of tetrapods (between fish and reptiles / amphibians) and massively expanded in mammals. Although rodents have lost many of the members conserved in most mammals, they still share 80 with humans, which is more than enough to achieve our goals. While we are using other models, living animals are the only choice to capture potential phenotypes at the organism level.

We purposely didn’t choose a specific life stage to leave all options open, as we don’t know what will be the effect of deleting specific REDACTED proteins. So far in the literature, work deleting the gene encoding for their cofactor protein TRIM28 shows a range of effects – it is embryonic lethal, but if removed in specific tissues can have phenotypes that develop over months – for example, sex specific cancer in the liver, or a stress phenotype in the brain. While it is unlikely that any single REDACTED protein will have effects comparable with TRIM28, since removal of TRIM28 results in the inactivation of more than a hundred different REDACTED proteins at once, we want to be able to assess effects developing on the long-term, while planning for possible developmental defects. Once we have a better idea of what kind of phenotype manifests for specific targets we will adjust our choice of life stage(s) to study to maximize scientific output while ensuring that animals experience no or minimal discomfort.

NON-TECHNICAL SUMMARY

34. Consequences of mitochondrial dysfunction in neurological disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Rats	neonate, juvenile, adult, embryo, pregnant, aged
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim is to understand the early consequences of energy failure within different nervous system cell types.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By understanding the early consequences of energy failure due to mitochondrial dysfunction in the nervous system the hope is that we will be able to identify drugs for neuroprotection.

What outputs do you think you will see at the end of this project?

We will be able to better understand the basis of symptoms as well as the gradual worsening of neurological function in people effected by demyelinating disorders, including multiple sclerosis, where the protective fatty layer called myelin is damaged and lost (demyelination). Understanding why nerve cells die in disorders with loss of myelin (demyelination) is crucial for identifying novel treatment agents and drugs for diseases like multiple sclerosis.

The testing of compounds and drugs to limit neurodegeneration and improve neurological function will lead to testing of such drugs, particularly for repurposing of of currently licenced drugs that are used for other human conditions and proven to be safe, in the clinical setting. Screening of compound libraries and approved drugs will further enhance the potential to discover new treatment options for demyelinating disorders.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

People with disorders where the protective fatty layer called myelin is damaged and lost (demyelination), such as multiple sclerosis. Identification of drugs for treating symptoms as well as stopping the gradual worsening of neurological function in patients will be of great benefit in maintaining quality of life.

In the short term, the discoveries made from these studies will improve the understanding of the basis of neurological disability in demyelinating disorders as well as uncover novel therapeutic targets. Further studies will be needed to valid these novel therapeutic targets as well as test compounds and drugs in phase I clinical studies.

How will you maximise the outputs of your work?

We will design experiments with minimal number of animals and avoid reproducing published work, unless absolutely necessary. We have access to a range of expertise to consult in case we need help in the future for delivering the out put.

Species and numbers of animals expected to be used

- Rats: 1000
- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be maintained for 3 weeks from birth and weaned as usual practice. The a small piece of skin, for example from the ear, will be removed so that we can perform a genetic test to identify whether the genes that we are interested in are present or absent in a given animal. The animals will then receive an agent called tamoxifen, a drug that is used frequently treat breast cancer and is safe in animals, using a gavaging method (oral administration). the animals will be maintained according to the recommendations for best practice until a time point where the experiments can be performed. The experiments will including testing behaviour and performance on well established platforms and equipment. Some animals will then undergo a surgical procedure to the nervous system under general anaesthsia where a small lesion will be made in the nervous system. The location of the lesion is such that the animal will not develop a permanent neurological deficit. Animal will receive pain killing agent(s) before surgery and will be closely monitored following surgery for any evidence of discomfort and sickness behaviour. We will study the impact of the lesioning on the nervous system as well as its function. We will administer agents, such as drugs and compounds, to protect the nervous system from the focal lesioning as well as to see if we can improve function such as by preventing fatigue.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some of the animals will develop performance related fatigue in the absence of a fixed neurological deficit. Eventually this will turn into a fixed neurological deficit and loss of weight. We will focus most of

our work on the early stages of the animal and before the fixed deficit becomes evident. However, it will be necessary to maintain some animals until a moderate severity phenotype is evident, particularly when testing the impact of agents such as drugs for its ability to delay and prevent the onset of fixed neurological deficits. Surgery to the nervous system rarely causes a transient weakness in backleg(s) of animals that last for a few hours. We will closely monitor animals for this adverse effect and contact the veterinary surgeons, if it lasts for more than 24 hours and take advice. If an animal fails to improve after 48 hours then we will consider culling it using humane methods and according to guidelines.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of the animals will have a mild severity phenotype (60-70%). We may maintain animals until a moderate phenotype develops, particularly when testing the impact of agents such as drugs and compounds on their ability to prevent and delay the onset of fixed neurological disability (a maximum of one third of animals that we will use). We will not maintain animals beyond a moderate severity phenotype in any circumstances.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Organism based system is essential to test the impact of agents such as drugs and compounds as symptomatic treatment for complaints such as fatigue in patients with neurological disorders. This feature, performance related fatigue, can not be models using non-animal methods tissue. Furthermore, nervous system is a complex organ with many different type of cells work together in order to execute its function. It is extremely challenging to put together the complex interactions in a suitable integrate experimental system to act as an alternative to the use of whole organisms.

What was your strategy for searching for non-animal alternatives?

We have experimental systems based on human inducible pleuripotent stem cells (iPSCs) to select drugs and compounds as treatment options for neurological disorders. It is necessary to test the selected agents in a whole organism to understand the establish the impact of agents on neurological function and behaviour.

Why were they not suitable?

The non-animal systems to do mode the complex and integrated networks that exist within the nervous system in the whole organism. Furthermore, it is not possible to test agents such as drugs for symptoms such as fatigue using non-animal systems where such symptoms can not be measured.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The proposed animal numbers are the result of discussion with statisticians and have been derived from power calculations based on published findings and preliminary data. The study design and written protocols will be submitted to the local veterinary surgeons for all experiments to minimize experimental variation and minimise animal numbers. In situations where previous experience is lacking, we will do pilot studies to determine the variance of the primary outcome measure before deciding on the number needed to show statistical significance with a 80% power. We will use the data generated in initial experiments to determine the minimum number of animals needed for each component of the experimental protocols.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will select the most reliable and reproducible measurement with the least variability as the primary outcome measure whenever possible, particularly when testing the impact of potential treatments. This will decrease the variability of a given set of experiments and decrease the number of animals needed to observe a statistically significant difference (i.e. to adequately power a study). We will use more than one behavioral test (and no more than 4 in a given animal), which helps to decrease the number of animals needed to achieve a goal and to identify agents such as drugs that can be potential treatments for patients.

What other measures apart from good experimental design will you use to minimise numbers?

We will ensure that the breeding design is such that all or most of the animals can be used for different experiments to minimise unnecessary breeding of animals. We will store sperm rather than maintain certain type of animal line if not needed for experiments. We will share tissue with our collaborators whenever possible rather than attempt to generate and replicate the models in our lab unless it is absolutely essential. Pilot studies will be performed to calculate the minimum number of animals needed for each experiment so that the study can be adequately powered an the use of excess number of animals can be avoided.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Nervous system cell type specific animal models will be used to study the consequences of energy failure within cells such as nerve cells and myelin forming cells. Cell type specific genetic models, using gene knockout methods, causes less harm than non-cell type specific models. Furthermore, most of the experimental planned will be performed when the animals do not show a phenotype or a fixed/permanent neurological deficit. We will study a specific aspect of fatigue, called performance related fatigue, in mice that show energy failure in the nervous system. These animals show fatigue before a fixed neurological deficit becomes apparent. The focus on early and reversible features minimise animal suffering. The lesioning to model the areas of tissue damage in diseases such as multiple sclerosis will be performed in a specific site (focal lesioning). This avoids large parts of the nervous system being damaged and avoids fixed neurological deficits or lasting harm.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Whole organism approach is needed to study aspects of neurological disorders such as fatigue. While it is possible to study such aspects in less sentinent species, the loss of myelin (fatty layer that protects the nerve fibres) using methods that are relevant to diseases such as multiple sclerosis requires mice and rats or more sentinent species, partly because of the way the immune system reacts when myelin is damaged. It is not possible to assess behavior and performance when animals are anaesthetised.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

When animals show signs of compromise and sickness behavior we will increase monitoring. All animals are weighed weekly. We will aim to administer agents such as drugs in the least stressful way, by considering dietary administration before gavaging and intraperitoneal injections. Animals will only be trained if needed for the experiment and we will avoid unnecessary training of animals. Analgesia will be routinely administered before surgery, or focal lesioning of the nervous system. To all animals, supportive care will be provided and their environment will be enriched with deep bedding. Mash will be used and animal monitored daily when mice develop a mild deficit and also when the clinical severity becomes moderate. We will use analgesics following all surgical procedures and monitor animals daily and administered when deemed necessary by research, animal house staff or NVS. Any sign of worsening in moderate severity animal or weight loss of >20% will lead to culling and harvesting to tissue. These parameters will be closely monitored from birth to death. Perfusion of animals will be carried out with terminal anaesthesia.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will regularly visit the 3Rs website (https://www.nc3rs.org.uk/3rs-resources) and EMA website (https://www.ema.europa.eu/en/review-update-ema-guidelines-implement-best-practice-regard-3rs-replacement-reduction-refinement) and take part in local and, when possible, national meeting aimed at 3Rs. We will make data publicly available so that duplication of studies can be minimised internationally.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will regularly engage with the local veterinary surgeons and colleagues locally as well as nationally. The team will attend 3Rs meeting and submit studies for such meeting. REDACTED. We will continue to implement advances made in 3Rs.

Explain the choice ofspecies and the related life stages

Animal models play a vital part in discovering and testing drugs for neurological diseases where the multiple different types of nervous system cells function in concert. As a result, it is extremely challenging to develop non-animal experimental systems to model the co-ordinated response the nerve cells trigger to a disease state. We have developed animal models where only one particular cell type is effected as this method minimises the impact of the experimental manipulation on the behavior and well being of the animal. As has purposely focussed on the very early stages of the behavioral disturbance, called performance related fatigue. This life stage is when a change in behaviour is apparent after a given physical activity rather than as a permanent feature. By focussing on early life stages we are able to minimise suffering and test drugs and agents at an early stage which will help protect eh nervous system before its too late.

Home Office

NON-TECHNICAL SUMMARY

35. Cortical and subcortical neuronal interactions during execution and observation of action

Project duration

5 years 0 months

Project purpose

None selected

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The main aim of this programme is to deepen our fundamental understanding of how the primate brain generates skilful hand movements and how unwanted movements are stopped. I will record activity of

individual neurons in the non-human primate (NHP) brain and investigate their behaviour during skilful hand movements. NHPs will be trained to reach and grasp different objects, and to observe a human experimenter grasping the same objects. On some trials, animals will be given a late instruction to stop their movement. Neurons in motor areas of the brain are known to be active during reach and grasp, but it was recently shown that some neurons are also active when animals are not moving themselves but observe the actions of a human experimenter. These neurons are called mirror neurons: their activity during the monkey's own movement is "mirrored" by their activity while it observes a human actor, without moving itself. Observation of the actions of others is central to human social interactions. Although we rarely move ourselves during action observation, much of the brain's motor network is active during action observation. Understanding mirror neuron activity can help us shed light on the fundamental question of how and when movement is generated, and when stopped.

For the first time I will investigate whether mirror neurons are affected by touch. Since touch of an object during one's own movement generates somatosensory feedback that is lacking during action observation, this might provide a key brain mechanism for discriminating execution vs the observation of actions.

Motor areas in the brain that control movements have a special 'hyperdirect' connection to areas of the brain that have been stimulated to treat patients with Parkinsons. This hyperdirect connection may be important for stopping unwanted movements that patients with Parkinson's suffer.I will, for the first time, investigate the functional role of the neurons in motor cortical areas connected to the STN during execution, observation and stopping of actions.

Different motor areas in the brain are connected to each other, and the strength of these connections can be changed using electrical stimulation. I will investigate how to induce connectivity changes in that enhance motor output for skilful action.

A retrospective assessment of these aims will be due by 28 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Skilful hand movements are critical to human culture but are often vulnerable to disease. This project aims to investigate several fundamental neuroscience questions that have potential long-term benefits for human patients suffering from PD (the second most common neurodegenerative disorder, affecting ~ 145,000 people in the UK (www.parkinsons.org.uk) and stroke (~100,000 new strokes in the UK each year (www.strokes.co.uk)).

Action observation is a key human characteristic. Although we rarely move ourselves while observing actions, much of the brain's motor network is still active. We also know that observation-related signals clearly survive in paralysed and disabled patients and they could be used to control Brain-Machine Interfaces (BMI). I will be investigating for the first time sensory properties of the mirror neurons. So far, it has not been tested how somatosensory input (touch, proprioception) influences the mirror neuron system. This is important, because incorporation of the somatosensory information into BMIs is essential for the future research and development in this area.

Research in NHPs has helped provide a better understanding of Parkinson's disease (PD), and led directly to the use of DBS of the subthalamic nucleus (STN) to improve motor symptoms of PD. In my research programme, I seek to investigate how cortical motor areas, important for movement, are connected to the STN to better understand mechanisms underlying DBS therapy and how current approaches could be improved.

Understanding of the connections between different motor areas and how these connections contribute to motor function is another major objective of my project licence. I will study how this contribution can be enhanced by using different electrical stimulation protocols known to alter cortical connectivity; such protocols could be implemented for example in rehabilitation after stroke.

In summary, a major, but not the only benefit, of the work outlined in this project license will be for researchers interested in the fundamental properties of the mirror neuron system, movement control, and neuronal interactions between different cortical and subcortical areas during complex behaviour. Results of this work will be widely disseminated to the scientific community through the publications in scientific journals and presentations on the local, national and international conferences. I have previously published my work in high impact scientific journals. Myself and members of my lab regularly attend international conferences and are invited to present results obtained in his lab in leading international centres of neuroscience.

In addition, the research described in this application will be disseminated to the general public. I am actively involved in communicating the results of my work in the public domain. For example, I was recently interviewed for a BBC3 TV documentary, which explored the need and significance of NHP neuroscience research.

Understanding of basic mechanisms of the mirror neuron system, the functional role of the cortical neurons projecting to the STN, and possible ways to enhance connectivity between motor areas, might have medium and long-term benefits for clinicians, clinical practices and ultimately for human patients.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

8 non-human primates (macaques) over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The procedure involves a number of stages for preparing non-human primates (NHPs) for long-term recording of single neuron activity in the awake state. This includes a number of separate and well-spaced implantation surgeries under deep general anaesthesia. These are carried out under full aseptic conditions and involve a full regime of pre- and post-operative analgesia. All anaesthetic procedures are carried out by qualified veterinary surgeon and all surgeries are performed under his/her supervision. Training and recording sessions involve head and body restraint while recordings are taken from multiple microelectrodes advanced into the brain through small, protected openings in the skull made during surgery. Neuronal activity is recorded while the NHP performs its trained task. Recordings are usually taken from pairs of cortical sites. During the course of these studies, which typically last for 2-3 years, both cerebral hemispheres are investigated.

All animals are pair-housed and are provided with natural light, an enriched environment and have large home cages, exercise pens and forage areas. They interact regularly during the day with investigators. The animal's health is being constantly monitored throughout the procedure, this includes at least weekly weighing and regular blood tests. The NVS is consulted in case of any behavioural or health problems. Possible solutions to potential problems will be discussed with the NVS, NACWO and HOI when appropriate and if problems could not be adequately resolved, the animal will be terminated. We have had no instances of this in the last twenty-five years of NHP research in this laboratory.

The prospective level of severity is severe. The retrospective (actual) severity level for all animals on REDACTED was assessed as moderate. At the end of this procedure, the NHPs are humanly killed by an overdose of anaesthesia.

A retrospective assessment of these predicted harms will be due by 28 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

This research programme aims to widen and deepen our understanding of fundamental questions about how skilful hand movements are generated and how unwanted movements are stopped. It therefore requires studying those parts of the brain that are essential for motor control. Because the macaque monkey and human motor systems are very similar in both structure and function, the

macaque model is the best one to use to address the questions posed in this programme of work. Neither New World marmosets nor non-primate animal models have a motor system similar to humans, and therefore these studies could not be carried out in such species. In addition, there are few substantiated reports of mirror neurons in species other than macaques and humans.

To understand the human mirror neuron system and its role in suppression of unwanted movements, we need some invasive work that will allow us to interpret correctly and to calibrate the results of human non-invasive studies. It is not yet possible to sample activity of single neurons in the healthy human brain, and recordings from small populations of such neurons in a non-human primate model are essential for our understanding and interpretation of non-invasive methods such as functional MRI, near-infrared spectroscopy (NIRs) and transcranial magnetic stimulation (TMS).

Data produced in the experiments described in this license are an extremely valuable source for theoretical modelling studies. Existing models can be tested and verified and new models can be created to inform future research and mechanistic understanding of the brain processes underlying behaviour under investigation and eventually for replacement of some aspects of the experimental research in animals.

A retrospective assessment of replacement will be due by 28 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

We use advanced experimental techniques which allow us to record more data simultaneously from different brain areas in a shorter time from a single subject. This directly leads to smaller number of animals being needed before enough data has been collected to allow thorough statistical testing of the scientific hypotheses.

A retrospective assessment of reduction will be due by 28 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The use of a non-human primate model is essential for this project. Mirror neurons were first discovered in NHPs. The macaque's motor system, including its mirror neuron component, closely resembles that of the human. Rodent models could not be used for this research due to substantial anatomical differences and their inability to perform the complex tasks required to achieve the aims of the project.

All of the techniques used in this laboratory have been refined to make it possible to carry out long-term neuroscience studies in young macaques, and we have had sustained success in terms of scientific productivity combined with optimal welfare.

Single-neuron neurophysiology in combination with stimulation techniques is the chosen method because it provides unparalleled inferential power to determine the causal role of neuronal activity in directly influencing behaviour. Simultaneous recordings of single neurons and local field potentials at different cortical and subcortical locations offers multiple advantages and refinements over traditional single neuron neurophysiology, including the ability to determine how different brain regions functionally interact to guide behaviour. In addition, such techniques produce substantially more data with fewer animals and fewer recording sessions than conventional single neuron neurophysiology.

We use high-resolution magnetic-resonance imaging (MRI) to guide and confirm targeting of brain areas including deep structures. This is an essential refinement since it reduces the number of surgical procedures and increases the accuracy of recording and stimulating electrode placement.

In combination with MRI, we extensively use 3D printing for development of implant prototypes. This allows us to design more complicated implants to reduce time of a surgical procedures needed to prepare animals for neuronal recordings.

We have achieved a number of refinements to the implantation technique for recording muscle electrical activity (EMG) by reducing size of the electrodes and connecting interfaces. This has helped to avoid potential problems with long term EMG implants.

Our research team places special emphasis on pre- and post-operative care of the highest possible standard, in consultation with the Named Veterinary Surgeon (NVS), who advises the most appropriate pre- and post-operative analgesic and antibiotic regimes. We are also keen to adopt additional NC3Rs-approved refinements, where appropriate, to improve the outcome of the experiment and to improve animal welfare.

A retrospective assessment of refinement will be due by 28 July 2025

The PPL holder will be required to disclose:

> With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

36. COVID 19 vaccine trial

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To test vaccine candidates against SARS-CoV-2 virus, the cause of the COVID 19 pandemic.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The COVID-19 pandemic poses the greatest health threat to mankind since the 1918 Spanish Flu outbreak. The lives of millions of people around the globe are under threat and the financial disruption caused by the measures implemented to limit its spread is endangering the very fabric of modern civilisation. Until vaccines are developed to protect people against the disease it will not be possible to curtail the pandemic.

What outputs do you think you will see at the end of this project?

The data generated by the study will show if vaccination with a specially designed synthetic nanoparticle induces an immune response likely to protect against COVID 19. If successful, the study will generate the data needed to support the progression of the vaccine into trials to determine its safety and confirm its effectiveness. The study will also establish the most effective route of administration for future mouse studies for nanoparticle vaccines.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The prime objective of the outlined work is to develop a vaccine to protect people against COVID-19. If the studies outlined below show that the engineered nanoparticles induce virus neutralising antibodies, and therefore are likely to be effective at preventing COVID-19 infection, then it will be made available to Biotech companies specialising in vaccine development for efficacy and safety testing. If successful, it is expected that the vaccine would initially be made available to health care providers, like the NHS, to protect their staff. Thereafter the vaccine would be used to create herd immunity within the general population to stop the inexorable spread of the virus and the disease it causes.

How will you maximise the outputs of your work?

If the outlined mouse studies are successful, the product will be advanced immediately into the testing phase need to demonstrate safety and efficacy. To this end a network of collaborators combines all the skills and experience required to deliver this project have been established together with contacts within Big Pharma . A sufficient amount of the first nanoparticle to be assessed has already been synthesised to enable testing to progress without delay. It is to be expected that the results of the initial studies will be available within a few weeks of the licence approval. In due course the findings of the study will be published in peer reviewed journals.

Species and numbers of animals expected to be used

- Mice: 280

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Upon arrival in the unit mice will be allowed to acclimatise for a week. A blood sample will be taken from a superficial vessel (not exceeding 50ul) to provide baseline values for subsequent assay systems. The mice will be inoculated with the vaccine by one of four routes, none of which will cause more than mild transient pain. A second blood sample will be taken approximately two weeks after primary inoculation and if analysis of this shows that the mice have produced a good immune response they will be killed by exsanguination under terminal anaesthesia. If analysis of the second blood sample shows an inadequate immune response the mice will be given a second inoculation by the same route. Approximately two weeks after the second inoculation another blood sample will be taken and if analysis of this shows that the mice have produced a good immune response they will be killed by exsanguination under terminal anaesthesia. If analysis shows an inadequate immune response the mice will be given a third inoculation by the same route and, approximately two weeks later, killed by exsanguination under terminal anaesthesia.

It is to be expected, based on previous published data, that only primary and secondary inoculation will be required for most mice.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The mice are not expected to experience more than mild transient pain at any point during the outlined studies.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity for this study is mild. All of the animals will experience mild transient pain or distress.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Good in vitro assays for modelling primary immune responses to vaccination aren't available. This is because of the complexity of the process which involves the uptake and processing of antigen by antigen-presenting cells in tissues, the transport of antigen presenting cells to the lymph nodes and induction of the primary responses at these sites.

What was your strategy for searching for non-animal alternatives?

Non-animal alternatives are not applicable to this study.

Why were they not suitable?

It is not possible to assess the immune response evoked by an antigen *in vitro*.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The initial pilot study will use a group size of 10 animals (see previous section). Four vaccines candidates have been developed and are awaiting testing, a further two are currently planned. During the initial pilot experiment three systemic routes of inoculation will be evaluated plus one mucosal challenge. A separate control group will be used for each of the four inoculation routes used in the pilot study. For subsequent studies, only the most effective systemic route (based on the pilot study data) plus the mucosal route will be used. Control groups will only be included in subsequent studies when there is a clear scientific need, however for the purpose of estimating the total number of animals it has been assumed that they will be required.

Initial Pilot study - (4 vaccinated + 4 control groups) x 10 mice/group = 80 mice

Subsequent studies – (2 vaccinated + 2 control group) x 5 vaccine candidates x 10 mice/group =200 mice

Total = 280 mice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The group size was calculated on the basis of published data from previous protein nanoparticle vaccines as set out above.

What other measures apart from good experimental design will you use to minimise numbers?

Follow analysis of data generated by the initial experiment the group size will be recalculated and adjust accordingly.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This study involves inoculation and sampling methods that cause mild transient pain or distress. None of the animals are expected to experience any adverse effects as a result of the procedures undertaken.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice have the lowest neurophysiological sensitivity of the animals suitable for these studies. It is not possible to conduct this study in less sentient species as they do not have immune systems comparable to humans.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The procedure undertaken will cause mild transient pain or distress. Anaesthesia will be used for procedures in which the stress of anaesthesia is less than that endured as a result of performing the procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All procedures will be conducted in accordance with LASA, NC3Rs Guidelines on best practice for the administration of substance.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I am a member of the REDACTED's AWERB committee and involved in the organisation of its annual 3Rs event. I am also a member of the Laboratory Animal Veterinary Association and regularly attend their annual conference.

Explain the choice ofspecies and the related life stages

Mice are the species with the lowest neurophysiological sensitivity suitable for these studies. They have been used extensively in immunological research including vaccine development. All of the necessary reagents to undertake the outlined assays are available for mice.

Home Office

NON-TECHNICAL SUMMARY

37. Cyclooxygenase in Cardiovascular Disease and Inflammation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

cardiovascular, thrombosis, blood pressure, blood vessels, pharmacology

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand how cyclooxygenase enzymes work in the body to protect the heart and blood vessels and in inflammation. We want to do this so we can improve the safety and effectiveness of medicines like ibuprofen and aspirin which work by blocking cyclooxygenase enzymes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cyclooxygenase is an important enzyme pathway in all organs within the body including those that make up the cardiovascular system. However, we still do not fully understand how cyclooxygenase works. Medicines that work by blocking cyclooxygenase enzymes are some of the most commonly used in the world and include household names like ibuprofen and aspirin. Aspirin is used to prevent heart attacks and strokes, but does not work for everybody and heart disease remains the leading cause of death in the UK and the rest of the world. Ibuprofen belongs to a family of drugs called NSAIDs which are used to treat arthritis and pain but they can cause heart attacks and strokes in people who need to use them every day. By learning more about the cyclooxygenase enzymes which both kinds of drug work on we think we can make new safer ways to treat arthritis and pain and make aspirin more effective at stopping heart attacks and strokes. In addition, by studying cyclooxygenase we will learn new things about how inflammation and cardiovascular disease develop and new ways to treat these conditions.

What outputs do you think you will see at the end of this project?

The ultimate aim of this project is learn about cardiovascular and inflammatory diseases and how medicines that work on cyclooxygenase enzymes (like ibuprofen and aspirin) work. We hope to find new ways to treat these diseases, and ways to use these medicines more effectively and safely. To start, this will be in the form of new scientific knowledge which will be published at the earliest opportunity in scientific journals and presetned at scientific meetings. For example, under our current project licence REDACTED. We will always keep in mind how to use this to help patients as quickly as possible. By the end of the project we hope to be able to understand enough to begin to develop some of the following:

1. Blood tests that can be used to predict which people who take ibuprofen-like drugs will have dangerous side effects.

2. New versions of ibuprofen-like drugs that are safer, especially to the heart and blood vessels.

3. Better ways to use aspirin and new aspirin-like drugs to prevent heart attacks and strokes.

4. Completely new types of medicines that could protect the heart or prevent inflammation.

The knowledge gained and publications generated in this project will only be the beginning but will be an important first step in each of these areas. Along the way we also hope to learn things we weren't expecting to find and that may include new ways of performing experiments to refine, reduce and replace the use of animals for medical research experiments.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term (0-5 years), we will generate new knowledge that will help drive scientific research. We will test our ideas and find new targets that can be the basis of medical tests and treatments to help patients. In the medium term (5-10 years), we can follow this work with studies on humans and patients with disease. In the longer term (10+ years), if these are successful we will be able to turn our basic scientific research into real benefit for patients living with arthritis and cardiovascular disease. Almost 20 million people in the UK suffer from one of these conditions so any new medicines or ways to improve existing ones will have an important impact.

How will you maximise the outputs of your work?

Maximising the outputs of any scientific research depends on communication and collaboration with other scientists and medical staff and keeping the public informed of any progress.

Scientific communication: We will communicate our findings to other scientists as soon as we can and in the highest profile ways possible so our colleagues will be able to contribute to the research. This will include publications scientific journals and presentations at meetings of scientists who work in the area. Importantly, we will make sure all our findings, either positive or negative are shared so that even if we are wrong about some things, other people can learn from this.

Collaboration: We will closely collaborate with other scientists and medical staff to develop the work in the fastest most effective way possible. At the earliest opportunities we will begin to work will medical staff to develop our scientific results into new ways to help patients suffering from disease.

Public engagement: We will also make all efforts to keep the public informed. We will send press releases about things we discover and directly interact with members of the public through events organised at our universities that are open for everyone.

Species and numbers of animals expected to be used

- Mice: 8000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most animals in our project will be genetically modified but not have any other procedures performed - they will only have samples of their organs and tissues taken for study after they have been humanely killed. Some animals will receive changes to their normal food, be treated with medication added to their water or by injection or very occasionally, have small blood samples taken while they are still alive. At the end of the protocols, animals will be killed humanely straight away or deeply anaesthetised for short surgical procedures to study their heart and blood vessels from which they will not be allowed to wake up.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We have worked hard to design the best possible experiments that will have the minimum effects on animal welfare. The majority of animals used in our project would experience a maximum severity of 'Mild'. This means we would not expect animals to experience more than minor and brief discomfort, for example, a short pain associated with an injection. Our project includes one protocol with 'Moderate' severity where animals would be treated with drugs that cause inflammation and this means they would experience strong flu-like symptoms where they feel generally unwell. We would not allow them to suffer in this way for more than 8 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild or non-recovery 90%

Moderate 10%

Severe 0%

What will happen to the animals at the end of the study?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals in our project because cardiovascular disease and inflammation are complex processes that involve many different tissues and cells working together. We don't yet understand all these processes, which cells and parts of the body are involved and how they cooperate so unless we study animals as a whole we cannot learn how to prevent and treat these conditions.

What was your strategy for searching for non-animal alternatives?

In our work we use many different types of experiments to answer our scientific questions. This includes experiments on cells grown in the laboratory, experiments on blood and tissue samples taken from healthy people and people with disease and some experiments that are performed virtually using computer simulation or computer analysis of online data. Wherever we can we will use these approaches to replace experiments on animals.

Why were they not suitable?

Unfortunately, we cannot always use simpler approaches in the laboratory with cells or tissues because until we understand the basic processes of diseases we don't know which cells and tissues to study and how to model them. Once we understand these things better we can and will move to replace whole animal experiments with other experiments that don't involve animals.

Another reason we can't always use simple non-animal alternatives in the laboratory is that they cannot show us how all the tissues in the body cooperate to control disease. As an example, we know that cardiovascular disease involves the heart, blood vessels, the kidney and cells in the blood. We can study these separately in the laboratory but unless we study whole animals we cannot see how they work together.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the numbers of animals we will use in this project by performing statistical power calculations to work out the numbers needed for each experiment and thinking carefully about the total number of experiments we will need to perform. These estimates of animal numbers have also been reviewed by other scientists who work in the area to give us confidence in them.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We carefully plan all our experiments to minimise the number of animals we need to use and get the most scientific information possible. This includes looking at experiments we have done in the past to see how these can be improved and animal numbers reduced, using tools like the NC3Rs Experimental Design Assistant to plan and organise all parts of the experiment, and taking advice from biostatisticians and other experts in our institute, for example, our REDACTED Statistical Advice Service.

What other measures apart from good experimental design will you use to minimise numbers?

We will take all reasonable steps to reduce the number of animals used in our project. Most of the animals used will be from genetically modified colonies which we will breed carefully at expert facilities in ways that minimise waste and ensure that every single animal can be used in experiments. We will start all our experiments with a small pilot of a few animals to be sure that there will be no unexpected welfare harms and to see if it is needed to go on to a large experiment with more animals. We will collect as much information as possible from every animal for example, making many measurements from the same animal over time. We will also collect tissues from all our animals, and share with other researchers, to perform experiments in the laboratory so no additional animals are required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use several different models to induce cardiovascular disease and inflammation and study how these effect the function of the heart and blood vessels. We will use simple models of coronary artery disease and high blood pressure where mice are given added fat or salt in their diet. These are very mild models so don't cause any distress or lasting harm and animals will be killed before they experience any adverse effects of the disease. We will use models of inflammation where mice are treated with substances that mimic a bacterial or viral infection, which can cause symptoms of an infection like flu. We use this because compared to other models it is very easy to control so animals experience the minimum suffering for the shortest time. At the end of the both protocols, we will use surgical procedures that let us directly and accurately measure how the heart and blood vessels function but this will only be done under deep anaesthesia from which animals will never wake up to so they don't experience any suffering or distress.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We will use mice and rats, in the simplest and most humane models possible. In most experiments, animals will be humanely killed without any harmful procedures or procedures will be carried out under deep anaesthesia from which animals will not wake up. We will mostly use mice because they are the least sentient species in which it is possible to manipulate how genes work, to model the diseases we want to study and measure the function of the heart and blood vessels in ways we need to. In a few experiments we will use rats because some blood vessels we want to study are too small to work with in mice.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have carefully chosen the most refined models that can deliver as much scientific value as possible with minimum amount of suffering. We will make all efforts to make animals comfortable whether or not they are undergoing an experimental procedure or not, for example, giving them a rich environment to live in and handling them in ways that don't cause them stress. During any experiment, we will closely watch all animals for any sign of discomfort and distress and either stop the experiment or humanely kill any animals suffering unexpectedly. Wherever some suffering is expected from an experimental procedures we will make all efforts to reduce this for example, in the case of animals with inflammation, by keeping them warm to reduce their symptoms or in protocols where animals will be handled a lot, we will get them used to people beforehand to reduce their stress levels. Through the project we will continue to look for new ways to refine our experimental protocols and make animals more comfortable.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will always aim to follow the best possible practice in performing any kind of experiment including those on animals. Although there is no specific guidance published covering the models we use, we will always search and review published information to find the best ways to perform our experiments. More generally, we will follow published best practice guidance for how to design, perform and report experiments to the highest standard including the NC3Rs PREPARE and ARRIVE guidelines and the Centre for Open Science Transparency, Openness and Reproducibility (TOP) guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will constantly review our protocols and experimental design to reduce, refine and replace the use of animals. We will keep informed about any advances by reading scientific publications and speaking with colleagues within our own universities and elsewhere. This will include not only other scientists but those directly involved in the care and welfare of animals. In our REDACTED there are also frequent meetings and training events to discuss the latest developments in the 3Rs and how to implement them including the annual Imperial College Animal Research Forum.

Explain the choice ofspecies and the related life stages

We will use adult mice and occasionally rats for our project because they can be genetically modified and are lowest and simplest species in which we know how to study the parts of the cardiovascular system we are trying to understand.

Home Office

NON-TECHNICAL SUMMARY

38. REDACTED

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this study is to examine the host immune response to infection REDACTED

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

REDACTED is a severe disease of sheep and has a significant impact in areas where it is endemic, both animal and human welfare. Most of the areas where this disease is reported to be endemic are in REDACTED. The disease can cause high levels of morbidity and mortality in affected animals. There is no vaccine, which is the ultimate goal for disease control. Sheep which are present and survive in endemic areas appear to be immune to the disease, however very little research undertaken to understand the host immune response to infection (and vaccination) with REDACTED. This work will examine and define the mechanisms of immunity of the host to REDACTED, the information from which will be used in future to develop vaccines and other countermeasures to REDACTED.

What outputs do you think you will see at the end of this project?

Defining the sheep immune response to REDACTED infection, with an eventual development of a vaccine, would be a major step forwards in controlling this disease in sub-saharan Africa. As well as being a disease which can kill up to 90% of sheep, the damage such losses can cause to the human communities which rely on these animals for food and economic prosperity can be catastrophic. Development of countermeasures to such a disease would increase productivity in endemic areas, and reduce the consequences of widespread loss of animals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Publication of the data generated upon completion of this study will allow fellow researchers to further develop vaccines and countermeasures to REDACTED. Long term application of the fundamental host immune responses to infection with REDACTED could be used to screen vaccine candidates in the host without the need for challenge, both refining and expediting REDACTED vaccine development in sheep. The data generated, and further definition of the sheep model to REDACTED infection can also be used to further investigate vaccine development to CCHF infection of humans (a lethal haemorrhagic disease virus).

How will you maximise the outputs of your work?

The date generated from this study, whether successful or unsuccessful will be published in peer reviewed journals to enable the immune responses to REDACTED infection to be disseminated.

Species and numbers of animals expected to be used

- Sheep: 51

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

To define the immune responses in the sheep, the animals will need to be vaccinated (experimental vaccine) and / or infected with REDACTED.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The vaccination of the sheep with the vaccine is not expected to cause any adverse effects other than short lived discomfort / elevated temperature as is normal with any vaccination, and is considered to be of a mild level of severity. The infection of sheep with the NSD virus is likely to cause an elevated temperature, discharge from the nose and eyes, and diarrhoea which may have traces of blood.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

These signs will be of a Moderate Severity. The Animals will be culled at the end of the study, or if they become too sick during the study, using the most humane methods of culling.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sheep are the target species for this virus, in that they will be the species in which the information generated will be used to assess immunity to vaccination / vaccine development in future. Due to the complex nature of the immune system, it is not currently possible to ascertain what component of the immune system is responsible for clearing an infection and protecting against future infections.

What was your strategy for searching for non-animal alternatives?

Cell culture based systems to amplify the virus will be used in place of using animals to amplify the virus. Dose rates will be derived from previously published studies. Whole animals need to be used to assess the immune response to the virus and / or vaccine

Why were they not suitable?

No replacements options are available to replace the whole animal at this time as an entire organism, including the immune system, need to be present to assess the immune response of an animal to a virus infection.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use statistical tools to determine the minimum number of animals that we will need in order to achieve our scientific aims and objectives, outlined above, with a high level of certainty. This number of animals has been selected assuming 4-5 animals per group, with 3 dose rates to define the challenge dose required to illicit an immune response. This also includes 5-6 animals per vaccine group with 3 doses of vaccine. This also includes 3 groups of 6 animals (naive, exposed to low dose of virus, and one vaccinated group) for subsequent challenge with virulent dose of virus. This equates to 51 animals.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The site statistician has been consulted and assuming similar response rates as other animals infected with similar viruses / vaccinated with similar vaccines, the estimated numbers wold be the minimum to achieve the scientific aims.

What other measures apart from good experimental design will you use to minimise numbers?

Given very little is known about the immune responses of sheep to REDACTED, we will collect and store tissues to be analysed and shared by other scientific groups from both samples required in this study, but also after asking other research groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

As explained, sheep as the target species, must be used as the model species so we have confidence that the data generated will be applicable to other sheep. There is no other animal model for REDACTED infection. The experimental vaccine used in this project to help further define the immune response to REDACTED will have first been screened in mice to ensure it has the potential to generate an immune response before it is trialled in sheep. We will only challenge animals with virulent REDACTED to assess protection once we have analysed the immune response to both vaccination and prior infection and are confident that there is a good chance these animals will be protected.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There are no other animal models for REDACTED infection, although mice will be used to screen the vaccine for immunogenicity before it is used in sheep.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be housed together with bedding and other items of enrichment. Highly trained animal technicians will monitor these animals throughout the day, ensuring they are comfortable and to maximise their welfare status. We have 24/7 CCTV surveillance which can be used to monitor the animals behaviour over time.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Adherence to the ARRIVE guidelines for reporting these studies, as well as to the FELASA guidelines for large animal health monitoring to help ensure the most robust health assurance for animals used in this study.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through continued CPD and frequent review of the CAAT (Center for Alternatives to Animal Testing) I will keep informed about advances in the 3Rs. Included in CPD will be annual attendance at national lab animal science conferences as well as naturally reviewing the current literature surrounding infectious disease research, in particular Nairoviruses.

Explain the choice ofspecies and the related life stages

These animals, sheep, are the natural host for REDACTED and no other animal models exist. Adult sheep are used as this best reflects the life stage of sheep which are naturally infected with REDACTED.

Home Office

NON-TECHNICAL SUMMARY

39. Defining the link between parental nutrition and offspring development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Parental diet, Gamete quality, Developmnetal programming, Mouse model

Animal types	Life stages
Mice	embryo, neonate, adult, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand the impact of parental diet on reproductive fitness in mice. Additionally, this project aims to define the long-term effects of poor parental diet on offspring health.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Developing a clearer mechanistic understanding of the link between paternal diet and offspring development is of fundamental importance for preventing life-long offspring ill-health. The research conducted under this project will provide new insight into the importance of parental diet at the time of conception for the health and well-being of offspring. This project will inform how poor diet impacts on the metabolic and reproductive health of the parents, and both the short- the long-term health consequences for the offspring. This study will define new biomarkers of sperm and oocyte quality, post-fertilisation development and offspring growth in relation to parental diet. Such data will be of value for human and commercially important animal species, as well as helping to inform the development of future nutritional guidelines for prospective parents to support directly healthy ageing across the life-course.

What outputs do you think you will see at the end of this project?

With the increased global prevalence of heart disease, obesity and diabetes, a greater understanding of how adult ill-health is determined has never been of greater importance. This novel study will provide new insight into the significance the diet of the parents have on the development and long-term health of their offspring. Under this project, the underlying biological mechanisms regulating heart disease, obesity and diabetes in adult offspring of dietary manipulated parents will be defined. Such insight will provide scope for the development of new interventions and treatments to alleviate their effects and benefit human health. In addition, this study will identify the interaction between sperm and eggs, both from parents fed a poor diet, to determine their combined effect on offspring development.

It is anticipated that several publications (both primary research and review articles) will be produced by the end of this project. Data generated under this project will have been presented at multiple national and international conferences by the principal investigator, post-doctoral researchers, PhD and graduate students.

Furthermore, this project will result in the generation of a significant bank of tissues which will act as a valuable resource for subsequent graduate project students, PhD students and collaborators. This tissue bank will also aid in the generation of preliminary data for subsequent grant applications. Furthermore, through interdisciplinary sequencing, lipidomic and proteomic analyses of these tissues, non-animal based bioinformatic and mathematical modelling research approaches can be developed reducing further need for animal research.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The results generated from this proposal will have broad benefits to many diverse groups within the academic community.
This study will define the impact of parental diet on sperm/egg epigenetic status, embryonic development, fetal growth and adult offspring health. As such, this study will re-define our understanding of the early origins of adult ill-health, providing
novel insight into the significance of poor parental diet for the development and wellbeing of offspring.

The findings from this project will be of significant benefit and interest to
those involved in assisted reproductive technology (e.g. IVF) research. This study will provide essential insight into the consequences
of using sperm and eggs from individuals on sub-optimal diets, providing novel biomarkers of perturbed post fertilisation
development and their impact on subsequent fetal growth. Data from this proposal will help define new assisted
reproductive technique methodologies and strategies for gamete handling, manipulation and usage, as well as preconception
advice for couples entering the clinic.

Wider research communities will benefit from the resources generated within this
project such as the development of novel mechanisms for analysing embryonic gene transcription, deposition of novel
sequencing data sets within online repositories (e.g. NCBI Gene Expression Omnibus), the development of new software
pipelines for analysis of gene expression profiles with associated epigenetic modifications and the impact of parental diet dietary modifications on epigenetic inheritance and offspring development.

Finally, findings from this proposal will be of benefit to health-care professionals offering dietary advice to intending parents, clinicians involved in assisted reproduction and fertility treatment, paediatricians, policy makers concerned with diet, adult health, fertility and pregnancy management.

How will you maximise the outputs of your work?

To maximise the output from this project, we will publish the research data in high-impact, open access journals. Furthermore, data collected under this project will be presented at international, national and institutional conferences, meetings and seminars. In addition, we will use publicly accessible outlets such as the Conversation UK to discuss research originating from this project.

Where ever possible, we will also collaborate and share resources (samples, knowledge, technical skills) with other researches (both within and outside of the REDACTED) to maximise the scope and impact of our research.

It is our anticipation that all data generated under this project (both positive and negative) will be made available.

Species and numbers of animals expected to be used

- Mice: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Under this project, we will define how parental diet affects their reproductive fitness, the development of the early embryo, fetal growth and offspring metabolic health. As such, two groups of animals will be studies under this project, parents and offspring. In both cases, both males and females will be studied.

Typically, parental mice (males and females) will be fed *ad libitum* either a control or an experimental diet (either low in protein or high in fat). For males, these diets will be given for several weeks prior to mating, while females will be fed for a specific duration around and during pregnancy (typically between 3 days and 3 weeks in total). Typically, these mice will then either be (i) culled for the isolation and analysis of their sperm/eggs (ii) mated to analyse how their diet affected the development of (a) early preimplantation embryos, (b) fetal growth or (c) the postnatal health of their offspring or (iii) receive embryos that have been generated *in vitro* and which will be allowed to develop to different stages of pregnancy or term. Females receiving donor embryos will typically be mated to vasectomised males (to render them pseudopregnant) prior to embryo transfer (either surgically or non-surgically).

While males and females are being maintained on their diets, it will be of interest to assess how their diets are affecting their metabolic health. This will typically involve glucose tolerance testing, where mice receive an intraperitoneal bolus of glucose followed by regular collections (over 2 hours) of blood from the tail vein for measurement of blood glucose and/or insulin levels. Additionally, males and females may undergo positron emission tomography scanning for in vivo analysis of metabolic uptake. This will involve injecting mice with non-toxic, non-radioactive stable isotope labelled metabolites (e.g. Fludeoxyglucose; 18F), being anaesthetised and then non-invasively scanned over a 2-3 hour period to measure the uptake of the metabolites into their tissues prior to full recovery.

Analysis of offspring (males and females) growth, reproductive fitness and metabolism will be conducted in a manner similar to their parents i.e assessment of glucose tolerance, metabolic uptake using positron emission tomography scanning and isolation of sperm, eggs and embryos. It may also be of interest to study how offspring from parents fed a low protein or high fat diet respond metabolically when also fed the same poor quality diet. Under these experiments, offspring (both males and females) will be fed either control or experimental diets in a manner similar (duration and stage of gestation) to that of their parents.

At the end of all experiments, all mice (parents and offspring) will be culled for the isolation and storage of tissues for additional analyses such as gene and protein expression, hormone levels and tissue morphology.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals fed experimental diets may experience significant changes in their metabolic and reproductive physiology. These may include significant gains in weight, underlying changes in blood glucose and lipid levels and reductions in sperm/egg quality and embryo development. It is anticipated that these physiological changes will last for the duration of the feeding regimen. There is also the possibility that a very small number of animals will find their diets unpalatable. In this instance, mice may experience some weight loss. However, these effects are not expected to result in significant pain, suffering or distress to the animals or their well-being or general condition.

During the project, several groups of mice will also receive intraperitoneal injections of various substances such as glucose, hormones or stable isotope labelled metabolites. These will typically be single injections which may result in inflammation at the site of injection. Similarly, for some animals, we will want to take blood samples from a tail vein for the analysis of metabolite or hormone levels. This may also result in inflammation and/or soreness at the sight of sampling. However, the impact will be localised to the site of injection and the duration should typically be no more than 24 hours.

Animals undergoing surgical embryo transfer may experience adverse effects from the anaesthesia (respiratory distress) or from the surgery itself such as post-operative infections, pain and/or wound breakdown. These effects are likely to occur during or shortly after the surgical procedure and will be mitigated for by constant monitoring of the animals and administration of appropriate pain relief. In worst case scenarios the animal may be culled.

Animals placed within the metabolic cages may experience stress due to the social isolation and minimal environmental enrichment. However, the effects are anticipated to be transient and all animals will be returned to their home cage and monitored or culled immediately after the cessation of the experiment.

Finally, some animals may be anaesthetised and injected with non-toxic, stable isotope (on-radioactive) labelled metabolites for the analysis of how these are taken up and used by the body. During anaesthesia, some animals may experience adverse reactions which may involve regurgitation of their stomach contents or difficulties in breathing. If this occurs, these mice will immediately be removed from their anaesthetic and allowed to recover.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Over the duration of this programme of work, it is anticipated that 90% of animals will experience procedures that are of a mild severity nature. The majority (70%) of these will be placed on diets of modified composition. It is expected that feeding animals the control, low protein or high in fat diet will result in mild severity changes to their weight, metabolism and/or reproductive fitness. However, in our experience, none of our experimental diets result in increased mortality, or the need to cull any mice, even after several weeks of feeding.

An anticipated that 25% of the animals will receive injection of substances for the analysis of glucose tolerance, hormonal induction of ovulation or for the analysis of metabolic status by positron emission tomography. These will typically result in mild severity short-duration effects on all animals. Effects will

typically be in the form of soreness and swelling at the site of injection and are likely to occur in all animals receiving injections and are of a mild severity.

Animals placed with metabolic cages (approximately 10% of all animals) will experience mild severity effects due to the isolation and minimal environmental enrichment. However, the effects of this will be temporary and are not anticipated to result in impairment of the well-being or general condition of the animals.

All animals undergoing surgical embryo transfer (approximately 10% of all animals) may experience moderate severity, short-term effects from the anaesthesia and surgery. However, these will be mitigated through the use of appropriate pre- and post-operative pain relief and constant monitoring.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The purpose of the work is to determine the effects of parental nutrition on sperm/egg quality, embryo development, fetal growth and adult offspring health. The manipulation of human fetal and embryonic tissue for the sole purpose of understanding their impacts on long-term offspring development and well-being would be considered un-ethical. Therefore, to achieve the aims of this project, the use of animals is necessary to cover the complex, inter-related, whole body nature of the study.

What was your strategy for searching for non-animal alternatives?

The aim of this study is understand how parental diet affects a multitude of reproductive, developmental and adult offspring phenotypes. As such, whole animal studies are required and can not be replaced in their entirety by *in vitro* alternatives such as **cell culture, organoids, 'tissues-on-chips' or in silico analyses** of published data sets. Furthermore, as non-mammalian species such as **insects, worms or fish** have dramatically different patterns of reproduction to humans and mice, their use in this project would not be conducive to answering the aims of this project.

However, where possible, individual experiments will be conducted in vitro (sperm morphology and motility, pre-implantation embryo development, isolated tissue function analyses) as well as numerous molecular and biochemical assays on collected tissues (gene and protein expression patterns, serum hormone and metabolite levels) thus minimising the need for repetitive experimentation on animals and maximising the data collected from any one individual.

Why were they not suitable?

A central component of this project is to examine the effects of diet on integrated, whole body systems e.g. parental reproduction, fetal growth, adult offspring metabolism. While complex *in vitro* systems have been developed to study central biological processes e.g organ on a chip, organoids, 3D-scaffolds for cell culture, these models represent isolated systems *in vitro.* Therefore, in order to understand how diet affects parental reproduction, growth metabolism, hormone balance (all interconnected) in an undisturbed system, live animal research is necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have determined the number of animals to be used in this project through the use of the NC3R's online Experimental Design Assistant and my existing body of mouse model data. Using these, I have calculated the necessary number of offspring litters required to observe statistically significant differences in the phenotypic measurements outlined. Animal numbers are provided below to estimate offspring replicates required based on an average litter size of 6 offspring per litter.

For the generation of 50 litters of adult offspring (10 litters per dietary treatment group; 1 control and 4 experimental with approximately 6 offspring per litter) 70 adult stud males and 80 adult females (allowing for natural redundancy based on existing studies) will be required. From my previous studies, an average litter size of 6 offspring is anticipated. However, this number can vary naturally and some litters, if lost during gestation or at birth, would need replacing. However, the number of litters lost and which require replacing is typically low.

For the generation of sperm, oocytes and embryos for analysis, a further 100 stud males and 150 females will also be required throughout the licence.

Vasectomised males (150 in total) will be purchased from a commercial supplier and used in batches of 50 (five treatment groups comprising 10 separate males in each) throughout the lifetime of the project.

For embryo transfer experiments, both donor and recipient female mice will be required, with a greater number of recipient females needed due to anticipated success rate of 60%. Therefore, it is anticipated that 200 donor females (100 naturally mated and 100 superovulated) and 150 recipient females will be needed.

Similar number of offspring litters are required as for the analysis of fetal development. This will require 10 litters per treatment group (1 control and 4 experimental with approximately 6 offspring per litter). As for the fetal analyses, some natural redundancy will occur and some litters will need to be replaced.

Furthermore, in some studies, a small number of F2 generation offspring will be generated. As such, an anticipated total of 500 offspring will be generated under this project.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Statistical advice was sought to devised an analytical approach which allowing us to take into account the multiple levels of interaction within our data and other potential confounding variables (e.g. parental origin, litter size, body weight etc). Using this approach we are able to factor into our statistical analyses the multiple use of any one male in more than a single experiment. Such analyses allow us to use stud males several times, reducing the number of stud males required.

In addition, we have used the NC3Rs experimental Design Assistant to confirm that an n of 10 litters per treatment group are necessary to observe significant changes in fetal growth (a major determinant of long-term ill-health) based on our existing data.

What other measures apart from good experimental design will you use to minimise numbers?

Where possible, stud males will be mated on multiple occasions prior to culling for the collection of tissues for subsequent molecular and biochemical analyses. This will ensure maximal data is obtained from each stud male and will minimise unnecessary repetition of experiments.

For our analysis of metabolite uptake using positron emission tomography we will conduct pilot studies to ensure optimal concentration of stable isotope labelled metabolites to be injected and the duration of the imaging necessary. Such pilot studies will ensure animals are maintained under anaesthesia for the minimal duration and prevent unnecessary repetition of experiments.

From all animals used within this project, a range of tissues will be collected and stored for later analysis. These will be used for under-and post-graduate studies within our laboratory, for the generation of preliminary data for further grants and will also be made available to collaborators where appropriate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice represent the most appropriate animal model as their use maintains continuity with my existing experiment data and will enable me to define the underlying biological mechanisms in unparalleled detail. Mouse reproductive physiology, mechanisms of sperm/egg maturation, patterns of embryonic

and fetal growth and regulatory mechanisms for adult metabolic health share significant similarity with that of humans. Non-mammalian species such as insects or fish are entirely inappropriate since they do not include internal fertilisation and embryo development, stages of fetal development or the presence of a definitive placental. As all these aspects will be investigated under this project, use of a mammalian species is essential. Furthermore, the use of mice, and especially the C56BL/6 strain, permits detailed investigations into the genomic and epigenomic mechanisms linking paternal diet with offspring health. The unparalleled annotation of the C56BL/6 genome, transcriptome, proteome and epigenome will allow for maximal levels of data retrievable from each animal. For these reasons, rodents provide the most appropriate non-human model for such studies.

During surgical procedures, animals will receive appropriate pre- and post-operative pain relief. Surgery will be conducted under sterile conditions using properly calibrated and maintained equipment for the administration of inhaled agents. To prevent unnecessary surgical procedures on females mice, where appropriate, the Non-Surgical Embryo Transfer (NSET) device will be used for both artificial insemination and embryo transfer.

Under this project we will use positron emission tomography (PET) scanning to determine the impact of parental diet on parental and offspring metabolic health. Typically, in order to analyse an individual's metabolic status, mice have to be culled for the isolation and analysis of specific tissues. However, positron emission tomography (PET) scanning, using non-toxic, non-radioactive analogues of key metabolites such as fludeoxyglucose (18F-FDG PET), is an increasingly used technique in murine models of human diseases. Under several physiological and pathological conditions, the use of PET can be used to look at the uptake of labelled metabolites such as glucose, amino acids or lipids into tissues. As real-time *in vivo* measurements of metabolite uptake can be conducted on live, anaesthetised animals, this represents a significant refinement over studies in which animals need to be culled.

In conjunction with the use of PET scanning, we will also use the Columbus Instruments system (CLAMS) metabolic cages. Use of this system will substantially reduce the number of animals required for experimental procedures and improved the quality of the experimental data as multiple measures are recorded simultaneously from the same animal. However, these metabolic cages provide a sparse environment as compared to the animals' home cages, thus further refinement will occur to a) minimise the time needed to be spent in the metabolic cage to obtain satisfactory data, and b) to determine whether providing environmental enrichment whilst in the metabolic cage is possible (for example baseless housing, provision of gnawing blocks) without disrupting the quality of the metabolic and behavioural data captured.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Patterns of non-mammalian reproduction display dramatic differences to that of humans. Patterns of sperm/egg development, fertilisation, fetal growth and offspring development are significantly different to humans. Furthermore, non-mammalian species do not possess a placenta, a key organ in the regulation of fetal growth. As such, in order to make the findings from this project relevant to human health, a model system that displays close reproductive and developmental similarities with humans is needed. As mouse reproductive physiology, fetal growth and offspring development share significant similarities with humans, they represent an optimal model for these studies.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All animals placed on experimental diets are monitored weekly for weight gain/loss, general condition, demeanour and behaviour. Any significant deviations from normal will be recorded and, where appropriate, result in discussions with staff withing the facility, the NVS or their deputy and appropriate action enacted.

All animals undergoing anaesthesia and surgery will be monitored daily for up to 72 hours post-procedure. This monitoring will assess welfare aspects such as general appearance, appearance of wound (where appropriate), spontaneous behaviour, provoked behaviour and weight. This monitoring will take the form of a 20 point scoring system with animals being rated as either (i) normal, (ii) requiring close monitoring with possible analgesia, (iii) requires humane culling and careful consideration of the protocol. Animals undergoing mild severity protocols with a score of 2 or greater in any category, or a cumulative score of 5 or more on the scoring sheet will be culled humanely. Animals undergoing moderate severity protocols with a score of 3 or greater in any category, or a cumulative score of 8 or more on the scoring sheet will be culled humanely. This monitoring system has been approved for use by our institutional AWERB and is currently in place.

In addition, to minimise the impact of post-operative pain in any animal, mice will be given a suitable pre-emptive analgesic and post-operative reactive analgesia as advised by the NVS or their deputy. To minimise further the welfare costs of the embryo transfer procedure, where possible and experimentally appropriate, we will use non-surgical embryo transfer procedures such as using the NSET device.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Throughout the course of this project we will make reference to multiple sources for best practice guidance. these will include:-

- Fund for Replacement of Animals in Medical Experiments: www.frame.org.uk
- NC3R’s website for details on experimental design: https://nc3rs.org.uk/experimental-design
- NC3R's ARRIVE guidelines: https://www.nc3rs.org.uk/arrive-guidelines
- Laboratory Animal Science Association (LASA) publications: https://www.lasa.co.uk/current_publications/

We will also keep up-to-date with the latest non-animal research models to ensure, where possible, non-animals based experimental models are adopted

- Altweb: http://altweb.jhsph.edu/

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I currently subscribe to the NC3Rs monthly e mail alerts which keep me updated to the most recent developments in NC3Rs publications, guidance and information.

We also receive regular updates and latest animal welfare guidance information via bulletins disseminated from our Biomedical Research.

Finally, information is disseminated and methods of best practice are discussed via our establishment users meetings of which my research group are involved with.

Explain the choice of species and the related life stages

Mice represent the most appropriate animal model for these studies for a number of specific reasons. Firstly, their use maintains continuity with my existing published research and permits us to make direct comparisons between our previous data and current studies.

Second, patterns of mouse oocyte and pre-implantation embryo development are significant similar to humans, making them the most appropriate model of understanding the environmental effects on embryo development. Non-mammalian species are entirely inappropriate since they do not include fetal development.

Third, the un-surpassed genomic annotation of the C56BL/6 strain permits analyses into the effects of parental nutrition upon offspring gene expression and epigenetic regulation, maximising the level of data retrievable from each animal.

Finally, the use of rodents allows for the isolation, culture, manipulation and cellular analysis of all all stages of the reproductive and developmental cycle. As such, by using rodents it is possible to understand the entire time-line looking at gametogenesis, embryo development, fetal growth and adult offspring health. Such studies are not possible in humans or non-mammalian species.

For these reasons, rodents provide the most appropriate non-human model for such studies into the effects of parental diet on sperm/egg quality, fetal growth and offspring health.

Home Office

NON-TECHNICAL SUMMARY

40. Defining the molecular mechanisms underlying hypoxic ischaemic brain injury

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of my group's work is the efficient discovery of mechanisms underlying brain injury which occurs in babies suffering a lack of oxygen to the brain during birth, and translating these discoveries into novel neuroprotective therapies. Such an ambitious aim can only be achieved through a considered approach which integrates *in vitro* and *in vivo* strategies to enable rapid translation to clinic.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Asphyxia (restricted blood flow/oxygen to the brain) during birth occurs in 2-3 term babies per 1000 in the UK, leading to the development of a condition known as hypoxic ischaemic encephalopathy (HIE) and permanent, life-long brain and motor disorders such as cerebral palsy. Following asphyxia, there is a delay of a few hours before the majority of brain cell death occurs providing clinicians with a valuable treatment window. The only available treatment, therapeutic hypothermia, is not always successful and new treatments are urgently required. However, therapeutic hypothermia does prove that intervening with treatment after the injury has occurred and within the treatment window can be effective.

This project is designed with the overall aim of identifying novel therapies to combat the devastating effects of this brain injury. Over the next 5 years, we will strive to improve our understanding of the cellular mechanisms underlying the evolution of the injury, enabling us to generate significant and realistic avenues for therapy development ready for preclinical testing. Primarily and most importantly, the success of this project will have far-reaching, long-lasting improvements on the lives of significant numbers of babies and their families but in addition, the basic science outlined in the project will be of substantial interest to all researchers in the field of brain development.

What outputs do you think you will see at the end of this project?

The outputs from this project are extensive and focus on identifying mechanisms leading to mitochondrial damage and using these data to provide new avenues for the targeting of treatments. Mitochondria are structures contained within all brain cells which provide the energy required for cell

survival and which are susceptible to damage following birth asphyxia. Using a variety of methods, we will generate large datasets of candidate molecules and novel pathways leading to mitochondrial dysfunction and will make these available to the wider scientific community using the appropriate platforms. We will have generated a significant body of basic mechanism data contributing to the understanding of mitochondrial biology in the immature brain. We will also have provided a solid foundation for the development of therapies aimed at preventing mitochondrial-mediated cell death triggered in response to this injury.

These outputs will be disseminated through publications and used to underpin further grant applications. If applicable, we will also consult with technology transfer colleagues to pursue any therapies in collaboration with pharmaceutical companies.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Birth asphyxia is the second most common causes of death and disability in children under the age of 5 years in 2010, resulting in the loss of 50 million Disease Adjusted Life Years (DALYs). As there is currently only one therapy for this injury, which improves outcome for only 1 of each 7 infants treated, there is a critical unmet need. Our project is designed with the overall aim of identifying novel therapeutics to combat the devastating effects of term brain injury and there are wide-ranging short and long term benefits which may arise on successful completion of our project.

Short term, the basic cellular science outlined in the project will be of substantial interest to all researchers in the field of brain development and mitochondrial biology. We will also identify potential therapies through repurposing existing drugs or developing novel mitochondria-based interventions. Depending on the nature of these compounds, we will engage pharmaceutical companies in order to facilitate required testing prior to clinical trial.

Long term, and most importantly, the success of our project will offer far-reaching, long-lasting improvements in the lives of significant numbers of babies and their families who suffer the devastating consequences of birth asphyxia.

How will you maximise the outputs of your work?

We will maximise the outputs of this work in a number of ways.

We will provide our data to the scientific community through presentations at conferences dedicated to perinatal brain injury REDACTED. These are necessary in order to generate new collaborations depending on the focussed areas into which our experiments lead. We will place our large datasets in appropriate repositories for use by the wider

scientific community and will publish robust data (including any *in vivo* negative data) in well-respected, open access, peer reviewed journals in the field.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will be bred in social housing conditions and may be ear notched for identification purposes.

Typically a post-natal day 9 mouse pup will be anaesthetised and undergo surgery for a maximum of 5 min and then allowed to recover in a warmed recovery box until the rest of its littermates have been through surgery. The entire litter is returned to the mother for an hour, whereupon the pup is then placed in a warm low oxygen chamber for around 50 min. During this time, the pup may experience mild seizures similar to those experienced by the human newborn following birth asphyxia. However these do not last once the pup is removed from the chamber. The pup will then be left alone, given an injection of a neuroprotective drug and/or cooled down to 33C for 5 hours. This hypothermia does not cause the pup any pain or suffering. Pups remain with the mother until weaning when they are subsequently maintained for non-invasive behavioural experiments or until the experimental time point of interest. Each mouse will experience this protocol only once.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

All pups undergoing surgery will be regularly monitored.

During surgery, exposure to hypoxia may cause seizure-like behaviour. However this very rarely lasts beyond the duration of the hypoxia (30-80min). Within the period of the previous licence, no animal experienced seizure activity following cessation of hypoxia.

Initially, following surgery, these mice will generally have a low level of weight loss but the weight gain trajectory is entirely normalised within a week. After this time, it is difficult to distinguish the experimental animals from the control, untreated animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All genetically altered mice that are being bred and maintained for the projects will experience mild severity only. Mice in protocol 2 will experience moderate severity as they undergo general anaesthesia for recovery surgery. However, subsequent recovery is usually in the mild severity category and the behaviour of mice is largely indistiguishable from their control litter mates. There are subtle behavioural differences, for example, forepaw preference can usually be observed in mice following the surgical procedure.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our project aims to understand the mechanisms involved in perinatal hypoxic-ischemic and infectious/inflammatory brain injury and to test neuroprotective strategies. As such, we need models that allow us to mimic human perinatal brain injury. Animals have to be used, as to validate a mode of action, experiments are required that cannot be conducted in humans for ethical and scientific reasons. In addition, interaction of the biological systems in whole organisms, with intact physiological barriers and excretion mechanisms, is key to inferring the potential of candidate therapies.

What was your strategy for searching for non-animal alternatives?

We have considered the feasibility of achieving our purpose by not involving animals at all, for example by using cell lines or in vitro recombinant methods, but no such alternatives are able to reproduce the brain injury we aim to investigate in this proposal.

However, where possible (for example, in altering gene expression *in vitro* or for testing the specificity of pharmacological activators/inhibitors), we will replace whole animals studies with primary cell preparations or experiments in appropriate cell lines (e.g. neuronal SH-SY5Y, microglial BV2, oligodendrocyte CG4 lines).

Why were they not suitable?

Our project ultimately aims to identify neonatal neuroprotective strategies formulated from evidence using *in vitro* cell systems. However, *in vitro* systems alone cannot mimic the unique and complex environment that exists within the neonatal brain. The brain is comprised of many cell types and *in vitro* systems cannot model the physiological interactions and communication between diverse cell populations. In addition, we are aiming to discover therapies beneficial to the neonatal brain, the environment and developmental trajectories of which are still being determined. Therefore to generate clinically relevant data, *in vivo* neonatal models must be used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used power calculations based on our previous licence and through refinements to the protocol.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We regularly use PREPARE guidelines and NC3R resources such as the Experimental Design Assistant tool to make sure we are adequately powering our experiments while minimising animal numbers. We also use the services of the REDACTED chartered statistician and subsequently follow ARRIVE guidelines for publication of *in vivo* data.

What other measures apart from good experimental design will you use to minimise numbers?

The REDACTED has an efficient REDACTED with highly trained staff which will streamline the breeding and maintenance of genetically altered and wild type mice (protocol 1). In addition, the methodology of protocol 2 has been refined over a number of years and is in routine use in the lab. For neuroprotection studies we will plan pilot studies according to the guidelines on the NC3Rs website.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will predominantly be using mice at an early life stage. The brains of mice develop late in relation to birth and at postnatal day (P)9-P12, mouse brain development corresponds to the term human brain. Importantly, they share several important features with the human brain with regard to brain complexity and injury response in white and grey matter and thus can be considered a valid model in which to deliver the objectives of the project.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There are other animal models we could use, some in which the brain structure is more similar to that of a term human (primates, piglets). However, we have decided to replace the use of such animals with mice, without detriment to the science. Mice are considered less sentient at an early age, easier to handle, breed easily and have a short generation interval. In addition, much is known about their genetics and physiology.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinements we propose to test will include increased monitoring of vocalisation following surgery as a measure of distress in very young animals, in which standard characteristics of suffering or pain may not be so obvious. Equally, for young animals we will minimise rejection by the mother by rubbing the hands of the experimenter in bedding
prior to handling the pups, to reduce transfer of unfamiliar smells. To this same end, routine monitoring will largely be through the side of the cage without disturbing the animals. Opening cages and handling animals will be limited to once daily as part of the standard observation and behavioural testing procedures within the project, unless a symptom of pain or distress is observed under which circumstance it may be appropriate to increase the frequency of monitoring.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

REDACTED

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed through the NC3Rs website REDACTED

Explain the choice of species and the related life stages

We are using mice for this project. Mice are easy to handle and a wealth of information is already known about their genetics and physiology which assists in the interpretation of data and the planning of future experiments. Brains of mice continue to develop after they are born so therefore we will be

predominantly using mice at the life stage of post-natal day 9 as this is the point at which their brain development is closest to that of a human newborn at full term. The mouse model of hypoxic-ischaemic brain injury outlined in this protocol is highly relevant to the human condition as it was used in the development of therapeutic hypothermia, currently the only therapy available to babies who have suffered from asphyxia during birth.

Home Office

NON-TECHNICAL SUMMARY

41. Detection of botulinal toxin

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Detection of Clostridium botulinum spores toxin

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Food producers are obliged to ensure the microbiological safety of all food supplied for human consumption (Food Safety Act, 2001). Food contamination by *Clostridium botulinum* can have severe and possibly fatal effects on consumers (man and animals) and is an important consideration in

production and processing of foods and feed. As *C. botulinum* is ubiquitous in the environment, detection of low-level contamination, particularly in foods destined for vulnerable groups of the population (e.g. infants) is an occasional but important need. In the UK hazelnut yoghurt outbreak in 1989, 27 people were affected and 14 people were affected in 2007 when commercially produced chilli products became contaminated. The oral lethal dose for an adult human is very low (5 ng) which means a very sensitive test is required when an outbreak is suspected. The MLA is the most sensitive and appropriate assay available with current technology.

The objectives of this project are to

1. Examination of food samples suspected of containing botulinal toxin/spores (following suspect processing failures or suspect botulism cases).

2. Suspect botulinal cultures isolated either in-house or by other food testing establishments or clinical isolates.

3. REDACTED

4. Examination of animal feeds (consumed by food producing animals) for the presence of *C. botulinum* spores/toxin.

A retrospective assessment of these aims will be due by 27 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Examining products suspected of being contaminated with C. botulinum and/or its toxin or examining clinical isolates suspected in cases of botulism, will help identify the contamination source and prevent further infection/intoxication by others. Examination of food samples will also help to reduce food wastage and/or enable appropriate disposal of contaminated products, thus reducing impact on the environment.

Advancing analytical technology is closing the gap between in vitro and in vivo methods. Should sensitivities indicate a possible move to in vitro models during the licence period, some mouse lethality assays may be required to finalise method validation to ultimately replace the animal- based bioassay.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice, young adult, up to 1000. Only 8 samples have been tested since 2010. Large numbers are only used in the event of an outbreak situation. Four mice are used per sample and four mice for each control.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

After intra-peritoneal injection of the sample extract mice are often subdued due to the injection for approximately 15-30 minutes, after which they recover fully.

Botulism toxin causes progressive paralysis and death through respiratory failure if humane endpoints are not applied. Mice are observed frequently (at least hourly for the first 24 hours), from experience, if symptoms do occur then they will normally appear in first 24 hours. If preliminary signs of botulism are observed (slight pinching of waist, rapid breathing) checks are increased until confirmed signs of botulism are observed (increased pinching of waist, cheyne stokes respiration, laboured breathing) at which point animals are killed humanely immediately. At the end of the test (3 days) all remaining mice are killed humanely.

Some mice (controls and spikes) may experience a severity level of moderate through exhibiting typical signs of botulism, however the majority will only experience a mild severity level as relatively few samples are found to be positive. The mice are checked regularly to ensure minimal suffering from botulism and are humanely killed as soon as typical symptoms are determined.

A retrospective assessment of these predicted harms will be due by 27 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Alternative in vitro detection assays i.e. immunoassays, endopeptidase assays, mass spectrometry and cell based assays have significantly progressed over the last 10 years although no single method has emerged that can detect all botulinum neurotoxins in food at levels similar to those achieved by the MLA (mouse lethal assay). Most alternative methods do not detect all toxin types, and many do not detect active toxin. Low levels of toxin may not be detected by in vitro screening techniques but will be positive with the MLA. This is particularly important when you consider the oral lethal dose for an adult human is as low as 5 ng (5000 pg) of toxin for some strains of *C. botulinum*. The mortality rate for botulism is still 5-10% despite modern therapy which is still high for a food borne illness. Rapid treatment with antitoxin is an important factor in reducing the fatalities and severity of illness, so rapid accurate sensitive tests are of paramount importance. Where possible non-animal alternatives (NAA) will be explored and if found unsuitable then the bioassay will be considered. At present NAA's would be appropriate where high levels of toxin are expected. This would allow effective sample screening with an in vitro method, but confirmation may still require the MLA. Negative samples would require further testing with the MLA to ensure toxin levels were not too low to be detected by the alternative method. The decision to perform the MLA would be made on a risk assessed basis and with consideration of the AWERB.

A retrospective assessment of replacement will be due by 27 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

The current method in use for the detection of *C. botulinum* or its toxins is the mouse bioassay. The number of animals used is the minimum number of animals required by this published method (4 per assay and four for each control).

Toxin typing is only carried out if required following a positive result. It is never undertaken without the confirmed presence of toxin present.

We do not quantitate toxin levels thus further limiting the number of mice used.

Ethical approval is sought prior to any testing to ensure that no unnecessary testing is carried out.

A retrospective assessment of reduction will be due by 27 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse bioassay is a regulated, recognised published method for the detection of botulinal toxin and details the choice of species to be used. This method uses the minimum number of animals to give the results required to determine the presence of botulinal toxin. Animals are observed frequently (at least hourly for the first 24 hours and then 4 times/day for remaining test) for typical signs of botulinum. If preliminary signs of botulism are observed the frequency of checks is increased (to every 20-30 mins) until confirmation of botulism. Once confirmed signs are observed, animals are killed immediately by a humane method. Experience has shown that if symptoms do not occur during the first 24 hours, they are unlikely to occur.

A retrospective assessment of refinement will be due by 27 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

Salmon	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to provide essential information surrounding the dietary and waterborne exposures of fish to plastic particles in the size range of 1 nm to 5,000 µm. We aim to better understand the influence of particle characteristics (e.g., size, shape, polymer type and presence of co-contaminants) on the uptake and toxicity in fish.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Plastics are lightweight, durable and inexpensive materials that are used in a wide range of consumer products. Global plastic production is above 335 million metric tons, of which around 40% was single use. Once released into the environment, heat and ultraviolet light can cause larger plastics to fragment into microplastics (<5mm), with concerns about the further degradation producing nanoplastics (<100nm). Environmental sampling of pelagic fish species has shown the presence of microplastics in the gastrointestinal tract. Of the laboratory studies conducted on fish, much of the work has focused on using embryos and/or short term exposures. Due to this, key questions surrounding the influence of exposure pathway on the uptake and toxicity of plastic particles in adult fish is lacking. Specifically, it is important to gain information surrounding the influence of particle characteristics (e.g., size, shape, polymer type, presence of co-contaminants) to inform risk assessment. The current project is important because the data will be used to inform a geospatial risk map to guide policy and management decisions for plastic pollution.

What outputs do you think you will see at the end of this project?

One outcome of this project is an enhanced understanding of plastic particulate uptake and toxicity in fish with regards to:

1. The role of exposure pathway.

2. The role of physical particulate characteristics.

3. The role of chemical co-contaminants vectors.

Each of the three objectives should produce at least one primary publication.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The significance of this project has been described in detail in a previous section (Background). There are 4 main beneficiaries to this work:

1. Other members of the research team will have access to the data. This will be of particular use to members who are investigating invertebrate systems to compare species sensitivity. This data will be available to other members as it is produced.

2. Chemical regulators as established methodologies are being followed so data between studies can be compared. This data will be compiled into publications, aiming for open access journals.

3. The data will inform on geospatial risk map of plastic pollution of shelf seas around the UK. The beneficiaries will be manufactures of plastics because we are going to increase their awareness of the problems their waste creates. This might inform on what they will do to minimize it. As we aim to publish data that is open access, this information should be of use to environmental regulators in guiding policy. The experimental data to be used in this risk map will be collected in the life of the project.

4. Industrial stakeholders who use plastic particulates, or larger plastics which can breakdown through the product life cycle or environmental degradation. The benefit here could be to convince plastic users to choose a more sustainable ways of use or material.

How will you maximise the outputs of your work?

The work from this project licence will be disseminated between the MINIMISE project members at regular intervals (biannually). New knowledge will be showcased at international conferences with a special interest in plastic pollution (e.g., Society of Environmental Toxicology and Chemistry and International Conference on Environmental Effects of Nanoparticles and Nanomaterials). The data will be compiled into manuscripts to be submitted to high impact journals for peer review, with each of the three objectives likely to produce at least one publication (>3 total).

Species and numbers of animals expected to be used

- Zebra fish: 2000
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Fish will be exposed to novel plastic particulates, with or without adsorbed co-contaminants, through the water or diet to assess their uptake and toxicity. The fish will be exposed via the food or water for a

number of weeks, with the only change to their normal husbandry being the addition of plastic materials at sub-lethal concentrations. We are not expecting any lethal toxicity from these materials.

The maximum exposure a fish will endure is 4 weeks. Each fish will undergo one procedure only before being killed by a schedule 1 approved method. The fish will then be dissected to remove the tissues for assessment of plastic and/or chemical uptake or toxicological assays.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We do not expect there to be any adverse effects to the animals. However, when using novel materials that have not been tested before, it is difficult to definitively say. Although not expected, some of the particles could cause transient gill or gut irritation at the start of the exposure.

Salmonids could display adverse effects including vomiting, loss of equilibrium, and changes in behavior or lesions. Zebrafish could display adverse effects including abnormal swimming orientation, lesions, scoliosis, scale and pigmentation loss, or become severely egg-bound. These will be recognized by generating species specific scoring index's, with fish monitored 3 times per day to check for development of clinical signs. It is expected that most of these symptoms would be transient, but if they persist for more than 24 h the fish will be removed from the experiment and killed immediately using a schedule 1 approved method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

As we do not expect any adverse effects, but cannot exclude them, we have selected the severity category to be Moderate. As we cannot currently say if a particle characteristic is toxic, the chance of them feeling any pain or distress could be around 50%.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our aim is to understand the uptake and toxicity of plastic particulates (and their co-contaminants) across the gills and gut of fish. The factors that determine the amount of chemical that stays in the body of a fish is dependent on the adsorption across the gill or gut, its distribution around the body through the blood supply, any metabolism, and any subsequent excretion that occurs from the body (e.g., from

the liver or kidneys). Therefore, to truly understand how these plastic particles affect fish, we need live fish to be used and exposed via the gill or gut. There is no suitable non-protected animal that would be a viable substitute.

What was your strategy for searching for non-animal alternatives?

As a vertebrate alternative, we have considered the use of *in vitro* gut and gill cell cultures systems, as well as *ex vivo* gut sac techniques.

As an aquatic organism alternative, we considered the use of invertebrates.

Why were they not suitable?

The media used to maintain the cells/tissues alive uses quite high concentrations of salts, which is known to affect the particle stability. The main problem with this is it can cause particles to aggregate and settle on the cells/tissue. This can lead to higher dose than would be expected when exposing fish to the chemicals. For example, using metallic nanoparticles, the tissue level techniques (e.g., the gut sac) suggests up to 20% of the exposure dose can be taken up by the intestine, whereas in exposed whole fish it is around 3% or less. Therefore, to ensure our results are realistic to exposure in the environment, live fish need to be used.

The use of invertebrates are also not appropriate to replace fish studies. Fish have a closed circulatory system (i.e., the blood supply) which can distribute chemicals around the body once they have passed either the gill or gut. In contrast, invertebrates have many tissues exposed to the surrounding water which means it is difficult to establish the relative uptake and toxicity from plastics in the water versus the food. Therefore, to understand how different exposure pathways affect the uptake and toxicity in organisms, fish need to be used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experimental design is for each treatment to occur in triplicate, with the tank as the recognized replicate. This triplicated experimental design has been scrutinized in peer review and is well established for experimental work with fish. To determine the total number of fish needed in an experiment, Mead's resource equation will be used.

For assessment of uptake, power calculations show n = 9/treatment need to be sampled. In a triplicated experimental design, this means n = 3/tank/time point. The longest planned study is 8 weeks (4 weeks

uptake and 4 week depuration), with a sampling rate for this analysis at once per week. Therefore, a maximum of 8 time points in one study equates to 24 fish per tank.

For toxicological assays, the same power calculation applies. However, a maximum of 4 sample points will be taken during the experiment. Therefore the total fish needed for toxicological endpoints are 12.

In order to ensure social hierarchies are stable until the end of the experiment, and additional 4 fish will be used.

Therefore the overall number of fish per tank is up to 40 fish (120 per treatment) in each experiment.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To determine the total number of fish needed in an experiment to allow for statistical differences to be achieved between treatments, Mead's resource equation and power analysis will be used. Power analysis has given estimates of 8-9 fish per treatment (n = 3/tank/time point/end point). The end points are two-fold: accumulation and toxicity (maximum total of 6 fish/tank/time point). For the toxicity end points (histology, biochemistry and molecular biology), multiple data points can be achieved by sub-sampling tissues from the same fish, which further reduces the number of animals involved.

To ensure robust data and to avoid repeating experiments (i.e., reducing the animals used), various sources of variation are being reduced. Many of the sources of variation are known due to previous experimental work being conducted in these systems. The tanks will be randomly allocated to account for any variation in the environment exterior to the tank (e.g., nearby cooling units). Previously, we have blinded treatments where appropriate (e.g., histological analysis) to prevent biases in analysis. An additional source of variability is dissecting whole organs (e.g., separation of the gallbladder from the liver) at sampling points. To control variability from sampling, the minimum amount of researchers dissecting fish on a given sampling day will be used, with only individuals with previous experience being involved (e.g., the NACWO). Also, dissecting tools will be acid washed prior to sampling to avoid contamination, as well as being washed between treatments.

What other measures apart from good experimental design will you use to minimise numbers?

To determine the total number of fish needed in an experiment to allow for statistical differences to be achieved between treatments, Mead's resource equation and power analysis will be used. Power analysis has given estimates of 8-9 fish per treatment (n = 3/tank/time point/end point). The end points are two-fold: accumulation and toxicity (maximum total of 6 fish/tank/time point). For the toxicity end points (histology, biochemistry and molecular biology), multiple data points can be achieved by sub-sampling tissues from the same fish, which further reduces the number of animals involved.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We are exposing fish via the water or gut to a range of plastic particulates (and/or co-contaminants) for up to 4 weeks. Salmonids could display symptoms including vomiting, loss of equilibrium, and changes in behavior or lesions. Zebrafish could display signs of abnormal swimming orientation, lesions, scoliosis, scale and pigmentation loss, or become severely egg-bound. These will be recognized by generating species specific scoring index's, with fish monitored 3 times per day to check for development. It is expected that most of these symptoms would be transient, but if they persist the fish will be removed from the experiment and killed using a schedule 1 approved method. The exposure concentrations are as close to environmentally realistic as possible, reducing the chance of pain, suffering, distress or lasting harm. Also, the delivery of the plastic particulates is in the same manner as those that fish are naturally being exposed to in the environment. As a result, we do not expect the fish to show clinical signs of exposure. The generated data is only satisfactory so long as the fish is healthy and not showing signs of ill health.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Part of this project will use less sentient animals; the OECD 236 zebrafish embryo toxicity tests (OECD 2013) will be used to screen novel plastic particulates where data for sub-lethal thresholds do not exist. These will then be used to inform suitable exposure concentrations. Also, where existing data to inform the exposure concentrations do not exist, a small pilot study will be conducted which will involve escalating dose design.

A fundamental part of uptake of particulate material is crossing a biological barrier to the blood supply for systemic circulation around the body (i.e., a closed circulatory system). Crossing of particulate material through this externally facing membrane is also a vertebrate specific anatomy, as invertebrates have open circulatory systems whereby the exposure media comes into contact with multiple tissues at once (e.g., mussels). While this can give a specific affinity for a tissue or tissue surface (e.g., digestive gland), it does not allow the rate limiting factor of uptake to be overcome – usually the basolateral membrane of the gill or gut epithelium – which will inherently affect the rate of uptake. Also, it allows sampling of internal organs which have not come into contact with the water or food so we can accurately assess what has been accumulated and not surface bound to the exposed tissues.

We cannot use terminally anesthetized fish as this would interfere with the overall uptake and excretion process, and hence the aim of this project.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will receive visual health checks 3 times per day. The water quality will be checked daily and reasonable adjustments will be made in case water quality parameters are unsatisfactory (e.g., increased flow rate/water changes). Any animals showing adverse effects will be removed from the experiment, so long as they are not thought to be treatment related. If clinical signs arise then the NACWO and/or the NVS will be contacted regarding the longevity of the experiment.

As the use of vertebrates is needed, part of our refinement is using fish and exposing them to sub-lethal concentrations, making them unlikely to be aware they are being exposed. Also, exposure concentrations of novel plastic particulates will be screened using the OECD 236 zebrafish embryo test (OECD 2013) to help determine sub-lethal concentrations.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the OECD 305 test guidelines. Also, where we do not have established data for threshold levels, small pilot studies will be used (e.g., escalating dose designs). Such experiments will start with a reduced number of experimental tanks (e.g., 2).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

This will be approached by:

1. Regular checks on the NC3R's website.

2. Contact with the Named Information Officer for any current updates.

Explain the choice of species and the related life stages

Salmonids and zebrafish are widely used in ecotoxicological studies, ensuring the plastic particulates we assess can be compared to a variety of other chemicals. Salmonids will be used for several reasons:

1. Their large size allows relative ease for sampling.

2. A large body of literature and previous studies exist on them, allowing for material comparison.

3. Part of the life cycle being in the ocean, it increases the degree of extrapolation from freshwater to seawater species.

4. They are commercially important species.

The zebrafish will also be used for uptake and toxicity studies. The main reasons for this includes:

1. Fully characterized genome and proteome for molecular studies of sub-lethal toxicity.

2. The small bodies will allow waterborne radiolabelled experiments to occur within the ionizing radiation regulations (IRR17) that larger fish make problematic for long period.

Environmental sampling of the gut contents of adult fish shows the presence of plastic particles. Therefore, to understand the effects these particles are having in the environment, we need to use the appropriate life cycle stage of the fish.

NON-TECHNICAL SUMMARY

43. Developing and evaluating imaging biomarkers in oncology

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

There are two parallel aims for the project.

1. To develop new imaging biomarkers for use in REDACTED studies. This work focuses around the technical and biological validation of imaging biomarkers (a characteristic by which a particular pathological status can be measured) that are not yet ready for decision-making
.

2. To use established imaging biomarkers to assess therapies. This work focuses on using imaging biomarkers for decision-making
.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Clinical imaging involves many approaches that include magnetic resonance imaging (MRI), computed tomography (CT), ultrasonography, positron emission tomography (PET) and single-photon emission computed tomography (SPECT). Imaging biomarkers, from these technologies provide a crucial role in the assessment of REDACTED patients, from early detection and diagnosis through to response assessment and prognostic and predictive evaluation.

As new therapies are developed, that target different aspects of REDACTED, so too there is a need to develop appropriate new biomarkers to detect, diagnose and monitor the new therapies. This need applies a) for both primary and metastatic disease; b) across a wide range of tumour types (e.g. Lung, Breast, Colorectal, Prostate, Gliomas, Renal, Gynae tract, Melanoma and others); and c) for a wide variety of targets (e.g. specific pathways, general microenvironment readouts such as hypoxia or immune cell populations).

As part of the above, new imaging biomarkers must be developed and then applied to studies of new targets related to the hallmarks of REDACTED. Developing biomarkers is a very complicated process that requires phantom, preclinical model and clinical studies. Similarly, evaluating new therapies requires preclinical model and clinical studies. This project licence is focused on developing and evaluating new imaging biomarkers in studies of various REDACTEDs.

<u>Aim 1:</u>

Many new imaging biomarkers are in development, but only a small minority make it through to clinical adoption. This is due to a failure to prove or validate the imaging biomarkers.

The need to have a rigorous framework of imaging biomarker validation is now recognised by the imaging science community. One key step is performing technical and biological validation steps in various preclinical REDACTED models, which include; Lung, Breast, Colorectal, Prostate, Glioma and Melanoma, as well as other models. In particular, this need has been articulated in an international consensus report, led by the PPL applicant.

Validation occurs using a variety of models, with choice of model determined by the biomarker in question. For example, imaging biomarkers of hypoxia (low oxygen content) should be developed in models that span a range of tumour types and have a range of values of hypoxic fraction. Similar principles apply to developing imaging biomarkers for use in immune-oncology, but the particular choice of models and the host mouse will differ since other biological systems will be more appropriate (e.g. syngeneic mouse v immunocompromised). Initial work will often begin in relatively simple models, but there is need to replicate key findings in more clinically relevant models (e.g. patient derived tumour implant models (PDX), metastatic lesions etc).

Aim 2:

Imaging offers the ability to perform real time and dynamic in vivo whole tumour tracking of response to therapy. This makes imaging an attractive tool in the assessment of new therapies or new combinations of therapies, since serial monitoring can provide information on the timing of anti-tumour efficacy for the primary tumour, secondary and metastatic disease across various modalities.

Again, choices of model will vary for each type of therapy under investigation, and a range of models starting from simple and moving to more complex (e.g. PDX, metastatic) should be used.

Furthermore, imaging may enable reduction of use of mice by providing methods that are more sensitive to detecting treatment effect. The PPL applicant's group have already begun to investigate how imaging may enhance experimental design by reduction of use.

What outputs do you think you will see at the end of this project?

The primary output of this project will be a substantial amount of data – information that advances our understanding of:

1. which imaging biomarkers should be selected for further application in preclinical studies/clinical studies, and;

2. mechanistic knowledge of therapies, based in part from established and new imaging biomarkers.

Outputs will be publication in peer-reviewed journals and presentations at scientific conferences and meetings.

It is anticipated that data will be used for subsequent grant applications.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Other preclinical scientists will benefit since the validation work (aim 1) will let them make informed decisions about which imaging biomarkers are accurate, precise and biologically relevant, for them to use in their own studies.

Clinical trialists will benefit since the translational work (aim 2) will let them make informed decisions about which imaging biomarkers are accurate, precise and biologically relevant, for them to use in early phase clinical studies.

How will you maximise the outputs of your work?

As well as publication (detailed above), we will aim to develop new collaborations. This is something that the group is doing already (with collaborators in the UK and other countries). We will also ensure that new knowledge is disseminated within the UK via education workshops that are run by the applicant.

Species and numbers of animals expected to be used

- Mice: 4800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most mice used in our project licence will undergo testing of drug regimens to confirm they are tolerable over a period of time ~25 days. New mice will then be injected with tumour cells of various REDACTED types to emulate the REDACTEDs patients display in the clinic.

Similar to patients we will monitor the tumour growth and dose them with relevant rationale for REDACTED treatment with a series of drugs or combination of these. These treatments may either be potential novel therapeutic agents, existing clinical agents or placebo administered by a variety of routes, but usually either by mouth, or by injection either under the skin or into the abdomen to study the effects on tumour growth and / or tumour composition. The mice will also have blood samples taken either from the tail vein or by sampling from a heart chamber under anaesthesia
.

In some cases the treatment will include radiotherapy in combination to chemotherapy for specific REDACTED types. Other experiments will also implement a combination of chemo/radiotherapy with immunological agents to augment the therapeutic benefit.

Along these treatment trials we will also aim to imagine the mice under very similar conditions to patients using equipment like MR, CT and PET scanner to visualise the intravital details of the tumour and biomarker of response. To simulate the patients with advance disease, in a large portion of the experiments we will excise the primary tumour and wait to monitor the growth of distant REDACTEDs (metastasis) which will then be treated and imaged as the primary tumour.

On some occasions it will be necessary to condition the mice for receipt of tumour cells by either modifying the diet or water (in the case of hormone positive breast REDACTEDs), administration of immune cells or radiation to prepare the host for tumour implantation.

Mice may be studied for up to 200 days after a period of therapeutic agent treatment for tumour growth to track long lasting benefit and imaged to confirm this. Fast growing tumours will always be monitored daily.

Mice will be group housed in ventilated cages which have their environment enhanced with items such as tunnels, houses, nesting material and gnawing blocks.

At the end of any protocol mice will be humanely killed by.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The greatest impact of the work carried on the mice will be primarily be the tumour growth and implantation procedures. Therefore it is possible that the tumour growth might affect normal physiological functions (such as locomotion or breathing depth) however, mice will be observed daily and any side effect that cannot be managed satisfactorily, e.g. loss of body weight by dietary supplementation with seeds, will be killed humanely.

Injections for labelling agents, tumour cells or drug delivery would only cause very transient minimal pain.

After surgical procedures for (tumour implants or removals) we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

The impact from the imaging sessions on the mice will only be limited to the insertion of the cannulas where required and the anaesthesia itself.

As with all procedures animal welfare will be first consideration and any harm or discomfort will be addressed leading to a termination the mice under schedule 1 methods.
The same will apply to the therapeutics intervention where the required pilot and toxicity studies will be done prior any large experiment to test tolerability of any compound or combination used along with the imaging.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of mice are only expected to experience the pain of repeated (daily) injections of therapeutic agents. We will aim to utilise the least stressful route, of administration wherever possible, such as oral gavage. All therapeutics regimes will be evaluated to minimise any induction of weight loss during treatments.

In the case sub cutaneous tumour growth we will monitor the progression on a regular basis to ensure that the scientific and humane end-points are followed.

For orthotopic models we will use palpation and intravital imaging to tract tumour growth and this will mean repeated anaesthesia for the purposes of imaging the internal tumours.

Therefore we foresee to have most of our mice, approximately 70% experience severities closer to the lighter side ofa moderate severity band.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While valuable studies of human REDACTED are performed using tumour material and cell lines derived from both mice and human samples, the mechanistic understanding of REDACTED pathogenesis and the biological & physical parameters of imaging requires use of living animals.

In particular, REDACTED development and spread involves a plethora of interactions between REDACTED cells and their surrounding host and their behaviour is governed by multiple signals originating from both their immediate neighbours and from distant tissues.

The REDACTED models implemented in our work, aim to closely mimic their human counterparts, and have the potential to test the effectiveness of novel REDACTED therapeutics along with the evaluation of imaging biomarkers. This cannot be replaced by in vitro studies which remain far less complex than a murine host.

What was your strategy for searching for non-animal alternatives?

We will use a variety of in vitro / ex vivo approaches to investigate how different drugs and therapeutic combinations can inhibit REDACTED growth prior to undertaking in vivo studies.

In addition, we will use molecular pathology (e.g. immunohistochemistry) to substantiate findings from our in vitro / ex vivo models in human tumour samples from clinical trials.

Other methods to be utilized include established cell biology techniques to measure; cell proliferation, survival, migration, and invasion. Where required we will also use biochemical and molecular biology techniques such as western blotting, enzymatic assays, proteomics, RT-PCR to study molecular pathways.

Why were they not suitable?

The study of cells in culture (in vitro) provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of the therapeutic regimes are established as they are part of clinical practice and clinical trials. In the case of novel agents or new combination (chemo/radio) we will in vitro methods to guide doses and combination rationale, this in turn will limit the number of animals required for the in vivo investigation stage.

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume following treatment combinations can be clearly determined using a minimal number of animals. In general, using 80% power, 95% confidence and 20% practical difference, group sizes of 6-10 animals per experiment should suffice. Pilot studies will be performed if applicable and, after analysis of the results using our published methodology, group sizes for subsequent experiments will be determined based upon these data.

We will be conducting and recording our experiments to be able to publish our results following the ARRIVE guidelines [https://www.nc3rs.org.uk/arrive-guidelines] and will use randomisation, blinding etc. where appropriate so as to minimise biases.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will discuss studies and powering of them, based upon data from pilot studies with local statisticians. Furthermore, adWe will discuss studies and powering of them, based upon data from pilot and similar archive studies plus in collaboration with a biostatisticians to cover calculating group size and ensuring statistical robustness. Furthermore, additional resources may be used to aid experimental design such as the NC3Rs experimental design assistant tool (EDA).

(https://www.nc3rs.org.uk/experimental-design-assistant-eda).

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be performed where required and after analysis of the results, group sizes for subsequent experiments will be determined based upon these data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use relevant preclinical REDACTED models that display true clinical features, will also have realistic clinical readouts like perfusion-weighted imaging (PWI), and diffusion-weighted imaging (DWI) that can inform biomarker derivation. This raw data will be used in a series of computer modelling to allow gaining the most insight from the captured data per experiment.

Past in vivo experience will be used to guide experiments to help to minimize potential suffering by regular monitoring of tumour size and potential impact on the general health status of the mice. For any

new procedure, we will seek expert advice from REDACTED staff (e.g. NVS, NACWO and HOI) follow the most refined techniques available.

For any inoculation/transplantation procedure we will follow the route that causes the minimal burden on the animal's well-being.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

• Mice are more comparable to humans than less sentient model systems (fish, invertebrates) in development, physiology, and genetic complexity. In mice we can we can model not only anti-tumour therapy effects but also drug metabolisms (absorption and excretion) profiles

• Non-protected species and less sentient species do not have a lung or the complex signalling required for development of the lung or mammary REDACTEDs.

In addition the imaging equipment is primarily designed to image live mice. Where possible we can introduce using organoids to some aspects of the project to inform future in vivo work.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To refine the type and number of procedures we will carry out an assessment on the data from the sizes of superficial tumours captured in our studies to derive a table where we can quantify the ideal tumour volume needed for imaging.

The total tumour burden should not exceed 1500 mm3, and volumes will be monitored closely, in the case of tumour approximately ~800mm3 of the maximum permissible volume, it will be measured more frequently.

During tumour growth, external tumours will be monitored for progression from local inflammation/irritation/pinpoint scabbing to an ulcerated state, depending on the tumour type (e.g. melanoma or breast) and especially after radiotherapy. Animals with ulcerated tumours will be cared for according to the best practice at REDACTED.

Where blood sampling is required, we will use microsampling. These samples will be taken according to good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of REDACTED, 102:1555-77 (2010)] using the least severe technique appropriate for both the strain of mouse and experimental requirement (e.g. venepuncture of a superficial blood vessel) with sample volumes being kept to a minimum and not exceeding published limits (10% at any one time and 15% over a 28 day period) and allowing appropriate recoveryperiods.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Throughout our work we will refer, consult and adhere to the guidelines and practices discussed in a series of key publications.

1. Miller AL, Leach MC. The Mouse Grimace Scale: A Clinically Useful Tool? PLoS One. 2015;10(9):e0136000.

2. Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, et al. Guidelines for the welfare and use of animals in REDACTED research. Br J REDACTED. 2010;102(11):1555-77.

3. Morton DB, Jennings M, Buckwell A, Ewbank R, Godfrey C, Holgate B, et al. Refining procedures for the administration of substances. Lab Anim. 2001;35(1):1-41.

4. Ullman-Cullere MH, Foltz CJ. Body condition scoring: a rapid and accurate method for assessing health status in mice. Lab Anim Sci. 1999;49(3):319-23.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

One of the team working on this PPL sits on the 3Rs Network committee at REDACTED where 3R initiatives are discussed and spread. Also by reviewing and reading regular newsletters from the NC3Rs.

Explain the choice of species and the related life stages

Mice are the ideal experimental host not only due to their size and quick life cycles but because their genetic, biological and behaviour characteristics closely resemble those of humans, and many symptoms of human conditions can be replicated in mice to a high degree of similarity. We use mice over 4 wks of age, as they are considered to be of adult age to sustain tumour growth and can tolerate a large degree of therapeutic interventions.

Home Office

NON-TECHNICAL SUMMARY

44. Developing fertility control as a management tool for REDACTED

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
Rats	adult, pregnant, aged
REDACTED	juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to produce an effective fertility control system suitable for use with REDACTED in the field.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The REDACTED has become widespread across much of England and Wales and is continuing its expansion northward into Scotland [Mammal Society, 2018]. Consequently the degree and extent of the problems caused by REDACTED have increased, which include threats to forestry and biodiversity. Importantly the continued spread of the REDACTED also threatens the remnant populations of the endangered REDACTED where they still occur across GB.

The only legal and effective tools to manage populations of REDACTED are lethal methods (shooting and live trapping with dispatch). Both are inefficient (especially at low densities of REDACTED) and unsuitable in many areas where REDACTED are common (e.g. urban and sub-urban landscapes).

Modelling work has indicated the potential value of fertility control in helping manage problems caused by REDACTED when integrated into a coordinated landscape-scale control program alongside other (lethal) methods. Fertility control may permit the cost-effective control of REDACTED populations at low- densities, as well as the management of populations where lethal methods are socially unacceptable (e.g. urban areas) or technically unfeasible. The most practicable approach to delivering fertility control for REDACTED is using oral contraceptive delivered in baits to free-ranging REDACTED. However this requires detailed studies to:

1. identify and characterize fertility control agents which are suitable for REDACTED (e.g. safe and with promising properties for fertility control)

2. develop and optimize the most practicable and effective formulation for a self-dosing deployment. For example the oral delivery of an agent may include research into the optimum combination of other ingredients such as adjuvants, additives, baits, preservatives etc.

3. validate the efficacy and ensure the humaneness of the most promising contraceptive in a proof of concept experiment

4. quantify key aspects of REDACTED behaviour and ecology in the field

i. to support the design and deployment of the field-based devices used to administer the contraceptive

ii. underpin mathematical models which will be used to provide replacement and reduction for this program of work

iii. enhance the benefit of the research by demonstrating the utility of the work to a wider audience and practitioners

References

Mammal Society (2018) A Review of the Population and Conservation Status of British Mammals (JP025)

What outputs do you think you will see at the end of this project?

We will have developed (a) formulation(s) with the necessary properties to contribute to an effective, humane and practicable fertility control system (e.g. enhanced fertility control, easy delivery) and selected the best candidate contraceptive for a proof of concept experiment using a breeding colony of REDACTED maintained for the purpose.

We will have undertaken a captive experiment demonstrating the efficacy and humaneness of one or more formulations.

We will have developed devices and deployment strategies suitable for use with the most effective and practicable contraceptive.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

If successful we will have developed a system comprised of tools (fertility control agent, formulation, delivery device and deployment strategy informed through mathematical modelling) which can be adopted by practitioners in the field and used as part of a comprehensive REDACTED control strategy. This should bring benefits to the economy (protecting crop trees), biodiversity (where trees and birds are threatened by REDACTED), as well as supporting the conservation of the REDACTED. This work

also acts as the foundation stone upon which further development of any of these tools may produce enhanced benefits in the future (e.g. application to other species and the solution to other human-wildlife conflicts).

Even if only partially successful, we will have driven forward the development of science in one or more of these component tools and contributed to a number of areas of basic science. Particularly the understanding of the reproductive physiology of REDACTED, their ecology and behaviour in the field, as well as some of the basic principles of developing immunologic approaches for wildlife applications which may bring benefits in other areas or for other species.

How will you maximise the outputs of your work?

Elements of the work will be published in the peer-reviewed literature and will be disseminated at technical and scientific conferences as well as meetings of practitioners and stakeholders.

REDACTED keen to see any benefits accruing from this work translated into practical benefits as quickly as possible, and communications plans are already being discussed.

Species and numbers of animals expected to be used

- Rats: 200
- Other rodents: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

REDACTED will be used in two types of study. In the field animals will be marked using PIT tags but will otherwise be unaffected by our work and will be released to continue their lives in the wild; we will use anaesthesia to make sure that this work is as refined as possible. Some REDACTED will be brought into a specialist wildlife facility in the laboratory to participate in experiments to develop a contraceptive. This facility is set up to care for the REDACTED as well as possible. Typically these animals will be

administered with a fertility control agent or formulation, and their responses measured using blood samples or non-invasive techniques (e.g. ultrasound) which require the REDACTED to be handled (refined using anaesthesia). Dosing REDACTED may involve injections or other regulated methods but candidate contraceptives are expected to often be self-administered in food or drink.

Rat (used as a model species) will be administered with a fertility control agent or formulation, and their responses measured using blood samples. This will involve injections, other regulated methods (gavage or oropharyngeal dosing) or be self-administered in food or drink.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

As our goal is the production of a fertility control system suitable for use in the field, we are working towards contraceptives free of harmful side effects to the REDACTED, or harmful effects on the environment. Most of the laboratory based research we will undertake will be using substances which are not intended to produce any harms to REDACTED, and are intended only to reduce their reproductive capacity. Developing the contraceptive will require some REDACTED to be injected, though any harmful effects these injections have are expected to be mild and short-lived. More generally, many REDACTED will need to provide periodic blood samples or be handled and observed closely (e.g. ultrasound examinations). These are best done by anaesthetising the animal, which reduces the stress it experiences as well as permitting work to proceed calmly and efficiently to produce the very best science. A small number of animals might react poorly to some treatments but close observation and rapid interventions to limit harms will ensure that suffering is minor and brief.

Some rats will be injected with a fertility control agent where they may suffer some mild and transient pain that is not expected tho last more than 72 hours. There may be an injection site reaction manifesting as sterile granulomas but causing no pain to the rats. Rats administered the fertility control agent via oropharyngeal dosing may experience some mild respiratory distress if the agent is viscious although this should be overcome by splitting the treatment into sub doses.

The REDACTED we study in the field should experience no significant adverse effects. Indeed competent staff will undertake a number of checks to ensure that the animal if fit for release, free of unintended injury, and able to continue living in the wild without detriment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most animals (estimated at 90%) will experience a mild severity. No animal will exceed a moderate severity.

What will happen to the animals at the end of the study?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Developing a contraceptive for REDACTED and a delivery device for its use in the field, as well as a strategy for deploying it to manage the environmental and economic impact by REDACTED cannot be done without research using animals. Whilst research discovering and describing new agents which can produce fertility control in REDACTED can use other rodent species as models for some aspects of the work (i.e. laboratory rats), key experiments still require us to study REDACTED to check and confirm our research. Using REDACTED is essential to demonstrate that our contraceptive is safe for REDACTED and effective. In addition, the practicability and cost-effectiveness of the system also depends on the performance of the devices we develop and how wild free-living REDACTED behave around them, requiring the study of wild REDACTED in the field.

However computer modelling study is running in parallel with the animal study to refine parts of the field trials.

What was your strategy for searching for non-animal alternatives?

REDACTED are unusual study species. Not much is known of their reproductive physiology and less is known of how to prevent their reproduction. As such non-animal methods known to robustly replicate their reproductive physiology are not available; requiring the use of animals to undertake the basic science as well as research how to control their fertility.

However, we do use mathematical modelling to identify when experimental work with animals has produced a contraceptive sufficiently good to use in the field. The modelling takes the empirical estimates we produce as part of this study (both of reproductive inhibition in captivity and behaviour in the field) and combines these to predict the efficiency of our fertility control system at the population scale across realistic simulations of real-world landscapes. This avoids undertaking extensive and lengthy study of animals in the field to provide the same evidence.

Why were they not suitable?

There are no non-animal alternatives to study the details of the reproductive physiology of REDACTED, its inhibition using previously unidentified contraceptives, or describe for the first time the behaviour and ecology of REDACTED in the field when presented with our self-dosing devices.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used our previous experience of identifying and characterising fertility control agents or contraceptives in other species to estimate how many animals we might use to achieve our goal of producing a fertility control system for REDACTED.

Where possible the most efficient statistical designs will be used (e.g. factorial designs), though where the constraints of animal housing (confounded blocking) or the measurement of unwanted interactions precludes this type of approach, power calculations will be used where appropriate to determine animal numbers required (usually groups of 7 to 10 animals). Thus where laboratory rats will be used as a model species smaller groups may be sufficient; and the greater variability expected in wild caught REDACTED suggest the slightly larger sample size. Wherever possible work will be planned to optimise the use of animals in control groups. Excepting specific study types (e.g pilot studies) many experiments will follow a pattern comparing a number of treatment groups with a control and use around 30 animals.

Laboratory rats are useful for studying some of the basic science around REDACTED reproduction and fertility control, or the initial work in describing the potential for a new substance or its safety to REDACTED. Whilst we expect most studies to be relatively small (use around 30 animals) we cannot know how many studies we may need to achieve our aims and have specified a number similar to that used on previous similar licences. However, we will always need to check our results in experiments using REDACTED to make sure that our understanding is sound and expect to use a similar number of REDACTED in laboratory studies (300 animals).

Our plan includes a proof of concept study where we demonstrate the safety and efficacy of our chosen contraceptive, and this needs to use the REDACTED in our breeding colony. Our breeding colony is currently established at 72 REDACTED. It is likely that some animals will be lost to old age through the course of study and need replacing. Thought this number is unlikely to be large it is difficult in this application to estimate accurately how many additional animals may be needed to maintain the colony in anticipation of our final proof of concept study. We have estimated the number needed here will not exceed 150 REDACTED. An additional 25 animals might be needed to just produce the basic descriptions of REDACTED reproductive physiology which we think will help us to produce better science as well as help us to design shorter and more refined studies.

About half of the REDACTED we might use will be animals which have marked with a PIT tag and then released back into the wild to continue their life there (approximately 300 REDACTED). The number of REDACTED we actually use in field experiments may be much smaller than this as the number present

in the woodlands where we work is always uncertain (woodland size and character affect the number of REDACTED present, as well as the season of study). We have anticipated two separate studies, each comparing three woodlands, each hosting about 50 marked REDACTED.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

All study designs will be subject to review by the PPLh (not the scientist leading the work), a statistician and the AWERB (including an independent statistician), all with a view to ensuring that studies are appropriately but not excessively powered to achieve their aims. Where the evidence required to design appropriately powered studies is unavailable (i.e. variation in dose-response to an agent), expert opinion and experience will be used to arrive at a suitably robust design for small pilot studies, which themselves will inform the design of larger experiments if these are required.

What other measures apart from good experimental design will you use to minimise numbers?

Our use of mathematical modelling permits us to potentially achieve a substantial reduction in the number of animals required to produce a fertility control system in REDACTED. Modelling allows us to identify, at the earliest moment when the development of contraceptive formulations and self-dosing devices can stop, and when their combination produces a fit for purpose system.

Useful fertility control systems do not have to be perfect, i.e. produce permanent, 100% infertility in 100% of REDACTED. Modelling has demonstrated how contraceptives delivered to sufficient REDACTED may still a cost-effective method to reduce the number of REDACTED at the landscape scale. Trade-offs exist in how the properties of the agent, its formulation and its deployment in self-dosing devices can be combined to achieve a useful reduction in the populations of REDACTED based on fertility control.
Modelling will be used throughout the progress of this work to identify when the development and optimisation of agents or formulations (both of which use animals) can be stopped in favour of enhancing the design of the self-dosing delivery devices or the schedule of deployment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Much of our work will require the use of live REDACTED, as it only in this model that the specific reproductive physiology we need to study and modify is expressed. This is also the target species for

our overall aim. However, work on REDACTED in the laboratory requires them to be brought into captivity, as well as being subject to the limitations of working with a wild animal (distress during routine handling, infrequent and seasonal breeding attempts), and a more tractable model for some of the basic science is available in the laboratory rat. Both are rodents and are likely to share similarities in some physiological processes. As laboratory rats are much more suited to laboratory based research on fertility control, being comfortable in captivity and constantly undergoing reproductive cycles, their use for some of the work is considered a substantial refinement.

Part of our work involves the study of REDACTED in the wild. Our use of anaesthesia to refine the experience of REDACTED as they are marked with PIT tags, and their prompt release back to the wild represents the most refined approach we can achieve. We will also ensure injuries and distress are reduced by using best practice in trapping (covering traps, regular checks etc).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There are no known models for the physiology of REDACTED that might be considered less sentient. Laboratory rats are no less sentient than REDACTED but are at least habituated to husbandry in the laboratory and are more comfortable being handled where this is required for the work.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The work applies refinement and continuous improvement to all elements of the work in this plan.

Specifically the care and husbandry of the REDACTED in captivity is under constant review by a specially convened species specialist team, which includes the NVS, NACWO, REDACTED scientists and REDACTED technicians who know their animals well. Refinements instituted by this team include minimising un- necessary contact with humans (e.g. remote observation 24/7 using infra-red video recording) and establishing strong routines (times, staff members) to reduce stress to the REDACTED. In addition, captive REDACTED have an evolved program of rolling enrichment, for both the facilities within their home pens (branches, hiding places, substrate) as well as feeding (food and presentation of food). This enrichment is considered carefully, as too much change is now thought to be stressful for the animals.

Additionally, most scientific interventions are refined using anaesthesia, which minimises the stress caused to the animal, permits the collection of multiple samples or observations through a single intervention without additional stress to the animals, as well as offering operators the opportunity to achieve protocol steps safely and securely, producing the best care for the animal and best science possible.

The breeding colony of REDACTED will be primarily monitored using remote CCTV so that there will be less disturbance and to minimise stress. Only if the REDACTED can not be observed via the CCTV or if there is cause for concern will they be psychically checked.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The two collaborating organisations have unparalleled experience at housing and breeding REDACTED in captivity. This success is produced in part by the unique research facility where the REDACTED are housed and provides the space and conditions for their optimum care; and also by constant attention to the refinement of regulated work involving captive REDACTED and enrichment of their care and husbandry. As part of both of these processes a REDACTED specialist group oversees the constant review of the care and use of REDACTED to ensure the highest standards are met.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

This plan is delivered as a collaboration between two organisations, both of which are committed to ensuring the most refined regulated work possible. The joint AWERB considers the 3Rs of all studies put forward and has expertise from a range of wildlife scientists, vets and statisticians. Both organisations employ staff who keep abreast of the latest advances in the care and research of laboratory rats. Both organisations also send staff to other organisations caring for REDACTED, or studying them, to bring back new ideas to further improve our culture of care for than animals in captivity and improve their experience during the research.

Explain the choice ofspecies and the related life stages

Only the study of REDACTED allows us to develop and demonstrate an effective and benign self-dosing fertility control system intended to reduce their populations in the field. The behaviour of free living REDACTED can only be studied in the field. Some animals will also be brought into captivity to permit the robust science and inference necessary to develop and test our contraceptives.

Where laboratory rats can be used as a model species, especially in the initial evaluation of fertility control agents or formulations, they will be used as they represent an effective replacement and one more suited to the laboratory environment and their reproductive cycle being shorter means that the studies can be quicker.

Home Office

NON-TECHNICAL SUMMARY

45. Developing Genetic Therapies for Respiratory Diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to develop genetic and cell therapies, e.g., by gene replacement, gene editing, gene silencing, or by engraftment of cells into the lung, for the treatment of inherited diseases such as cystic fibrosis and primary ciliary dyskinesia, or infectious diseases such as Covid-19 affecting the lung.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are several inherited diseases that specifically affect the lung including cystic fibrosis, primary ciliary dyskinesia (PCD), surfactant protein deficiencies, alpha1- antitrypsin deficiency and others, that are currently untreatable. CF affects about 10,000 people in the UK while PCD affects about 1,000. CF patients on average are dying in their thirties although there are some new drugs available for about half of patients but the other half still requires new treatment alternatives. PCD is not quite so serious but still can require lung transplantation in serious cases. Genetic approaches offer the possibility of new therapies for these diseases. While preliminary work can be performed in human cultured cells, it is important for most of these conditions to evaluate in living lungs as the complex structures and physiology and anatomy cannot be modelled in vitro.

Covid-19 is a global pandemic caused by SARS-Cov-2 virus, a coronavirus, that primarily manifests with respiratory symptoms. It can be transmitted by inhalation and enters the airway epithelium via the coronavirus envelope spike protein binding to the ACE-2 receptor. The route of uptake also involves protease activation. The genome has been sequenced and is available for research projects. While intense research efforts are in progress to identify a vaccine, concerns persist that an effective vaccine may be years away, and so alternative anti-viral therapies may be required and more effective in the shorter term. Nucleic acid therapeutics offer a wide range of therapeutic options and it will be important to evaluate these in animal models.

What outputs do you think you will see at the end of this project?

We hope to develop new therapies, such as gene therapy for respiratory diseases such as cystic fibrosis, primary ciliary dyskinesia and Covid-19, and learn how to deliver them most effectively and safely.

We aim to identify novel nanoparticle formulations that will be useful in the ongoing development of these therapies as well as methods of delivery by inhalation or systemic delivery.

We anticipate that numerous scientific papers, abstracts, posters and seminar presentations, will be produced from these studies that will directly benefit others working in this field.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the long term, our primary goal is to benefit the patients suffering from respiratory diseases such as CF, PCD and Covid-19 that have no other forms of treatment and face life-shortening problems along with the impact of these diseases on their everyday life.

In the shorter term, other scientists working in the same field will benefit in their research from our findings which we will share through the normal channels (publications, conference presentations, press etc.)

How will you maximise the outputs of your work?

Information on our findings and progress in this research will be disseminated to the scientific community by means of peer reviewed publications and oral and poster presentations at conferences and seminars. Where possible open access publications will be used as the vehicle for our research to maximise availability. Our websites will also be regularly updated to make information on our research freely available. Content will also be provided in a lay format. REDACTED will also publicise our findings and our institutional press offices will be notified of noteworthy findings for wider disclosure in the press. We will also communicate findings to companies at business/academic joint conferences and Knowledge Transfer Network meetings.

Species and numbers of animals expected to be used

- Mice: 5,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Experiments, will involve anaesthesia followed by delivery of reagents such as nanoparticles or cells to the lung by different methods of inhalation, e.g. simply by breathing in an aerosol, by instillation via the oral or nasal route, or by injection into the blood through a vein. These procedure are all performed quickly taking less than 5 minutes per animal.

In some cases, where we aim to improve efficacy of nanoparticle delivery mice will be pre-treated with agents that improve access to some lung cells 2 hours before delivery of the test agents. In some other

experiments mice may be pre-treated with alginates or other mucus modifying agents, particularly in Scnn1B mice, 2 hours before delivery of the test agents.

In experiments where we aim to use cells as the therapy, the lung may be pre-treated with a mild detergent, such as polidocanol, which removes cells lining the upper lung, to create space for the new cells to adhere and so repair the CF lung.

Mice will then be allowed to recover for 48 hours then treatment may undergo repeat dosing up to four times at intervals up to 7 days. Mice will be killed humanely by a schedule 1 method up to 1 month after the final dose, to assess efficiency of delivery, changes to gene expression, and safety of treatment by analysis of lung tissue sections or lung fluids.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The different treatments we are proposing generally have no observable effects. Occasionally there is weight loss at 24 h but by 48 h the mice are again putting on weight.

Administration of reagents into the lung by any of the proposed routes may cause a short period of hyperventilation from which mice usually recover within minutes.

We do not expect any effects on behaviour or tumour formation in the lung or anywhere else.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Wild type mice including reporter gene transgenic mice: - we have 20 year's experience of lung delivery of nanoparticles and other agents and rarely observe any side effects in these mice.
90% no effect; 5% mild; 5% moderate.

Scnn1b mice; from our experience over a period of about one year, we estimate that 20% of heterozygous mice die at the neonatal stage for unknown reasons but once weaned the mice show no signs of ill-health.
90% no effect; 5% mild; 5% moderate.

NOD/SCID mice are maintained in a sterile environment and will only be treated with sterile reagents or cells and so in our experience we do not expect to observe suffering of any severity.
90% no effect; 5% mild; 5% moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are many diseases that affect the lung for which there are no effective treatments. These include inherited diseases such as cystic fibrosis. The aims of this research are to develop and evaluate new therapies for currently incurable diseases of the lung. Mice are the smallest animals with lungs that it is practical to use in laboratory experiments. Structurally the lung is a complex branching structure with many cell types that vary at different stages of the branched structure. In the upper parts of the airways, the trachea, bronchi and bronchioloes are lined with cells that produce numerous hair-like projections called cilia, that wave to and fro, moving mucus and embedded particles up towards the mouth in a process called mucociliary clearance. These anatomical and phsiological features of the lung cannot be replicated in vitro. Access to the different stages of the lung by methods and routes of delivery also cannot be investigated in vitro.

What was your strategy for searching for non-animal alternatives?

We will use cultured cells for many experiments including air-liquid interface cultures where human primary epithelial cells differentiate to form the epithelial cell types including mucus-producing and ciliated cells. These cells also express ion channels including the chloride and sodium channels involved in cystic fibrosis. We will do as much as we can in these models to develop the most promising therapies.

Why were they not suitable?

The lung is a complex organ and there is no way to reproduce that complexity in a dish in the lab. Cells are cultured on a flat dish where the lung is a complex 3-dimensional organ, so live mice are necessary for these studies to have maximum scientific value.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animals wil be used from breeding Protocols 1 and 2 while other wild type mice wil be purchased from authorised suppliers. We already have a lot of experience in these kinds of experiments. Power calculations will be used to predict numbers of mice required to obtain statistically valid date with the

minimum number of mice. These calculations are based on more than 20 years' experience of in vivo lung delivery and analysis of gene expression and so these power calculations will usually be based on established experience. In some cases, where that prior experience is not available, we will perform pilot studies to generate data for this purpose.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Local statisticians will be available to advise on experimental design and wewill use the NC3Rs Experimental Design Assistant.

As part of this project we will continue to develop and apply non-invasive imaging modalities including bioluminescence and fluorescence imaging to monitor and assess tissue responses, in the hope that this will allow the identification of earlier endpoints. The use of live imaging may also lead to a reduction in animal numbers.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be performed for each protocol step as required to determine the minimal number of mice to generate valid scientific data. We also have more than 10 years of experience already in performing such experiments and so that experience will be valuable in our design. Imaging experiments in real time with the same animal will help to reduce numbers of individual animal measurements.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We intend to use mice, since a major aim of this project is to develop treatments for inherited genetic disease and there are many mouse models of human genetic disease. They have been designed to carry defects in the same respective genes, and in some circumstances show very similar lung diseases. Importantly, exactly the same gene therapy vector or cells that we use to treat a mouse can then be used to treat a humanbeing.

Some of the mice have genetic defects that cause thickened mucus in the lungs, as found in CF, and so provide a more refined, informative model than wild type mice.

The reporter mice we propose to use are specifically informative on efficiency of delivery for example of CRISPR or mRNA therapies.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We require animals that have lungs and the mouse is the smallest and most practical option. Adult mice will be used mostly as they are easier to work with in terms of size and better represent the lungs of patients. The developing lung for example in neonates may not contain the fully differentiated epithelium that we aim to treat and correct.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The animal models of disease to be used in this programme may not always mimic the human condition precisely but have been chosen because they are recognised by those in the field to be the most appropriate available. We have extensive experience in the development and refinement of these models, over a number of years allowing us to use the smallest species possible, reduce numbers of animals, limit invasive procedures and limit discomfort to a minimum consistent with a reproducible, statistically significant pathologic outcome.

The Named Veterinary Surgeon will be consulted whenever necessary. When work under terminal anaesthesia is involved, the level of anaesthesia will be maintained at sufficient depth for the animal to feel no pain.

We will continue to monitor our own practices and the literature, and will incorporate new approaches whenever possible to further refine, reduce and replace the use of animals. For example, we are investigating inhaled aerosol delivery methods with a small mask for the mouse rather than the more invasive instillation methods.

In general, our procedures and analytical protocols have been refined to allow us to use mice in most of our studies. Mice are also the species of choice due to the greater availability of genetically modified strains.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow ARRIVE and PREPARE guidelines for planning experiments as well as the NC3Rs experimental design asssitant for experimental design and for administration of substances by different routes.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I am a registered user of the NC3Rs newsletter and will regularly check the NC3Rs website for news of advances. We will also communicate with our local qualified staff for recommendations and updates on advances in 3Rs and how best to implement them.

Explain the choice ofspecies and the related life stages

These experiments to develop novel genetic and cell-based therapies for incurable genetic respiratory diseases such as cystic fibrosis and primary ciliary dyskinesia. Mice are the smallest laboratory animal that have lungs similar in anatomy and physiology to those of humans. We aim to use mice to confirm delivery of our novel therapeutics to the lung, an organ which contains many different cell types and a complex, branching structure that cannot be mimicked in the laboratory. Live animals also produce physiological responses to treatments that cannot be mimicked any other way which may be important for assessing efficacy, safety and toxicity of treatments. Adult mice will be used in most experiments although we may also use neonatal/pre-weaning Scnn1B mice to assess enhanced survival by treatment early in life.

Home Office

NON-TECHNICAL SUMMARY

46. Developing pre-clinical models of Prader-Willi syndrome

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Development and characterisation of preclinical mouse models which faithfully recapitulate clinical aspects of Prader Willi Syndrome (PWS). Assess the use of these PWS REDACTED as pre-clinical models to further understand, validate, test therapeutics and potentially treat symptoms of PWS.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

PWS is a genetic neurodevelopmental disorder that occurs approximately once or twice in every 30,000 births. It is known to be caused by the absence of a set of paternally expressed genes on human chromosome 15. Symptoms are multiple and debilitating, including hypotonia and feeding problems in infancy, intellect and learning disabilities, anxiety, behavioural and sleep abnormalities, incomplete sexual development, skin picking and severe hyperphagia leading to obesity. Patients also have a higher tolerance to pain which can lead to injury and infection. Later in life patients can develop psychosis and depression as well as secondary metabolic problems linked to obesity which are life limiting. Additionally there is an increased risk of sudden unexpected death at any age, with a prevalence of about 3%.

Although the group of genes involved in PWS are known, it is not understood which of these genes contribute to each symptom, and the mechanisms through which the symptoms are caused.

The only approved therapy for PWS is growth hormone, which helps with some symptoms but has no impact on hyperphagia, anxiety, sleep or behavioural and intellectual challenges. Symptoms of obesity can be helped with a strictly controlled diet, however the drive to eat is always present and exacerbates anxiety, depression and behavioural problems as children that feel hungry are denied food from their carers.

Previous models of PWS have been of some use but have been limited by sub-optimal model development using older transgenic technologies, incomplete phenotypic characterization, the heterogeneity of assessment methods and the lack of comprehensive, rigorous and standardized phenotyping. This programme of work aims to address these issues, firstly to generate meticulously quality controlled genetically altered REDACTED carrying modifications in PWS genes (this step is carried out on another licence), secondly to phenotype these lines through multiple phenotyping pipelines resulting in comprehensive data regarding all aspects of PWS that can be recapitulated in mouse models. Finally, validated models along with any mechanistic information that has been garnered from their study, will be used for basic research to better understand the pathophysiology of PWS and to trial new therapeutic drugs to treat humans with PWS.

A more complete characterisation and validation of mouse models of PWS may open up new avenues for understanding of the genes, proteins and mechanisms involved in this disorder and discovery of

drug targets and potential therapeutic approaches. To ensure this characterisation and validation is done in the best possible way, a collaboration has been set up involving specialist researchers and clinicians throughout Europe and the United States who regularly meet to discuss and review plans and progress.

What outputs do you think you will see at the end of this project?

We believe that development and validation of preclinical mouse models of PWS can be best accomplished through a collaborative effort that will leverage the know-how and expertise of various laboratories beyond what could be achieved by laboratories working in isolation. In addition, the network will provide comprehensive and unbiased data across developmental stages and phenotypic abnormalities as well as recommendations and best practices on mouse models of PWS for the scientific community. This will help guide researchers to select the most relevant mouse model and protocol for their study. Because PWS is a complex disease affecting many functions that may be inter-related, comprehensive phenotyping across multiple systems may provide important information on the relationship between these different functions (e.g sleep and cognition). In addition, the network will serve as a preclinical drug screening platform that will help accelerate the therapeutic development for PWS.

There will be four main outputs from this project.

1) Comprehensively evaluate at least five mouse models of PWS and make available to the scientific community.

2) Complete datasets on all PWS models available to all researchers to analyse and interrogate.

3) Advice on best practice to researchers using PWS models.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the initial stages the outputs will benefit the wider scientific community as data generated from this project will inform future studies.

However, there are very few treatments for PWS as the mechanisms are so poorly understood. It is reasonable to think that once further mechanisms and targets have been highlighted through these studies, there may already be drugs available that could alleviate some of the PWS symptoms. Efficacy testing these drugs in validated preclinical models will be the first step in getting new treatments to PWS patients. The aim of this licence is to validate and characterise these models and make them available for efficacy testing to other researchers on other project licences.

How will you maximise the outputs of your work?

The project is led by FPWR, a patient research-driven organization who is committed to improve and validate preclinical mouse models of PWS for the benefit of all. FPWR is regularly communicating about the importance of the project for the scientific community including pharmaceutical industries

developing therapies for PWS, as well as to patients and caregivers. Data and recommendations will be shared with the community that will include access to data, procedures and publication in a scientific peer-reviewed journals. These recommendations will be enforced through the FPWR grant program. In addition, mouse models will be made publicly available through the EMMA (European Mouse Mutant Archive) network.

One of the critical remits of this project is to increase the quality and usefulness of mouse models for PWS. This includes informing the community on which symptoms are not recapitulated and which models are not appropriate, as well as models and symptoms which are.

Species and numbers of animals expected to be used

- Mice: 41500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Many of the mice on this licence will be used only for breeding. This is due to the complex nature of PWS and the need to carryout several steps of breeding to get to a cohort that can be studied. We will also maintain breeding lines at Harwell to ship to collaborators for use on other projects authorised to accept GA lines.

In terms of testing at MRC Harwell, approximately 3500 mice will go through one of three pipelines. A pipeline that focuses on behaviour aspects of PWS, a second pipeline that focuses on metabolism and a third on nociception. Each pipeline involves 12-15 tests, most of which are non-invasive, a small number (two in each pipeline) involved anaesthesia used for immobilisation only. Mice are then finally anaesthetised and a terminal bleed carried out. All pipelines are expected to end by 30 weeks of age.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Humans with PWS suffer from hypotonia, feeding problems and failure to thrive, insatiable hunger drive, excessive eating (hyperphagia) leading to life threatening obesity, hypogonadism, cognitive impairment, sleep impairment, behavioural features which commonly include obsessive compulsive behaviours, anxiety, temper tantrums, and mental illness with a high prevalence of autism, psychotic

episodes, and affective disorders. It may be that some or all of these are recapitulated in various different GA lines on this licence. Previous models of PWS have shown only a subset of these clinical signs, it is also not clear how some of these signs will manifest in mouse models, for example psychotic episodes and temper tantrums. However, it should be assumed that it is possible that a mouse could display all of these symptoms and potentially other unknown phenotypes that are not seen in humans.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

7500 mice on the mild breeding protocol are not expected to suffer any adverse effects and the vast majority will not reach higher than a sub-threshold severity.

On the moderate protocol, it should be anticipated that any mice carrying the disease causing phenotype could exhibit a moderate phenotype. Other genotypes will also be born from these crosses, so approximately 50% of the 7500 mice may suffer a moderate severity.

3500 mice on the metabolic and behavioural phenotyping protocol are all expected to reach a moderate severity. This is partly due to the phenotype of the mice, in which the genetic alteration could lead to a moderate severity in around 50% of the mice (the other 50% being unaffected controls). However, all mice will reach a moderate severity due to a small set of the phenotyping tests causing moderate suffering, for example overnight fasting for blood sampling, or fear conditioning. Whilst these moderate affects will be short lasting they will increase the maximum severity of all animals on this protocol to moderate.

Similarly, of the 600 mice on the nociception pipeline, around 50% may reach a moderate severity due to the nature of the genetic alteration. Control mice should suffer no more than mild severity as the phenotyping tests included should result in no more than mild, transient discomfort.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Prader-Willi Syndrome (PWS) is an imprinting gene disorder caused by loss of expression of a cluster of exclusively paternally expressed genes on human chromosome 15. The PWS imprinted gene cluster includes six paternally expressed genes and two major clusters of the paternally expressed small nucleolar RNAs in humans. Non-mammal vertebrates lack at least five of these genes. In mice

the PWS imprinted gene cluster is found clustered together in a very similar way to the human gene arrangement, with the exception of one primate specific gene.

PWS is a complex disorder involving multiple genes and affecting tissues throughout the whole body, additionally the mechanisms through which the symptoms occur are poorly understood. Only by studying a whole organism will we be able to disentangle which genes are responsible for which symptoms and under which circumstances. There is not yet enough knowledge to study these changes in tissue culture as it is not clear which tissues/cells should be utilised.

The complex characteristics of PWS together with the well conserved genetics between the human and the murine region lend importance to the development of mouse models for PWS. Because of the changes in the disease manifestations across lifespan, mice will be analysed at three developmental stages (neonatal, juvenile and adult), across a comprehensive battery of tests to assess multiple system function including motor system, metabolism, cognition, social behaviours, sleep, circadian rhythms, temperature regulation, respiratory function, gastrointestinal and other functions that are impaired in individuals with PWS.

What was your strategy for searching for non-animal alternatives?

Some cell models for PWS have been developed. They comprise of fibroblasts, dental pulp cells and induced pluripotent cells derived from individuals with PWS as well as cultured cells originating from mouse models of PWS. Studies have shown defective PWS gene receptor trafficking, neuronal developmental and signaling defects. However, these cell models have not helped to discover molecular and cellular signatures of the disease and the extrapolation of the cell culture phenotypes to human symptoms in such a complex disoder cannot be done without further information, which needs to be generated in an animal model.

FPWR is also funding efforts to develop alternatives to animal models and has recently launched a PWS iPSCs biobank (https://www.fpwr.org/ipsc-biobank) to foster the development and characterization of cell models. As with the mouse models, FPWR are committed to building a repository of highly quality controlled and well characterised iPSCs which can be used by researchers around the globe. Developments in stem cell research will be continually assessed and any possibility to move research to stem cells or organoids will be investigated as it become available.

Why were they not suitable?

The biology of PWS is poorly understood, whilst the genes in the affected region have been identified it is not clear which of the genes causes the specific phenotypes or whether some genes are working in combination. PWS is a multi-system disorder comprising aspects of behaviour, sensory and metabolism. Since there are multiple genes acting on multiple organs it is difficult to model this in an organoid system. By using mouse models to increase understanding of which genes effect which tissues, and how they influence each other, it may be possible in future to build sufficiently complex tissue culture conditions. At present there is not sufficient knowledge to do this.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals used for phenotyping is based on power calculations using previous baseline data. This takes into account both the effect size and variability of data for each test and also the pipeline of tests as a whole. For example, previous baseline data for C57BL/6J males, shows that for open field total distance moved, the average is 2108cm, with a standard deviation of 510. To pick up a 25% drop in activity by the GA lines, with a power of 0.8 and a type I error rate of 5%, we would need n=15

Current estimates are that we will need a sample size of 15 per sex and genotype for the behaviour and metabolic pipelines, and a sample size of 10 for the neonate and nociception pipeline. However this will be reviewed as baseline data is collected for more of the tests.

Additional cohorts sent to collaborators will be larger as in-depth behavioural testing requires larger sample sizes of 20-25 depending on the paradigm.

Pipelines have been designed to gather the most meaningful data. Tests which can inform each other will be carried out on the same mouse to remove inter animal variability and increase the power, thereby decreasing the sample size.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

A local bioinformatician has been involved in helping us calculate sample sizes based on the pipeline and taking into account previous data. Online power equation calculators have been used to look at individual tests.

SOP's have been written and used routinely for previous projects. This standardises the way the data is collected and reduces the variability and therefore the sample size.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding numbers are calculated taking into account average litter size for that stock as well as known neonate mortality. Breeds are set up in a controlled, time restricted manner, to ensure that all mice born are the correct age for the study.

Where breeding information is not known (i.e. for new lines) a small pilot breed will be carried out first to assess viability. These mice, if viable, can be used for the first cohort of the study, and remaining larger breeds will be set up taking into account information gathered from the pilot breed.

All animals will be randomly assigned to cages and technicans and data analysts will be blinded to genotype until the study is completely finished and data analysis complete.

The aim of this project is to produce well defined clinical ready models to be used by the entire PWS research community. As such, large biobanks of tissues will be set up and tissue collected from all models on termination of the experiment. Once the data is validated and phenotypes assessed, tissues and data will be made available to the community.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

It is not yet clear which GA strains will best model PWS. In this study we will characterise mice with genetic changes in the PWS region. Initially these will be global deletions, however depending on the phenotype of these mice we may move to conditionally deleted mice, removing the gene in a tissue or time specific manner rather than throughout the whole organism for life. A full characterisation will be carried out to assess any overlap of symptoms between humans and mice. It is possible that some of these GA strains will not characterise the disease well. We will publish both the positive and negative data on each strain. It is hoped that this research will provide data for the scientific community, full characterisation will inform researchers which models they should use to study certain aspects of PWS, and which models are not useful.

Mice are generated and bred on a co-isogenic inbred lines to remove any confounding factors of genetic background.

Test	Why is this the most refined method?
Ear biopsy	Mice need to be ear clipped for identification and the same piece of tissues is used for genotyping. Genotyping protocols have been optimised to use this very small samples for all types of genotyping currently carried out at REDACTED. This is more refined than other methods such as tail biopsy.
Induction of transgene expression	In most cases this will be done by oral gavage on five consecutive days. Previous data has shown that this number of doses is necessary for sufficient induction of expression. This is more refined than injection, as whilst it involves restraint there

	should be no pain. Injection may be necessary depending on the type of recombinase line used and the time at which it needs to be activated.
SHIRPA	SHIRPA is an observational test that involves placing the mouse in an arena or a jar and looking for abnormalities. This is non-invasive and can provide a lot of phenotypic information that can be followed up in further, more complex tests. This is also a good opportunity to pick up any more subtle welfare concerns.
Open field	Open field gives us data on the reaction of the mouse to a novel environment. This arena is anxiety inducing in that the mouse has not seen it before and the light is relatively bright. There are no smells or sounds that should cause any further stress to the animal.
Grip strength	The grip strength tests is the quickest, least invasive way of measuring animals muscle strength. The test lasts for less than one minute and should cause no pain, only stress induced by handling.
Rotarod	Rotarod is useful to measure activity when the mouse is encouraged to run by placement on a moving rod. It is also a useful cross laboratory comparison to ensure reproducible phenotypes. Where possible, we will use voluntary wheel running to assess co-ordination or motor function as there is less stress induced from handling and the animal can choose whether to use the wheel or not.
Gait analysis	This involves placing the mouse in an arena and videoing for a short time. This is the most refined method of running this test as, unlike some other gait analysis equipment, it does not involve any stimulation to force the mouse to move.
Acoustic startle and pre-pulse inhibition	For this test it is necessary to assess the response of the mouse to an audible stimulus. Whilst the stimulus itself is anxiety inducing, efforts are made to reduce stress by having a constant background noise and carrying out the test in the dark. A protocol has been developed over many years to give useful data over as short a time as possible.
Spontaneous alternation	This is none invasive and involves placing a mouse in an arena and allowing it to to explore. Light levels are set so them mouse can see but are not intended to by anxiety inducing.
Elevated plus/zero	This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are anxiety inducing in some areas of the arena but other areas are darker. This is necessary as the test is assessing the preference of the mouse to the darker or lighter areas.
Social recognition	This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are low to reduce anxiety. In this test another mouse is present in a section of the arena. This mouse is in a small cage to stop any aggression but the scent and sight of it is needed to assess behaviour of the test mouse to a social stimulus.

Novel object recognition	This test is now carried out in a home cage environment. This reduces the stress on the animal and the novel object may be seen as a form as enrichment.
Temperature taking	This is done using a rectal probe that should cause no more than transient discomfort. The animal is only lightly restrained and the test is done in the shortest time possible, usually less than one minute.
Urine collection	Mice are held and urine caught in a container, or in some cases mice a placed on a plate and allowed to explore while urine collects below. In both cases this is less stressful than placing the mouse in a metabolic cage and collecting urine over night.
Light dark box	This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are anxiety inducing in some arena of the arena but not others. This is necessary as the test is assessing the preference of the mouse to the darker or lighter areas.
Ophthalamascope	For this test the mouse is held and the eyes examined. This is more refined than more in depth imaging as it does not involve general anaesthetic. However, the data collected is more subjective and there may be times when in-depth imaging is needed, in which case mice will undergo optical coherence tomography (imaging of the eye under general anaesthesia).
ECHO-MRI	This test involves less than one minutes of light restraint whilst body composition is measured. This is more refined that alternative tests which require general anaesthesia and a longer time to gather the data.
Blood sampling	Blood samples are collected to a maximum of 15% total blood volume of the animal, which has shown no adverse effects in previous studies. Samples are taken from the tail vein using a very small cut and mice have local anaesthetic applied to the area twenty minutes before the bleed takes place.
Tolerance tests	Blood samples are collected to a maximum of 15% total blood volume. Fasting for this tests is usually 18 hours due to the need to allow animals to use up glucose supplies and enter gluconeogensis. However, where possible fasting times will be reduced (e.g. 6 hours maximum for insulin tolerance). This test is more refined than other methods of measuring glucose which require surgery to implant indwelling catheters.
Video tracking for sleep	This is non-invasive and measured in the home cage, however due to recording equipment animals have to be singly housed.
Circadian	This is non-invasive and measured in the home cage, however due to recording equipment animals have to be singly housed.
Voluntary wheel running	This is non-invasive and measured in the home cage, however due to recording equipment animals have to be singly housed. This is a refinement on the rotarod test as animals can chose whether to run on the wheels.

Standard calorimetry	This is non-invasive in home cage like equipment. Bedding is provided and animal shelters are used when activity measurements are not needed. This test is used to measure oxygen and carbon dioxide levels and use them to calculate metabolic paratmeters.
Advanced calorimetry	This is non-invasive in home cage like equipment, however the floor is gridded and no shelters or bedding are available. As this is more stressful than standard calorimetry it will only be used when it is essential to have parameters that can only be measured with this equipment. This test is used to measure oxygen and carbon dioxide levels and use them to calculate metabolic parameters. In this equipment it is also possible to alter the temperature and lighting regimes, as well as measure body weight and food weight.
Metabolic cages	Mice are housed for as short a time as possible, usually 20 hours. This length is needed to collect a large amount of urine and assess overnight food and water consumption. Red houses are placed in the cages to provide shelter and respite from the grid floor.
Home cage monitoring	This is non-invasive and measured in the home cage. After initial insertion of a microchip this test involves no further pain, suffering or distress to the mouse. This generates large amounts of data with no adverse welfare effects. The main parameter measured is activity but videos may be used to assess other behaviours.
Stress induced hyperthermia	This test is necessary to assess stress without relying on activity. Mice will be closely monitored throughout and protocols have been designed for the shortest time possible. At all times mice are in a home cage but will be singly housed and with limited bedding as it is necessary for this to be a stress inducing environment.
Cold test	Mice are placed in a cooled environment (approximately 4 degrees centigrade) for up to 6 hours. Mice are closely monitored and removed if the temperature drops too low. This test is used to assess how well the mouse can regulate it's own body temperature.
Hot plate	This test has been refined so the mice are removed from the apparatus at the first sign of a response to the heat. Two technicians and multiple mirrors are utilised to ensure the first response is not missed. This test assesses the thermal pain response of the mouse.
Von Frey	This involves putting pressure on the mouse paw with a filament. The number of filament presentations has been reduced in this method as legacy data on mice shows the need to focus on a particular size of filaments. Mice are habituated to the arenas to reduce stress. This test assesses the mechanical pain response of the mouse.
DEXA/X-ray	DEXA and X-ray are not done using one piece of equipment which has been refined to allow constant observation and the use of gases anaesthetic. Both tests can be done together to reduce the need for further anaesthesia. This test measures bone

	mineral content and density, as well as producing an image to assess bone structure and abnormalities.
Echo-ultrasound, Echocardiogram	These tests are done under gaseous anaesthesia. When mice require both tests they are carried out under one anaesthetic. Potential skin damage from shaving has been mitigated by the use of hair removal cream. These tests image the heart to measure structural abnormalities and produce a reading of the electrical activity of the heart.
Auditory brainstem response	This test is done under general anaesthetic due to the extremely sensitive nature of the measuring electrodes and the need for a completely sealed sound proof box. Mice are monitored at all times through a window and the electrodes themselves should cause no pain. This test measures the electrical response of the brain when specific sounds are presented.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Prader-Willie Syndrome (PWS) is caused by 6 genes on chromosome 15 not being expressed and therefore not making any proteins. In this same region are sections of DNA that code for another type of nucleic acid, RNA, these RNA's control several processes within the cell and are also missing in PWS patients. The DNA that codes for these genes and RNA are found together at the end of chromosome 15 in humans and are all lost together by large deletions in PWS. In mice, with the exception of one gene which is specific to primates, this cluster of genes is also found together on chromosome 7. Therefore it is possible to create the same type of deletions in mice as it is in humans. Non-mammalian vertebrates lack 3 of these genes and no similar sequences to another two genes of these genes were found in chicken and fish. Making these animals less useful to model this particular disease.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

For all tests it is important that the animal has no additional stress, therefore mice are handled calmly and habituated to testing rooms as well as arenas if possible.

For all tests mice are only housed in modified cages or arenas for the minimum time needed to gather meaningful data. Mice undergoing phenotyping tests have increased monitoring and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests. Mice which have had anaesthesia have extra monitoring until fully recovered and extra checks when back in the holding rooms. When general anaesthetics are necessary, the combinations with least adverse effects will be used, for example for all tests inhalation anaesthetics will be used, with the exceptions of Auditory Brainstem Response and Optical Coherence Tomography which cannot be carried out with the mouse on a face mask. Pain from tail bleeds is reduced by using local anaesthesia.

This licence involves no surgery.

Pipelines are designed with thought given to the overall experience of the mouse and the number of type of tests any one animal will go through.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Routes and volumes for administration of substances are taken from LASA guidelines.

The animal house has full AAALAC and ISO9001-2015 accreditation. To conform to these standards we must ensure a high level of quality control on all fronts including husbandry, phenotyping and administrative processes.

Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at https://www.mousephenotype.org/impress

ARRIVE guidelines will be followed at all times.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Projects leads will attend general 3R's symposiums in the UK and abroad over the course of this project. From these we may gather information on refined phenotyping techniques or housing and husbandry methods. Moreover, it is our intention to continue to present any techniques that we develop ourselves in posters and papers in the relevant scientific/animal care forums.

More specifically, members of the research team will attend PWS specific conferences that focus on all aspects of the disease, from humans, to model organisms to *in-vitro* and *in-silico* work. Any new developments which could impact these studies will be discussed with the Pre-Clinical Models Network, a panel of experts set up to design and oversee this project.

Explain the choice ofspecies and the related life stages

It is necessary to use mice for this study due to the similarity of their genome to the human genome in the PWS region. PWS is characterised by the loss of paternally expressed genes in a section of human chromosome 15. Whilst some of the genes in this region are found in non-mammalian vertebrates, at least three of the genes are not found. We need to study the region as a whole and the interactions between the genes, this therefore cannot be done in species other than mammals. Mice contain almost the full complement of PWS genes on mouse chromosome 7, with the exception of one gene which is primate specific.

We are studying neonatal, juvenile and adult mice due to the nature of the disease in humans. Symptoms are seen early in life in newborn babies and these symptoms change overtime until adulthood. To study these different characteristics it is necessary to study the mice at various life stages,

from birth, through to adulthood and ageing. Where GA mice are not viable we may study embryos to help us understand why the mice cannot survive without a particular gene or set of genes.

NON-TECHNICAL SUMMARY

47. Development and function of immune cells in the uterus

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to determine how immune cells in the uterus develop and how they contribute to the success of pregnancy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Immune cells in the lining of the uterus help the placenta to implant at the beginning of pregnancy, and are involved in the initiation of labour at the end. Both of these processes have to be carefully regulated in order for pregnancy to succeed. For example, insufficient placental implantation can lead to miscarriages and disorders of pregnancy such as pre-eclampsia. Similarly, going into labour too early or too late are both associated with a greater likelihood that the baby will die.

My lab uses samples from human pregnancies to look at how these immune cells function in health and disease, but there are limits to what we can do using these approaches. Therefore, we will support and inform our human work by doing studies in mice, which allow us to specifically remove and add back immune cells to see how they develop and how their presence or absence affects pregnancy. These experiments will help us to identify cells and pathways that we can target in the future to improve outcomes of pregnancy for mothers and babies.

What outputs do you think you will see at the end of this project?

Advancement of scientific knowledge

The major output from this project will be new information about how immune cells develop in the uterus, and how these immune cells can help pregnancy to succeed. I will disseminate this information through scientific publications and presentations, as well as to my clinical colleagues and to the public through my engagement work with school pupils and patients.

Identification of targets that can improve outcomes of pregnancy for mothers and babies

A secondary output relates to the possibility that laboratory finding could be translated into a clinical setting. By integrating the animal work outlined here with the work that I do with clinical samples, and by working closely with my clinical colleagues, we may be able to identify new cells and pathways that could be targeted to improve the outcomes of pregnancy for mothers and babies, for example by reducing the likelihood of disorders of pregnancy such as recurrent implantation failure, miscarriage, pre-eclampsia and preterm birth.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Scientists

In the short and medium terms, the main beneficiaries of this project will be other scientists studying pregnancy, who will be able to use its findings to inform their own work.

Clinicians and patients

In the longer term, potential beneficiaries include couples who are struggling to conceive, and those who experience recurrent miscarriages and disorders of pregnancy such as pre-eclampsia and preterm birth. This study, and later ones informed by it, may help with the design of diagnostic tools and clinical interventions that can improve the outcomes for these families.

How will you maximise the outputs of your work?

I will maximise the outputs of this work within the scientific community by publication of my findings in peer reviewed journals and presentation of my work at national and international meetings. I will also publish negative findings, to avoid unnecessary duplication of work.

In the course of my group's work on human tissues, we collaborate closely with clinicians working in the field of reproduction, and will communicate the findings to our clinical colleagues, in order to facilitate any potential translation of our findings.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

About 75% of the mice used in this project will be genetically modified animals used for breeding. Males and females will be kept together and allowed to have pups until they are 15 months old. At the end of the breeding period, the mice will be killed humanely.

About 20% of the mice used in this project will undergo minor procedures, such as receiving an injection or giving a blood sample. This will help us to characterise their immune systems in more detail.

Less than 5% of the mice in this project will undergo irradiation to "make room" for new immune cells, which we will inject into the mice, to grow. The mice will be kept for between eight and sixteen weeks to allow their new immune system to "settle" before we use them in further experiments.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The genetically modified animals that we will use in this project may have defects in their immune systems, but when kept in the very clean conditions that we use in our animal facility, their lives will not be very different from those of normal mice.

The mice that undergo minor procedures, such as receiving an injection or giving a blood sample, will only experience momentary pain or discomfort.

Mice undergoing irradiation prior to transfer of immune cells may experience more severe adverse effects, similar to those that a person having radiotherapy as a treatment for cancer. They may have gut problems, such as diarrhoea, and are more likely to get an infection. When this happens, it usually occurs within the first two weeks after irradiation. The mice will be more carefully monitored during this period and any mice that lose a lot of weight or behave as if they are ill will be killed humanely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild: 95% of animals

Moderate: 5% of animals

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In this project, I will also examine immune cells taken from human tissues and this will reduce the number of mice I have to use. However, access to human tissue is limited and there are also certain kinds of studies that cannot be carried out on humans. Working with mice allows me to make changes to the animals – such as genetic modification – that would not be ethical or practical in humans. Therefore, using the mice will provide valuable additional information that could not have been collected from work with human samples alone.

What was your strategy for searching for non-animal alternatives?

This project also involves the use of primary human tissues and cells, and cell culture approaches.

Why were they not suitable?

These approaches are useful and will provide important information, but there is a limit to what they can tell us. In particular, using mice makes it possible to examine the complex interplay between immune cells (which may move around the body) and cells in the uterus, such as those of the placenta and blood vessels. It also gives us the ability to determine the effects of particular genes by using knockout animals. Neither of these is possible using patient samples or cells in culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have estimated the number of genetically altered animals that I will breed based on a rate of 300 animals/year for the duration of the project. This is roughly in line with what I currently breed, allowing for animals bred for tissues only and those animals produced as a byproduct of breeding mice of interest, which do not have a useful genotype.

For experimental protocols, where suitable preliminary data exists in the literature or in my laboratory, I have used it to calculate the required experimental group sizes. Where such data does not exist, I will first carry out small pilot experiments to determine the required group sizes.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

I have designed efficient breeding strategies using guidance from JAX laboratories, especially for conditional knockouts, found here:

https://www.jax.org/news-and-insights/jax-blog/2011/september/cre-lox-breeding-for-dummies

I have designed the experiments using statistical approaches that I learnt in the mandatory statistical training that I attended in order to be allowed to hold a project licence, and summarised here:

http://www.3rs-reduction.co.uk/

What other measures apart from good experimental design will you use to minimise numbers?

I will reduce the number of animals used by:

- Efficient breeding strategies
- Statistical approaches to determine the smallest sample size that can detect an effect
- Taking multiple tissues from each mouse where possible
- Taking multiple measurements from each mouse where possible
- Tissue sharing with other groups where possible

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The vast majority of mice in this project will suffer no more than transient pain or discomfort, with no lasting effects. Those mice that undergo irradiation before immune cells are transferred to them may experience gut trouble and increased susceptibility to infection, but this is an unavoidable consequence of the need to use radiation in these experiments.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The two groups of animals with similar reproductive immunology to that of humans are non-human primates (for example, macaque monkeys) and rodents (for example, mice). I have chosen to use mice in this study because they can be considered less sentient than non-human primates and because a number of genetically modified strains of mouse are already available. The fact that these strains have already been made will mean that we do not have to start from scratch, which would require many more mice.

In this study, which requires animals to mate, they must necessarily be conscious adults.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The following refinements are described in the protocols:

- Increased monitoring following irradiation

- Avoiding the unnecessary use of antibiotics
- Increased monitoring of pregnant animals following intraperitoneal injections
- Administering topical analgesia to avoid pain during repeated blood sampling

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

I will use guidance published and kept up to date by NC3Rs:

https://www.nc3rs.org.uk/3rs-resources

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I receive monthly email updates about 3Rs issues from NC3Rs. Our animal facility is also very good at communicating new ideas about 3Rs through email updates, posters displayed in the facility and through conversations with staff when my team and I are working in the facility.

Explain the choice ofspecies and the related life stages

I have chosen to use mice because they have a similar immune and reproductive system to humans, and because genetically altered animals that allow me to define the roles of different immune cells are available. Because the project looks at the immune system in pregnancy, I have to use adult, pregnant animals.

Home Office

NON-TECHNICAL SUMMARY

48. Development of Bacteriotherapies for Cancer

Project duration

1 years 6 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Cancer, Immunology, Therapy

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

It is now understood that our digestive system has an entire ecosystem of microbes that are essential for normal health and when this is altered, in the case of taking antibiotics, it can lead to the development of other conditions. We have identified that the mix of microbes varies greatly from person

to person and that the specific make-up can influence the response to various treatments. A very recent finding has been that this can affect the development of cancer and also the response of cancer to many treatments we currently use. They might also explain the difference in the side-effects that patients experience.

We have begun to identify particular types of microbes, in particular bacteria, that correlate with the response a cancer patient has experienced to treatments. We aim to use this knowledge to develop cocktails of bacteria that could eventually be given to patients to either help treat cancer directly or to boost the activity of other cancer therapies.

A retrospective assessment of these aims will be due by 22 January 2022

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The significant shorter-term output of programme of work will be to generate data to demonstrate bacterial cocktails can be used to progress to pre-clinical development in preparation for clinical studies in humans. In the longer term, we expect our lead novel bacteriotherapies to treat cancer in humans to reduce morbidity and mortality. The results of the research will be published in scientific journals and presented at scientific conferences. New mouse models may be patented and shared with other researchers.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Over the 18 month period of the project, we anticipate to use 920 mice.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Up to 120 mice will be used in breeding to generate the experimental mice we require. Up to 700 mice will be used in our cancer studies and will experience moderate severity as we have to handle them

more in order to carefully monitor the tumour growth. They will be injected with cancer cells to their side to generate a small lump and are measured regularly to track lump size and mice are humanely killed before the product of maximum length and maximum width of lump reaches 1.2cm2. The length and width of the lump size will be measured using callipers. These mice will also be colonised with particular bacterial species either using samples obtained from human cancer patients or what we have grown in the lab. Sometimes in order to help these bacteria grow we first need to give the mice antibiotics either in drinking water or via intra-peritoneal injection to eliminate the bacteria that already live in their digestive tract. At various times they will be treated with our candidate bacterial cocktails given via oral gavage by putting a small tube into their throat for a very short period of time to deliver the bacteria into the stomach. We will use the least invasive way possible to administer the antibiotics some of which can be in the food and drinking water but occasionally due to the antibiotic we need to do this by injection. In general the bacteria needs to be administered via oral gavage as we are using anaerobic bacteria that can grow in the absence of oxygen and ensures the delivery to the correct location. A subset of these mice will be used in our therapy studies and will be administered via intra-peritoneal injection with anti-cancer drugs such as those treatments that are currently used in hospitals to treat cancer patients. All these procedures will cause minimal suffering to the mice. All the mice will be check daily by qualified technicians. A small number of mice who are cured of their cancer and the small lump is no longer detectable will be injected again with the same cancer cells to their opposite side. This may allow us to show that the effect on the immune system is long lasting and represents good candidates for long-term therapeutic benefit to cancer patients. When the mice reach the endpoint of the study, defined by a humane endpoint such as tumour size or timepoint, they will be humanely killed prior to tissue collection. Some mice could have small blood samples collected while they are alive so that we can track the effect of a treatment or larger volumes collected after they are humanely killed. Mice typically do not show any altered behaviour when administered cancer cells, however on some occasions they may not have control of the cancer cell growth or the immune response can be so effective it leads to other side effects such as nausea also seen in cancer patients. We select the cancer cells to be administered to be the most suitable for our experiment which give rise to masses that are well tolerated. Very rarely the mice may scratch at their lumps causing the skin to be broken and if this is observed the mice are humanely killed. Some of the immune system treatments, as they are designed to provoke the immune system, can give rise to symptoms such as increased temperature and diarrhoea. This will be closely monitored (twice a day or more if necessary) and when it exceeds certain thresholds the affected mice will be humanely killed.

The final 100 mice will be used for studies without a tumour to understand how the bacterial cocktails interact with the immune system to cause the therapeutic effects that we observe. Half of these mice will experience mild severity as they will be colonised with the bacterial cocktails prior and subjected to a small number of injections of immune system altering agents. The remaining mice will experience moderate severity as they will be administered the bacterial cocktails and immune system altering agents on multiple occasions. Some mice could have small blood samples collected while they are alive so that we can track the effect of a treatment or larger volumes collected after they are humanely killed. These mice could experience some side effects from the treatments which is quite similar to a bad cold, they are carefully monitored and if they exceed the criteria they are humanely killed. We will provide extra bedding and additional support to the mice to minimise these effects.

The models and experimental protocols that we are using are well established, widely used and designed to cause the least pain, suffering and distress to the mice.

A retrospective assessment of these predicted harms will be due by 22 January 2022

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The cells of the blood system and their interaction with tumours is very complex and requires the interaction with other cell types for which it is not possible to use a non-animal alternative. Also, it is not possible to add in the extra complexity of the microbes using in vitro methods as these contain agents to stop the microbes growing. We will use existing data sources rather than duplicating where these exist and also harvest additional tissues for use in alternative lab-based experiments where possible. Should new lab-based or computer-based models exist which generate comparable data these will be adopted.

A retrospective assessment of replacement will be due by 22 January 2022

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use various statistical approaches to determine the minimum number of animals to use in an experiment and where possible combine experiments. We will also harvest additional tissues from mice at the end of experiments to use in laboratory-based assays to reduce numbers needed. Proper design of the experiments and controlling for sources of variation such as the age and sex of the animals will also help increase the robustness of the experiment and result in an overall reduction in animals needed. When publishing our data we will follow the ARRIVE guidelines to ensure comprehensive reporting and will release all data including where we do not find any alterations as this can be as informative to prevent assays being repeated in other laboratories. The results of the research will be published in scientific journals and presented at scientific conferences.

A retrospective assessment of reduction will be due by 22 January 2022

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We use mice for select experiments as they represent an ideal model to study host-microbe and immune cell interactions and serve as an invaluable pre-clinical model for anti-cancer therapy development. The use of mice in cancer studies is well established and the models we plan to use are considered 'gold standard' and are used in the development of therapies that are now used in the clinic and resulting in good responses in some cancer patients. In all our experimental work we will minimise the number and severity of procedures applied to the mice, this could be via the selection of the substances that we administer causing the least number of side effects, administering substances together if possible. We will use cancer cells that are pathogen free and that will not make the mice sick and will investigate alternative methods to monitor the growth of the cancer cells in the mice to minimise stress from handling. When we are performing experiments requiring mice to be anaesthetised for a period of time we will use agents that allow for a rapid recovery and that will not affect the mice. As we can monitor the survival of the bacteria in the mice via collection their poo we can minimise the number of administrations of bacteria via oral gavage. Also, we will investigate the possibility to colonise mice by co-housing as the microbiome can be transferred in this way or via bedding from other mice. The substances that we administer to treat them will be of the purest grade and screen for possible contaminants that could mice sick.

The use of a sophisticated mouse tracking system allows accurate tracking of all health concerns associated with the mice to be used in this study and to enable rapid investigation where they occur at a higher than expected incidence. All people who work with the mice in this study are thoroughly trained and continuously assessed for their ability to perform these procedures, with procedures refined following advice from the vet/NACWO or other international guidance. In addition, a comprehensive staff training and competency assessment process is implemented for all animal users within the establishment with continuous evaluation of procedures to ensure they are performed optimally or adjusted to benefit animal welfare. Mice are group housed in an enriched environment.

A retrospective assessment of refinement will be due by 22 January 2022

The PPL holder will be required to disclose:

> With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

49. Development of novel therapies for the treatment of stroke

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The central aim of our research is to develop new therapies for stroke and the complications of stroke such as chronic pain.

A retrospective assessment of these aims will be due by 18 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Stroke is brain injury caused, in most cases, by the blockage of a blood vessel that supplies blood to the brain. There are approximately 150,000 strokes per year in the UK and it is the largest cause of adult disability. There is currently only one approved acute pharmacological therapy, tissue plasminogen activator (TPA) which must be administered to stroke victims within 4.5 hr of symptoms onset. However, only 3-10% of patients will receive this medication primarily because most do not arrive in hospital early enough to be eligible; or because they are taking medications that make them ineligible for the clot busting therapy. Thus, there is a desperate need for new therapies.

What outputs do you think you will see at the end of this project?

1. The development of drugs which have multiple mechanisms of action. The information from our work could potentially be used to design studies in humans. We would publish our findings in peer-reviewed journals and present atnational and international conferences.

2. The development of a vaccine for stroke. This would allow the treatment of large numbers of patients who are at risk for stroke. The information from our work could potentially be used to design studies in humans or design monoclonal antibodies or drugs. We would publish our findings in peer-reviewed journals and present atnational and international conferences.

3. To better understand the body's own protection mechanisms against stroke and to understand how these messages may be transmitted to subsequent offspring. This knowledge could be used to develop new therapies. If we are able to identify new pathways that are involved in conditioning, the information from our work could potentially be used to design new neuroprotective drugs. We would publish our findings in peer-reviewed journals and present at national and international conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

If we are successful in developing a new therapy for stroke, this could have huge benefits for humankind. Stroke is the third biggest cause of mortality and the biggest cause of adult disability worldwide. A new therapy for stroke that could benefit large numbers of patients is desperately needed. We also have the potential to help individuals who develop complications of stroke such as chronic pain.

By the end of this body of work (5 years), we hope to have identified:

1. 1-2 new drugs, that could be ready for human testing

2. Tested a vaccine for safety and efficacy preclinically, ready for advanced toxicology studies.

3. Identified mechanisms that underlie conditioning. This information could be used to design new drugs that target those pathways.

How will you maximise the outputs of your work?

Publication of results in peer-reviewed scientific journals will be a major element in the dissemination strategy of this body of work, therefore making the research available for exploitation by stroke and pain researcher worldwide. Additionally findings that will result from this proposed body of work will be disseminated by presentations at national and international conferences.

Furthermore, in order to widen the scope for knowledge transfer, visits and collaborations with other laboratories in the UK, Europe and/or USA will be organized during the duration of the project. I have very strong relationships and ongoing collaborations with several laboratories worldwide and my laboratory team members will be encouraged to visit these laboratories.

Species and numbers of animals expected to be used

- Mice: 3200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of the animals that will be used in this project will undergo induction of ischemic stroke. Some animals will undergo transient or permanent occlusion of the middle cerebral artery (MCA) by inserting a nylon microfilament into the MCA, through the carotid. Some other animals will undergo permanent MCA occlusion by direct occlusion of the MCA by eletrocoagulation. Some other animals will undergo MCA occlusion by injection of a clot into the MCA through the carotid.

All animals will be tested for functional outcome, including neurological evaluation, motosensory evaluation, development of pain and cognitive impairment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Following transient and permanent MCAO, animals will show transient weight loss and neurological impairment as a result of the surgery and the experimental stroke. Activity can be subdued for a few hours after recovery from anaesthesia. The weight loss recovers around 48 hours. The functional impairment starts to improve significantly after 48 hrs and is very mild after 72 hrs and specialised functional tests such as the Garcia scale are used to detect the functional deficits because they are so mild.

About 30% of animals are expected to be sacrificed at 48 hours. The rest of the animals will survive to about 30 days post-surgery to look for long term functional improvement.

We have recently discovered that animals develop a mild hypersensitivity to pain in the affected limb which appears to persist to about 30 days. However, this pain and is mild and does not appear to affect activity, feeding or other behaviours.

The therapeutic agents that are being tested could potentially have toxic effects which may manifest in weight loss, reduced activity and feeding but we have not encountered such effects with the agents we have tested. If toxicity is encountered then these animals will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The stroke model we are using mimics the human disease. After induction of stroke, animals will develop neurological deficits. Most of the transient middle cerebral artery mice are expected to reach severe level early after surgery (48hrs) and recover very well after that and have little observable deficits subsequently. In the permanent stroke models the deficits are very mild and mice have excellent recovery - all these mice reach moderate severity. All animals will be closely monitored and any animals exceeding the expected severity level will be terminated.

For the PK studies, the mice are expected to reach mild to moderate severity only.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 18 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The overall objective of this project is to develop, new therapies for acute stroke. We have used *in vitro* cell culture models and other *in vitro* assays to identify candidate molecules in previous and ongoing studies. Those studies allow us to select the best candidates for testing in animals.

For approach 1, animal experiments are needed to optimise and determine the best dosing that will be required for efficacy and safety.

For approach 2, previous *in vitro* work has identified candidate target molecules for development. We now need to test efficacy and safety in animals.

For approach 3, we need to confirm our preliminary studies that appear to show transgenerational protection. Candidate mechanism will be explored using *ex vivo* and *in vitro* approaches wherever possible but it is inherently impossible to do transgenerational studies using cells.

What was your strategy for searching for non-animal alternatives?

The most frequently used in vitro model of cerebral ischemia is the combined oxygen and glucose deprivation (OGD). Retaining glucose in the hypoxic chamber is less suitable for modeling an ischemic event, which always is accompanied by breakdown of the nutrient supply. Additionally, Compared to *in vivo* models, there is a need for a longer episode of energy deficiency to induce neuronal death.

Another way to model ischemia in vitro is the organotypic brain slice. This approach has the advantage of a functional system with preservation of the neuronal morphology and the presence of glial cells and network connections in particular when using hippocampal slices. However, the lack of perfused vessels in brain slices clearly represents an artificial situation, despite the fact that allows separation of the ischemic effects on neuronal tissue from those due to actions on the cerebrovascular system.

In vitro models allow the investigation of specific basic biochemical and molecular mechanisms under conditions of energy deficiency similar to ischemia. The fundamental critical control points and molecular pathways of necrotic cell death, programmed cell death and autophagy are also amenable to direct study in vitro. However, the complex situation of ischemic stroke cannot be modeled in an *in vitro* system with single cells or pieces of brain tissue with the absence of intact blood vessels and blood flow as well as the lack of infiltration of leukocytes.

Why were they not suitable?

Although *in vitro* experimental research has been an important component of our overall development plan, it is not, however, sufficient on its own because stroke involves complex interplay of multiple mechanisms in various organs. For example, the peripheral immune system as well as other inflammatory processes outside the CNS can influence the integrity of the blood brain barrier which is an important barrier against stroke injury. This can only be tested in living animals. Furthermore, an important part of stroke efficacy and safety evaluation is the study of functional and behavioural outcomes which is not possible using *in vitro* experiments or computer simulations.

A retrospective assessment of replacement will be due by 18 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A statistician has provided input in study design and statistics.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The number of animals will be kept to minimum by ensuring that the experimental designs to be used are rigorous and that all personal licensees (and dedicated animal care staff) working on this project are appropriately trained and suitably competent. This will enable a high success rate to be achieved with minimum number of animals being used.

Initially, we will test efficacy at 24 hr and only if the efficacy is observed at 24 hours will the chronic experiments looking for efficacy and safety at 28 d will be carried out. This will reduce the number of animals that will be exposed to the experimental protocol for 28 d. Chronic testing is essential because it is possible that our candidate therapeutics may be efficacious at 24 hrs but this protection is not sustained over the longer term.

What other measures apart from good experimental design will you use to minimise numbers?

Wherever possible, we will use published literature (and if more appropriate conversations with colleagues in the field) to guide any experiments. For example, choice of a starting dose will be based on previous experience with that drug and analogues. We will also do pilot studies for new drugs.

Wherever, possible, we will use *in silico* modelling to assess toxicity and potential organ toxicity of a drug before starting experiments.

A retrospective assessment of reduction will be due by 18 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Choice of species

An experimental stroke model requires an animal with an intact cerebral circulatory system. In order to mimic clinical stroke lesions, we require an experimental species high on the evolutionary tree. Mice are a common and desirable choice of mammalian species and are widely used in scientific research. Their cerebral vasculature is relatively well documented and in many ways resembles the Circle of Willis in man. The models proposed here are standard ones used by many previous workers in this area of research including the applicant who has over 20 years of experience with this model.

The models

The MCAO model of ischemic stroke is the primary model used in experimental stroke research.

The methods proposed here involve the intraluminal filament method whereby a coated filament is introduced in to the common carotid artery and advanced along the internal carotid artery to occlude the middle cerebral artery (MCA). For transient ischaemia, the filament is withdrawn after about 90 mins. For permanent ischaemia, the filament is left in place. The stroke can also be used by drilling a small hole in the skull and closing the main blood vessel.

A more recent modification of the model requires injection of preformed blood clot introduced via the carotid artery to occlude the MCA in an attempt to more closely model human stroke.

Although these models were originally developed in the 1980 and 90s, detailed analysis of these model and subsequent refinement have revealed that strict experimental control can be applied to reduce the variability of infarct size seen in other models. Thus, these models produce a reliable and reproducible infarct volume. This programme of research will use the transient and permanent model of MCA occlusion. To reduce variability, we will ensure that there is occlusion of the MCA using laser Doppler. In addition, we will ensure that core body temperature is maintained during surgery which can drastically affect the extent of neurological injury. There is, however, some inherent variability in this model. This is largely due to variability in the cerebral vascular anatomy and therefore collateral circulation.

Recently, a new paper (IMPROVE guidelines) has been published providing a step-by-step guide to improve animal welfare in stroke models. We will work with our veterinary surgeon to determine how we may implement some of these refinements in our existing stroke models to reduce pain, suffering and distress.

Severe limit protocols

To determine whether our experimental treatments can reduce the ischemic damage, it is necessary to create a sufficient size of brain infarction which will cause some functional deficits. These functional deficits include moderate degrees of deficits such as paralysis of the contralateral limbs, sensory loss and neglect. In some cases, the brain damage may cause mortality, although this is on occasions unavoidable, we aim to minimise any mortality by humanely killing any experimental animals which appear unlikely to recover.

In particular, any animal which shows persistent barrel rolling, respiratory distress or loss of the righting reflex will be killed humanely. We anticipate that less than 10 per cent of animals undergoing surgery will either die spontaneously or exceed the severity limits and have to be culled.

All animals are carefully and regularly monitored. Post-operative monitoring sheets are completed and kept with the animals ensuring their progress can be identified by any member of technical staff. Data obtained from animals undergoing surgery indicate that roughly 20% of animals will show weight loss of 20-30% at 48 hrs.

Weight loss is undoubtedly a significant factor in the recovery following surgery and we implement a number of measures to promote feeding and drinking following surgery. Animals will receive fluid supplements via subcutaneous injection immediately after surgery. Subsequently, they will receive mash/wet gel. It is also useful to place these in the cages for a few days prior for the animals undergoing surgery in order for them to become acclimated to this food source. In addition, following surgery, movement of animals is restricted and loss of body heat it is a potential problem – although local heat can be supplied via the use of heating lamps, all post-surgery animal cages will be housed in an environment chamber which is beneficial for providing a constant source of heat.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In order to properly mimic stroke preclinical we need to use species that are higher in the evolutionary tree adn show a central nervous system similar to the human one. Additionally the cerebral vasculature of rodents is relatively well documented and in many ways resembles the Circle of Willis in man, critical for stroke.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will closely monitor the animals following stoke induction, in particular for the first 72hrs, to make sure that the animals are properly recovering from the surgery despite the impairments that will occur following ischemia onset. Additionally, we will closely work with the NVS and NACWO to improve the outcomes of our procedure and minimise animal distress.

We will constantly refine the use of experimental animal models and reduce the impact on the animal. We are working on refining our surgical methods that are used to induce MCAO which can affect the results and also reduce the impact/severity on animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the STAIR guidelines and monitor for any updates as well continuously check the literature for any novel improvements to the animals welfare, for example the IMPROVE guidelines may provide additional steps to improve our animal models.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will continuously check the literature, check the NC3Rs portal, and have conversation with the NC3Rs Regional Programme Manager .

Explain the choice ofspecies and the related life stages

Previous work has used in vitro approaches to select candidate drugs and therapies which underpin the three approaches that we have proposed in this body of work. Our previous work has allowed us to select candidates with the highest likelihood of success. However, going forward, in vitro work cannot replace animal experiments which are needed to confirm efficacy and safety.
The outcome measures that need to be tested include functional and behavioural testing which cannot be tested in cells. In addition, stroke injury involves a complex interplay of many different cells in the brain and many organs systems. This cannot be tested using in vitro approaches.
Therefore the need of performing in vivo experiment for which adult mice is the most appropriate species.

A retrospective assessment of refinement will be due by 18 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

50. Development of novel treatment options for REDACTED infection

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

There is currently no effective treatment for REDACTED infections (which include rabies virus) once the patient or animal has developed clinical signs. This project is to develop proof of concept for utilisation of novel live attenuated rabies vaccines for post-infection treatment (PIT) of rabies and other REDACTED.

A retrospective assessment of these aims will be due by 15 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Every year there are at least 59,000 human deaths associated with infection by rabies virus, 40-50% in children under the age of 14 years. Whilst effective vaccines and post exposure treatments exist, provision of vaccine and other important rabies post exposure prophylaxis (PEP) tools, e.g. human rabies immunoglobulin (RIG), are not available where they are needed most, generally due to the expense involved in manufacture across the developing world.

What outputs do you think you will see at the end of this project?

The in vivo assessment of various approaches to post infection treatments (PITs) for rabies and other REDACTED.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

If successful and subsequently developed these treatments would contribute to a significant reduction in the 59,000 human deaths that occur annually across the world.

How will you maximise the outputs of your work?

As well as scientific publication, the research group is member of various European and International collaborations, REDACTED

Species and numbers of animals expected to be used

- Mice: 900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Unless controls all will be injected with PIT treatments (300), PIT treatments that show no adverse effects the second type of experiment will involve infecting mice with rabies as well (300). If the PITs are successful apart from the controls there should be no clinical effects of this infection, there are safeguards of humane endpoints for controls and candidate PITs that are shown by the experiment not to offer protection.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There will be impacts around the methods injection of the PIT and which include intracerebral for which anaesthesia and pain relief will be given.

The PITs under investigation are based on replication competent rabies vaccines expressing heterologous genes. Although vaccine strains of rabies are generally avirulent when administered via the peripheral routes, disease can occur following intracranial inoculation.

Animals will be monitored following inoculation to assess any adverse effects of the PIT or procedure. If any adverse effects are seen that are deemed to be a result of the inoculation procedure then animals will be assessed and the outcome determined by advice from the NVS.

When rabies infection is given the impact will vary with at what stage of the experiment it is given. Initially rabies infection will be given after treatment with PITs, this will allow earlier humane endpoints to be used when initial signs of disease are seen. Candidate PITs that pass this stage will be used on

mice showing early stages of clinical disease and because of this the mice will be constantly monitored a later humane endpoint maybe necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

75% may be moderate or below, 25% will up to severe.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 15 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complexity of REDACTED infection spread and its impact on the central nervous system, the influence of animals immune system and impact of the blood brain barrier on efficacy of treatment may mean that animals have to be used.

What was your strategy for searching for non-animal alternatives?

The non-animal alternatives considered are given below and have been incorporated in the build up to the animal work.

The demonstration that both plant-produced and cell-culture produced ScFv are able to effectively neutralise rabies in vitro;

ScFv produced by novel rabies post infection treatment (PIT) preparations will also be shown to neutralise rabies virus;

Furthermore, wherever possible these novel rabies PIT preparations will be analysed in a novel blood-brain barrier model to confirm that the live-attenuated virus is able to cross the BBB to produce

neutralising ScFv behind the BBB.

If ScFvs fail at any point they will not go onto the animal phase

Why were they not suitable?

They are useful to dissect individual aspects of the work but ultimately candidate ScFvs that have passed the in vitro assessment need to be tried in the more complex in-vivo model.

A retrospective assessment of replacement will be due by 15 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are estimation based on an estimation of the number of candidate PITs thought to be generated and the experience of working with rabies vaccines previously.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

When the in-vivo work starts these will be refined using pilot studies, followed by confirmatory experiments designed to test specific hypotheses. Where appropriate, full power analyses (e.g. using nQuery Advisor) will be used to calculate sample size, taking into account the likely effect of size. REDACTED

What other measures apart from good experimental design will you use to minimise numbers?

Experiments are staged (below), with candidate PITs having to pass each stage before moving onto the next stage. The in-vivo stages are below

Assessment of candidate PITs by different routes (without virus challenge) to ensure safety

Successful PITs administered before and after natural virus infection (pre-clinical signs).Then if they provide protection in this scenario.

The PIT administered after initial signs of clinical disease

A retrospective assessment of reduction will be due by 15 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice are the biological system of choice for these studies. They are sufficiently immunologically similar to humans to allow confident extrapolation of findings, yet they are more amenable to laboratory experimentation at the organisation than dogs, cats or non-human primates which would otherwise be the species of choice for these studies. Further, physical size, social structure and husbandry requirements are conducive to humane care in containment laboratory settings.

It is becoming increasingly apparent that although rabies virus is considered to be 100% fatal following the development of clinical disease, exposure to virus will not always result in disease. Indeed, infection with lyssaviruses via different routes can result in different clinical outcomes. From established mouse studies, inoculation of neat preparation of virus via the IC route generally causes 100% development of clinical disease although rare exceptions occur where IC inoculated animals survive infection. As the IC route is invasive, applica. The mechanism behind survival following IC inoculation is unclear.
Importantly, even live attenuated vaccine strains, when administered by the IC route, can cause clinical disease whilst peripheral inoculation renders these viruses avirulent. This will need to be assessed to ensure safety following peripheral inoculation. Furthermore, even with clinical disease confirmed in IC inoculated animals, inoculation of the same virus via a peripheral route will often lead to a reduction in the number of animals that succumb to infection. For this reason, when trying to mimic natural routes of infection larger group sizes are required to ensure that enough animals develop clinical disease and can be studied closely. Those that do not succumb are assumed to have had an abortive infection whereby: 1) virus has replicated within the infected animal and is cleared by the host immune response and serological evidence of exposure is seen or; 2) for undefined reasons neither serological nor

clinical responses occur. Different strains may be used for experimental studies to minimize variation within and between experiments.

REDACTED. Using this we will be able to keep the PIT treatment pre and post infection protocol to moderate severity as mice will be killed humanely at early signs of clinical disease. However on exceptionally rare occasions animals have been found dead on morning checks
.

For successful PIT candidates it will be necessary to treat mice showing clinical signs of lyssavirus infection so this protocol we consider will be severe. Treated mice will be monitored throughout the day at hourly intervals until as late as is possible in the evening and euthanased as soon as clinical score 2 is reached.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

To assess whether a PIT based on replication competent rabies vaccines expressing heterologous genes so a competent immune system is required, this involves using fully developed animals with associated sentience.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

As well as pre-start meetings involving the NVS, NACWO and animal care staff to ensure current knowledge is brought to bear, all projects are followed up by a wash up meeting. All aspects are discussed, was the project a success, what went well and if there was anything that could be done better. If there are any suggestions for refining the procedure they will be considered and if appropriate, incorporated into the protocol.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office The Harm–Benefit Analysis Process

Home Office Guidance to ASPA

Home Office Code of practice

RSPCA Guidance on Welfare of mice

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I have regular contact with the NIO, NACWO and NVS through various forums and use of the library function which can scan for relevant publications. In developing this work I have been in contact with other researchers outside of the organisation who also specialise in rabies disease work.

Explain the choice ofspecies and the related life stages

Mice are the biological system of choice for these studies. They are sufficiently immunologically similar to humans to allow confident extrapolation of findings, yet they are more amenable to laboratory experimentation at the organisation than dogs, cats or non-human primates which would otherwise be the species of choice for these studies. Further, physical size, social structure and husbandry requirements are conducive to humane care in containment laboratory settings.

The established model uses mice at a few weeks of age, they are fully immunologically developed and do not have any issues of old age.

A retrospective assessment of refinement will be due by 15 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

51. Development of therapies against degenerative diseases

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this programme of work is to use animal models to assist in the development of new therapies for the treatment of degenerative diseases (such as Parkinson's, Huntington's disease or amyotrophic lateral sclerosis).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The primary benefit of this study is the identification of best drug candidates suitable to treat the previously intractable degenerative diseases in human. The molecules selected in these studies will be further developed in the clinic.

Due to the increased prevalence of neurodegenerative diseases and the lack of effective treatments available the impact of this project might be very high.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice are required as they provide good models of human diseases. We expect that ~ 20 000 mice may be required.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Mice will be maintained in a social environment and environmental enrichments will be provided to improve their wellbeing. Both genetic (GM) and pharmacological models of degenerative diseases will be used. Mice whose disease progression will be monitored closely, will be kept until they develop the disease symptoms but will be culled at the latest when the clinical signs like weight loss or hindlimb paralysis are present. Some mice will be treated with pharmacological substances. The administration might cause intermittent distress but no lasting adverse effects are expected. In most cases substances will be administered by the oral route. Behavioural testing will be used to assess the disease phenotype. In most cases behavioural tests that will be applied to mice are non-invasive and are not expected to cause any lasting distress or harm. On very rare occasions mice might be subjected to a more invasive test, which involves touching a plate of increased temperature (max. 55ºC), however, a mouse is free to remove its paw or tail once it starts to feel uncomfortable. These tests are essential to determine the efficacy of treatment in the disease prevention and is required to validate a tested compound as a potential future therapeutic. At the end of the procedure mice will be humanely killed

and pathology as well as drug efficacy will be monitored by postmortem tissue analysis. In one of the genetic mouse models to be used, the genetic modification leads to limited number (<5%) of sudden deaths not preceded by detectable signs of disease, and so not possible to predict. We will search for refinements to our methods, protocols and monitoring procedures in order to decrease the incidence of mice found dead suddenly and unexpectedly.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We have a group of molecules with a high potential to ameliorate degenerative diseases. These molecules are being extensively studied in order to select the best drug candidates to be moved forward to clinical trials.

Testing in animal models is an essential prerequisite of clinical trials. Prior to being used in humans, there is a legal requirement for virtually all new disease treatments to be tested in animal models of the disease(s) in question. The mouse is best suited for this work since, of all existing models, mouse models are highly relevant to the human diseases.

Whilst tissue cultures provide some useful information, they cannot fully replace mouse models. They do not provide the physiological conditions, the complex interactions amongst different cells and the metabolic treatment of a drug that is seen in a normal living body.

Before being tested in mice the candidate drugs will be carefully selected by tests on cell lines or in ex vivo cultures and only the most promising candidates will be tested in vivo.

The work in mice that we propose is essential to validate our approaches and may have a big impact on human health.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The minimum number of mice will be used in each experiment, while ensuring that the numbers are large enough to obtain solid and reliable data. The mouse numbers will be chosen based on published data, previous studies or determined based on statistical power analysis.

To reduce the sources of variability and bias mice will be randomly assigned to experimental groups. Experiments will be run in a blind fashion.

Mouse breeding will be carefully monitored to ensure that surplus animals are not generated.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The most refined and the most appropriate models to answer the question asked will be chosen for the studies. Mouse models of common degenerative diseases exhibit the essential features of the human diseases. It is necessary for the validation of disease modifiers identified in cells to address their relevance in mouse models. At present, no valid alternative to animal models exists.

Mice will be housed in a social environment with environmental enrichments in order to improve the wellbeing. Only mice needed for the scientific purpose will be kept up to the moderate severity limit. Signs of the disease and the adverse effects will be limited to the minimum required for a valid scientific outcome and in all cases the general health and condition of an animal will remain the overriding determinant. Behavioural testing will be applied in order to reveal the disease phenotype at early stages of the disease.

Home Office

NON-TECHNICAL SUMMARY

52. Discovery and characterisation of genetic mechanisms affecting metabolic health and ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to exploit human and animal genetics to identify and functionally characterise new mechanisms that underpin susceptibility or resilience to metabolic disease.

Ultimately, we aim to develop new therapeutic interventions for these conditions in humans

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The last 40 years has witnessed an exponential increase in the prevalence of obesity, type 2 diabetes and related metabolic conditions - in large part due to lifestyle changes. The health and healthcare burden from these diseases has overtaken malnutrition as a leading global cause of morbidity and mortality. At the same time, advances in healthcare have markedly increased survival rates from infectious diseases and other conditions such that the ageing population has also expanded rapidly. Ageing is associated with increased risk for numerous metabolic diseases such as diabetes, cardiovascular and atheromatous disease, dementias and certain cancers. Whilst a number of frontline medicines have efficacy against some of these conditions in subsets of the population, the molecular mechanisms underpinning the adverse metabolic health effects of poor lifestyle choices and ageing across the wider population are incompletely understood and remain a pressing unmet clinical need. Ageing per se is currently therapeutically intractable. Our genes, the inherited information from our parents that determines all our bodily attributes, strongly influence our susceptibility, or resistance to metabolic disease and ageing. We have unprecedented access to ever more detailed genetic information about our populations such that medicines may soon be more individually targeted to improve therapeutic outcomes. By identifying and understanding novel genetic mechanisms underpinning metabolic disease susceptibility/resilience, this project seeks to illuminate new biology and uncover novel therapeutically exploitable gene targets discovered in human and animal models.

What outputs do you think you will see at the end of this project?

We will have identified new genes that can control how much body fat we carry when exposed to unhealthy versus healthy diets, or as we naturally get fatter with age.

We expect to publish several new studies telling us how one of the new genes we discovered that protects against diabetes works, and whether new medicines that target this gene can prevent diabetes.

We may have identified new medicines that could be further developed for the treatment of diabetes and its related diseases

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

In the short term our project will have tested whether several newly identified genes predicted control how much fat we carry represent new ways to treat diabetes and related conditions.

In the longer term, we may be able to identify new drugs that can be used to prevent diabetes in those people who do not respond to, or have a bad reaction to, existing diabetes medicines

How will you maximise the outputs of your work?

We will publish all studies undertaken in learned journals that have open access

We will work with industrial partners to maximise the chance to develop new effective drugs that target our new genes

We will present our work at national and international conferences to get feedback and to inform our world-wide colleagues.

Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, a mouse would be housed on its own so we can accurately measure its food intake, energy expenditure (my measuring oxygen consumption and carbon dioxide production from only that individual in dedicated metablic chambers). We would establish the normal nutrient (glucose, fats) metabolism profile of the mouse by giving an oral bolus of glucose and measuring the disappearance of the glucose over time. We would then make the mouse obese and diabetic by exposing the mouse to high fat diets for a period of time that represents poor food health durations in humans (e.g. 20 weeks; equivalent to 10 years of poor lifestyle choice in a human). We would then repeat the measures the metabolic health of the mouse as above halfway through the study (e.g. 10 weeks) to identify whether any genetic modification or medicine administration impacted early onset disease. We would repeat

these measurements again at the end of the study to determine the longer term effect of genetic or pharmaceutical intervention on metabolic health.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Long term high fat diets (e.g. 20 weeks) can cause diabetes which is associated with higher levels of urination, weight loss and eventual organ failure. The strain of mice we use for the vast majority of our obesity/diabetes studies are resistant to the complications of diabetes over this time course and will be humanely culled before severe symptoms manifest.

Mice may be injected with substances (transient pain) or have surgery (string analgesic and careful recovery protocols are in place) which causes pain that is managed.

Mice with accelerated ageing mutations will become frail, develop metabolic disease and die younger than normal mice - we will scale all specifically reduced severity interventions to fit the known equivalent mean age stages (middle and old age) using previously published in depth studies on mortality rates.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The maximal severity is moderate. The proportions of animals used in each category (20% for Protocol 1; 15-20% for Protocol 2) are based upon the larger proportion of "unused genotypes" used in breeding programmes to generate necessary intermediate but unwanted (e.g. non-experimentally useful compound heterozygote mice) mice and the smaller proportion of female mice used in experimental studies (50% of all mice generated by breeding but only a fraction of 20% (e.g. 1%) used as experimental cohorts for specific proof-of-concept on gender specificity).

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Metabolism is a highly integrated physiological processes that reflects complex interactions between the brain (e.g. appetite) the adipose tissue (storage of excess fat), muscle (calorie usage), liver (calorie storage and integration), etc. Because of this there is no way to replace the insight that investigating

gene effects in whole animals provides.
Ultimately we must understand what such manipulations would do in living humans.

What was your strategy for searching for non-animal alternatives?

We use clonal cell models of several tissue types to test key hypotheses before animal experimentation is considered. For example, cultured fat cells have been used in our research to show that one ‘lean gene’ prevents defects in release of healthy fat cell hormones. Similar approaches are being taken with cultured human liver cells and cultured mouse muscle cells. .

Why were they not suitable?

Whilst a reductionist cell type specific approach in vitro helps us understand how each tissue might contribute to an overall effect, only whole animal studies can show how these changes affect an animals overall health and, importantly, how effective any new drug would be in the whole organism setting.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use statistics (power calculations, factorial designs) based on extensive experience of our metabolic studies (for e.g. body weight, blood nutrients and hormones) to determine the minimum number of mice needed to confidently measure meaningful differences caused by gene alterations or therapy. We routinely use mice that are used commonly in our research community and that are genetically identical to minimise variation in experiments.
We will use non-invasive technologies to determine fat mass and calorie burning capacity of mice that will allow reduction of animal numbers because we can do ‘before and after’ measurements (pairing of data across longitudinal studies) rather than using two separate groups of animals.
We work with other scientists with projects that allow them to use some of our post-mortem animal tissues to inform on their research on heart, blood vessels, inflammation, etc, reducing the need to use more animals in some cases.
Regular meetings of our research group ensures maximal use of our materials animals and assessment of our experimental design and statistical rigour.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We use statistics (power calculations, factorial designs; much of this consulted through local statistical experts and the NC3R Experimental Design Assistant) based on extensive experience of our metabolic

studies (for e.g. body weight, blood nutrients and hormones) to determine the minimum number of mice needed to confidently measure meaningful differences caused by gene alterations or therapy. This avoids underpowered studies that are poorly reproducible (which ultimately increases animal use). We also use non-invasive technologies to determine fat mass and calorie burning capacity of mice that allows reduction of animal numbers because we can do 'before and after' measurements (pairing of data across longitudinal studies increases power) rather than using two separate groups of animals.

What other measures apart from good experimental design will you use to minimise numbers?

We outsource genotyping (identification of mice in colonies that carry the relevant mutations) to a cost-effective professional company (REDACTED) which gives us rapid control of colony management, minimising the wastage of mice across large breeding programmes.

We work with other scientists with projects that allow them to use some of our post-mortem animal tissues to inform on their research on heart, blood vessels, inflammation, etc, reducing the need to use more animals in some cases.
Regular meetings of our research group ensures maximal use of our materials animals and assessment of our experimental design and statistical rigour.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use animal models best suited to address the biological question/ under study. For example, mutant obese mice are used for obesity studies. Obesity-prone 'normal' strains of mice are chosen for dietary obesity studies. Mice mutations affecting cholesterol/lipid metabolism are used in combination with high cholesterol diets that focus research questions related to atheroma as a consequence of obesity. These models are used extensively, globally, and are recognized as the mildest interventions possible whilst delivering better cross-centre replication of outcomes (e.g. obesity, atherosclerosis)
For surgical procedures, appropriate anaesthetic and pain-killers, and sterile techniques will be used. Drugs will be administered at non-toxic dosages and if unknown, this will be tested in a carefully graded dose-finding protocol.

The introduction of new non-invasive, low stress procedures for body fat mass determination allows us to minimise suffering while maximising the amount of information obtained from each animal We will use new home cage chambers that allow us to follow metabolism in real-time without interfering with the animal (Indirect calorimetry measures oxygen used/CO2 respired). This removes the need for metabolic cages that have grid features in most studies.

We follow a path of progressive method development and refinement. For example, for nutrient metabolism exploratory methods such as oral administration of glucose with blood sampling are used to test for major effects of gene alteration on broad outcomes such as ‘does diabetes improve’. Only then if an effects is clear are in depth methods used, such as using infusions of labelled nutrients (e.g. glucose) and tracking what happens to them in a living animal are employed to work out mechanisms of health change. The use of any invasive (e.g. surgical) techniques are discussed with colleagues performing similar work locally and across the country. Monitoring systems will be tailored to each model and strict humane endpoints will be applied to minimise suffering.

Training and good practice is encouraged through group meetings and regular discussions with the NVS and key staff.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The nature of complex mammalian metabolism, and its dysregulation in metabolic syndrome and ageing, cannot be adequately modelled to the level of conserved mechanistic detail reuired for therapeutic insight in lower organisms.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We are always looking for effective ways to improve our operating procedures (surgical and experimental) in line with best practice. We will regularly send members of our team to dedicated courses on cutting edge methods in out field that include refinement of procedures. Two examples planned for the current project include the introduction of small continuous glucose monitoring implants in mice which will obviate serial tail nicks in longitudinal studies on diabetes (high glucose). The other is the adoption of a state of the art dual catheterisation method for whole body insulin sensitivity assessment that includes, for example, infusion of washed red blood cells to maintain normal blood volume (one of the drawbacks of multiple blood sample withdrawal in some studies). We constantly strive to improve the quality of our methods, thus generating better quality, less variable data and more optimal study power.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We follow the ARRIVE guidelines and look for any updates.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will attend the annual 3Rs conference held in REDACTED annually.

We will follow and check for updates in good practice on the 3Rs web interfaces.

Explain the choice ofspecies and the related life stages

Mice are mammals with very similar fundamental physiology to that of humans. This is graphically demonstrated by the identical adverse metabolic and reproductive deficits found in both in mice and humans carrying mutations in the leptin gene and other well characterised genetic pathways. Mammalian biology and the rapid generation time of mice allows timely testing of hypotheses relevant to human metabolic disease and ageing within traditional research cycles. We choose adults for studying metabolic disease because metabolic disease predominantly manifests in adulthood in humans. We choose accelerated ageing models to more rapidly identify potential anti-ageing, anti-diabetic and anti-metabolic syndrome effects as powerful initial screen that informs on the more time and cost-intensive "normal" ageing process.

NON-TECHNICAL SUMMARY

53. Disease mechanisms and treatment of neuromuscular disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

a) To breed, maintain and create mouse models to study neuromuscular diseases. This will provide mice for use in other protocols.

b) To understand the pathogenesis of neuromuscular diseases, (including Duchenne muscular dystrophy, Spinal Muscular Atrophy, Fascio-scapular-humeral dystrophy, Collagen VI deficiency, limb girdle muscular dystrophies, mitochondrial DNA depletion syndrome, Congenital muscular dystrophy), in skeletal muscle, heart and brain.

c) To understand the responses of muscle to injuries that mimic different aspects of neuromuscular disease (e.g. muscle fibre necrosis, muscle regeneration, prevention or reduction of muscle stem cell function).

d) To identify changes in gene and protein expression, or changes in activation or type of cells present, in injured skeletal muscle.

e) To identify factors that may improve muscle regeneration.

f) To investigate therapeutic approaches for neuromuscular diseases, including cell-based therapies, gene therapy, small molecule therapy and RNA therapies (i.e. antisense oligonucleotide therapies on exon-skipping, exon-inclusion or gene silencing).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neuromuscular conditions affect more than 60,000 people in the UK and an estimated 7 million people worldwide. For most of these diseases, there are no effective therapies. Examples of neuromuscular diseases include Duchenne muscular dystrophy, which has an incidence of 1 in 5,000 male births, spinal muscular atrophy which has an incidence of 1 in 6,000-10,000 births, and dystroglycanopathies which are one of the most common group of congenital and limb-girdle muscular dystrophies.

These are progressive diseases that start in childhood and have a profound impact on quality of life and mortality. They represent a significant burden for carers of affected patients and for the health care system. Several promising new treatments are in clinical trials or have recently been approved by the European Medicines Agency and/or the Food and Drug Administration for some but not all neuromuscular diseases. These new treatments include gene therapy and RNA therapies for

Duchenne muscular dystrophy and spinal muscular atrophy. For the first time, these treatments have demonstrated efficacy at significantly slowing down disease progression. However, there is room for improvement in three main areas: further increase their efficacy, improve or expand the ability of these treatments to slow disease in all affected tissues (including heart and brain), and determine whether these treatments can be adapted to treat additional neuromuscular disorders. Therefore, the primary aim of our proposed project is to improve and expand current treatments. To achieve this aim, we will also need to increase our understanding of disease processes in different neuromuscular disorders. This new knowledge may lead to the identification of new treatment opportunities and interventions that could be developed into novel standalone or combinatorial treatments
.

What outputs do you think you will see at the end of this project?

We hope to have a deeper understanding of disease mechanisms in neuromuscular diseases and to have determined the effectiveness of possible therapeutic strategies in different mouse models of neuromuscular disease. We will obtain more information on the molecular causes of cardiac disease and on the cognitive, emotional and behavioural problems that occur in some neuromuscular disorders.

We expect more novel experimental therapies for different neuromuscular diseases will be validated in the related mouse models, with potential of clinical translation (i.e. clinical trials initiation).

We will publish data from our work in peer-reviewed publications.

We will also present our data to relevant patient groups (e.g. Muscular Dystrophy UK, Duchenne Parent Group, Spinal Muscular Atrophy (SMA)support UK).

New treatments for neuromuscular diseases.

Greater understanding of disease mechanisms and biomarkers in neuromuscular diseases.

Development of new outcome measures for pre-clinical studies.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We will have gained a deeper understanding of disease mechanisms in neuromuscular diesases and possible therapeutic avenues. In particular, we are working towards defining the molecular underpinnings of cardiac disease and cognitive/emotional/behavioural co-morbidities in neuromuscular disorders.

In the short term (towards the end or after successful completion of our project), our data will benefit the scientific community, particularly those working in the field of neuromuscular disease.

In the medium term, our research would be of interest to the pharmacological industry, if for example, we discover a therapeutic agent that successfully treats a muscular dystrophy in one of our mouse models.

In the longer term, our work might progress to clinical trials and, if these are successful, ultimately to patient clinical benefit.

How will you maximise the outputs of your work?

We will present our data to relevant patient groups (e.g. Muscular Dystrophy UK, Duchenne Parent Group, Spinal Muscular Atrophy (SMA) support UK) and to scientists and clinicians at scientific meetings and conferences.

We will also present our work at Institute open days.

We will publish our data in high impact journals.

We also intend to publish null or negative results in, for example, Wellcome Open Research.

Species and numbers of animals expected to be used

- Mice: Wild type - 1000; Immunodeficient - 500; Genetically-modified without a neuromuscular disorder - 1500; Genetically-modified models of neuromuscular disease - 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, mice will be bred and may be genotyped, usually by ear biopsy.

Some mice will be used to study treatment efficacy and disease mechanisms. Mice may be administered potential therapeutic substances by the most appropriate route (orally, or by injection). Most of these mice will not be anaesthetised, but for intracerebroventricular or intrathecal injections, mice will be under an appropriate anaesthetic. Blood samples will be taken from some of these mice. Some mice will undergo assessments to track changes in their behaviour, motor function, and/or blood pressure over time.

Some mice may be imaged to look at disease progression in specific organs, for example cardiac MRI may be performed to assess cardiac function.

Experiments will generally last from 2 weeks to 1 year.

Other mice will be transplanted with stem cells. Skeletal muscles of these mice may be irradiated or injured, as this has been shown to promote donor cell engraftment. Muscle irradiation, injury and intra-muscular and intra-arterial cell injections will be done under general anaesthetic. Regenerated muscles will be re-injured in a subset of the mice. Some mice may be exercised. Blood may be sampled from some mice. Experiments will typically last from 4-12 weeks.

We will investigate the effect of injury on skeletal muscle regeneration. Skeletal muscles of these mice may be irradiated or injured. Substances may be administered to mice, intra-muscularly, systemically or topically. Depending on the route of administration, some mice may be anaesthetised. Blood may be sampled from some mice.

Mice will then be culled for tissue collection for additional post-mortem analyses.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some mice may experience pain as a result of surgery, but this will be controlled by the use of analgesics. To avoid pain following injection of substances, we will only inject up to the maximum recommended volumes for each injection route.

Some older mice, or mouse models of neuromuscular disease, may exhibit weight loss. We will not allow mice to lose more than 20% of their body weight.

Tumour formation can occur in aged mice. 9% of mice carrying a mutation in dystrophin develop rhabdomyosarcomas after 12 months of age. Tumours typically develop near the neck/shoulder area or hindlimbs.

Scoliosis and muscle wasting can occur in mouse models of Duchenne muscular dystrophy after 15 months of age.

If a mouse either loses more than 20% of its body weight, or it displays signs of ill health, it will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild: 50%

Moderate: 50%

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals as we are investigating potential treatments that may affect multi-organ systems (e.g. skeletal muscle, nerves, brain, heart) and we need to optimise delivery methods in vivo and achieve efficient target-organ engagement for future clinical applications.

Disease mechanisms include interactions with the immune system, or pathologies that develop over time, that cannot be investigated in vitro.

What was your strategy for searching for non-animal alternatives?

Wherever possible, we use tissue culture to achieve our aims. Most approaches have already been optimised and tested in vitro. We are already using cell lines to test and optimise conditions for therapeutics as much as possible, before validating in vivo. For example, we test reagents such as antisense oligonucleotides in patient-derived cells in vitro as the first step. Only the lead and most efficient agents identified in vitro are selected to be tested in the subsequent experiments in animal. We are also developing human induced pluripotent stem cells and are considering organoid systems as an in vitro model.

Why were they not suitable?

Protocols for differentiation of induced pluripotent stem cells do not currently allow full maturation of the cells into cardiac and skeletal muscle tissue to faithfully reproduce disease and test therapeutics. These in vitro systems cannot replicate the complex tissue structure and cellular interactions, especially interactions with the immune system, that are a feature of the diseases we are studying. From a therapeutic perspective, these in vitro systems are insufficient to determine complex drug delivery in vivo and the efficient biodistribution required for a new drug.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated these based on the numbers of mice that we will need for each of the projects we will perform under this licence in the next five years and power calculations performed in our grant applications.

Our proposed work includes behavioural studies and muscle performance studies, that require between 10 and 15 animals/group to demonstrate statistically-significant differences, based on our power calculations.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We took advice from statisticians and used NC3R Experimental Design Assistant to determine the minimum number of mice required to achieve statistically-significant results.

When performing intra-muscular interventions, our experimental design includes using, wherever applicable, both legs, to reduce the number of mice needed to demonstrate significant differences between experimental variables.

Where possible, we will use littermates as controls.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding colonies of mice will be managed to match the number required for specific experiments and replacement of breeding pairs. When genotyping, we will use the least invasive method compatible with accurate genotyping.

Wherever possible, we will use other tissues from our mice for other experiments, e.g. as controls in laboratory-based assays.

Where the effect of a specific intervention is unpredictable and the potential variation is uncertain, pilot trials using a minimum of 3 animals per group with a limited number of groups will be used to assess the value of a larger scale experiment using a range of doses with group sizes determined using power calculations. In some cases it may be possible to use a factorial design that reduces group sizes to 3-4 per group.

For experiments that require only one gender, we will wherever possible, use mice of the other gender for other gender-neutral protocols.

We are beginning to use in vivo imaging to test efficacy of approaches (e.g. cell transplantation, therapies to improve heart function), that will allow serial analysis of one mouse and thus reduce numbers.

We have purchased mice expressing therapeutic constructs transgenically (micro- and mini-dystrophin constructs used in gene therapy) to avoid the need to inject animals with adeno associated viral (AAV) vectors carrying these constructs. We are treating mice with AAV vectors only to test new constructs in a setting that best mimics clinical trial conditions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In order to achieve our objectives, we will use mice that are:

- Mutant or transgenic models of neuromuscular diseases.
- Genetically altered, in which either an ubiquitous, muscle specific or cell-specific promoter drives either a marker, or a potentially therapeutic, gene.
- Immunodeficient (dystrophic, or normal)
- Normal
- Aged

Most of these mice show mild disease features, but as they get older, some of them have a worsened phenotype. Most mice will be used young, but when we use older mice, we will carefully monitor them.

When testing potential therapeutic agents, only innocuous substances would be of interest for administering to human patients suffering from neuromuscular disorders. Where appropriate, these agents will be evaluated in in vitro systems prior to applying them to mice. We will obtain guidance on doses from existing studies on humans or mice and use doses shown not to have toxic side effects. If the agent being tested is likely to have any overt toxicity, a small pilot study will be performed first. Although we cannot absolutely predict toxic effects, our checking regime will ensure that any agents causing deleterious effects will be rapidly identified. Wherever possible, we will use the least invasive effective route of delivery.

Most of the muscle injury protocols aim to mimic events that occur as a result of muscular dystrophy (muscle fibre degeneration and regeneration). We will use the most refined method for our scientific purpose and minimize as much as possible the use of the more severe injuries (e.g. cryodamage). Some agents used to induce muscle degeneration are harmful (e.g. snake venoms), but we will apply these locally to the muscle at volumes and concentrations that will not harm the mouse.

We have refined our muscle injury protocols and the age at which we apply them, so that they have the least adverse effects. We always use the most refined method that is effective for our purposes.

We have refined the breeding scheme for SMA mice from a published scheme to a new one that suits this mouse model better, based on our vast experience gained in the last several years when working on this mouse model.

We have established protocols to differentiate human induced pluripotent stem cells to undergo differentiation into skeletal and cardiac muscle cells and nerve cells in vitro. We also use expression of a myogenic regulatory factor, MyoD, to induce fibroblasts to differentiate into skeletal muscle cells. We are using these cells to test potential therapeutic approaches in vitro.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We will only use mice in this project, as the models of neuromuscular diseases that we require are mice.

We need to use mice that are at the stage of their life at which they exhibit symptoms of neuromuscular disease.

When applicable, we will use mice at a more immature life stage, (e.g newborn or young adult).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

In experiments that involve running mice on a treadmill, we will not use electric shock, but instead will use gentle prodding to encourage the mice to run.

Motor function assessment to test endurance or forced running may cause fatigue and animals will be allowed to recover in their cages.

To minimize stress that may be caused during motor function assessment, mice will be acclimated to the equipment and procedure a week before data recording.

We will stop performing specific motor function tests if animals show fatigue and are unable to complete the test.

Following muscle injuries, appropriate analgesia will be given, as advised by our named veterinary surgeon.

Anaesthesia will be under continuous supervision and animals will be kept warm. After recovery, animals will initially be closely monitored until the mice are moving around the cage and then checked at least once daily for 2 days.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) guidelines (Wurbel 2007: NC3Rs #9 Environmental enrichment and systematic randomization Jan 2007 and Prescott 2017 Lab Anim (NY). 2017 Mar 22;46(4):152-156. doi: 10.1038/laban.1217), to ensure that our experiments are conducted in the most refined way. We will also refer to TREAT-NMD protocols for animal models of neuromuscular diseases.

We will follow the ARRIVE guidelines on reporting of in vivo experiments.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our REDACTED sends emails to licencees on the Latest news from the NC3Rs and we consult the NC3Rs website for the latest information and guidelines. We will ensure that licencees attend any relevant courses and will implement any advances that are applicable to our work.

Explain the choice ofspecies and the related life stages

We have chosen mouse models of neuromuscular disorders that best model disease in patients and are best suited for us in pre-clinical studies to test therapeutic approaches. The models we have chosen are mild to moderately severe. We are looking at all life stages because this protocol is interested in studying the natural course of disease progression and long term effects of treatment interventions.

We will use mice, as there are appropriate models, either already available to us, or that will become available, of the following:

- Mutant or transgenic models of neuromuscular diseases.

- Genetically altered, in which either an ubiquitous, muscle specific or cell-specific promoter drives either a marker, or a potentially therapeutic, gene.

- Immunodeficient (dystrophic, or normal)
- Normal
- Aged

Home Office

NON-TECHNICAL SUMMARY

54. Dissecting central mechanisms of obesity and neurodegeneration

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to identify shared mechanisms and treatments that both reduce obesity and slow the progression of neurodegeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The proposed project addresses metabolic disease (e.g. obesity) and neurodegenerative disease (e.g. brain cell damage and loss), which are both major human health issues lacking broadly effective solutions. Our studies may reveal the processes that produce these diseases, which could lead to new treatment strategies. We will also test whether certain drugs can reduce obesity or slow the progression of neurodegenerative disease in mice. If these studies are successful, they would pave the way for potential treatments in humans.

What outputs do you think you will see at the end of this project?

The intended outcome of these studies are 1) increased biological understanding of the molecular and cellular pathways involved in metabolic and neurodegenerative disease, and 2) drugs that act on these pathways to reduce obesity or slow the progression of neurodegeneration, which could be advanced to pre-clinical studies.

We expect the data from the experiments covered in this license will lead to several publications in peer-reviewed journals. In addition, we will publish protocols and results, sometimes also including data on experiments that did not work, in databases that are open to the general public (e.g. protocols.io and BioRxiv).

Outputs based on our broader goals are more difficult to predict, but we intend them to have a wide and positive impact. In particular, neurodegenerative diseases and obesity contribute to more than a third of the total burden of disability-adjusted life years (DALYs) in the elderly population. By shedding light on the processes in the brain that may lead to metabolic disease (e.g. obesity) or damage to brain cells (e.g. neurodegeneration), we may contribute to the future development of more effective treatments for these major diseases.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Diet and neurodegeneration: In the short-term, our studies would prompt us to isolate the relevant dietary or metabolic factors that affect the neurodegenerative progress. In the longer term, these

findings could affect how individuals at risk for neurodegenerative disease might alter their lifestyle to reduce their risk.

Drug treatments for neurodegeneration: In the short-term, we aim to understand how some drugs given to treat diabetes and obesity (e.g. Liraglutide) also improve brain function in Alzheimer's disease and Parkinson's disease. In the longer term, we would test additional drugs and additional mouse models of neurodegeneration, or even test promising drugs in humans suffering from neurodegeneration.

Drug treatments for metabolic disease: Our plans to test whether drugs that act on cultured human brain cells also affect food intake and body weight will test how well cultured cells can predict effects on body weight, and may reveal new ways in which food intake is regulated. In the longer term, these drugs or drug combinations could be tested in humans, especially since we will preferentially work with drugs already approved for use in humans.

Central mechanisms of metabolic disease: In the short-term, these studies will explore and identify genes that act in the brain to regulate food intake in order to link genes associated with obesity and behavior that contributes to obesity. In the longer term, drugs targeting these genes might lead to new treatments for obesity and diabetes.

How will you maximise the outputs of your work?

Our research work will be carried out in collaboration with research teams who have years of experience in working with mice that develop neurodegenerative disease. All our research findings will be made available to other scientists through presentations at scientific conferences and publication in peer-reviewed journals. In addition, protocols developed for this work will be freely distributed to the community (e.g. Protocols.io). Negative results may be published on open-access servers (e.g. BioRxiv). Data will stored in electronic format wherever possible and stored for at least 10 years to enable our group and collaborators to easily retrieve and build on past results, or reanalyse data using new methods.

Species and numbers of animals expected to be used

- Mice: 19,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will undergo a brief surgical procedure which involves injecting infectious proteins (Prions) into the brain to cause brain damage (neurodegeneration). About a week later, mice will be given food that

is high in fat and/or carbohydrates, which they like to eat so much it makes them fat. Following this, mice will be given experimental drugs to reduce obesity, or reduce the signs of neurodegeneration. The effect of drugs on obesity and/or diabetes will be analysed by measuring their food intake and activity along with body composition imaging to find changes in body fat. Blood samples may be taken to measure hormonal changes in the blood and mice may also be exposed to a brief test similar to one used in humans to see if their diabetic state has been reversed. To analyse the effects of the drug treatment on neurodegeneration, mice will be tested for changes in behavior (e.g. burrowing pellets of food) and the amount of certain proteins in the post-mortem brain tissue. Experiments will typically take 4-24 weeks.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

- Prion-injected mice will develop defects in their movements and memory at a predictable time after injection, unless they are killed sooner. In case of obese mice, these defects may appear sooner. All prion-injected animals will be regularly monitored for onset of early signs of clinical disease. Once these signs are observed, mice will be inspected daily to determine if additional signs of the disease emerge, and twice daily if prion signs are progressing quickly. We will monitor the general condition of the animal and pay specific attention to breathing, coordination, posture and gait. All signs will be documented on clinical observation sheets. Mice will be killed as soon as clinical prion disease can be diagnosed.

- Most animals will experience transient pain or discomfort due to drug administration, which will be treated with appropriate anaesthesia/analgesic.

- Mice fed with modified diets will exhibit long-lasting increase in food intake (hyperphagia) and obesity which may cause type 2 diabetes. These conditions may be reversed in the presence of therapeutic interventions as a part of the experimental design.

- Food restriction and insulin tolerance tests may cause a drop in blood sugar (glucose) levels (hypoglycaemia), which will be treated by either giving mice food, or directly giving them glucose. Mice will be killed if hypoglycaemia is not reversed within two hours of these interventions.

- Mice that undergo surgery (prion injection, osmotic mini-pump implantation and guided injection into the brain) may develop complications such as failure to eat and/or to move normally, or failure of the wound to heal normally. In these cases, the NVS will be consulted. In rare cases (expected < 2%), animals may experience wound breakdown or infection, which will treated and wounds re-closed within 48 hours post-surgery.

- Treatment with substances (e.g. drugs or viruses) targeting genes and cell types important for regulating metabolism are expected cause a change in food intake, body weight and body condition score (observed as a readout of the experimental design as well as a measure of animal health). Mice will be killed if their body weight drops more than 15% below the weight of age-matched and sex-matched control mice or if they show other clinical signs or deterioration in body condition score.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The expected severities are mild (approximately 30% of mice) and moderate (approximately 70% of mice).

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Metabolic and neurodegenerative disorders affect millions of people worldwide. These diseases are mostly untreatable, and represent a large, unmet clinical need that cause a substantial economic impact. These diseases may have shared causes, which are still poorly understood, but likely interact at the level of the whole animal rather than a single cell type. For example obesity leads to increased blood pressure and activation of the immune system, which are thought to independently contribute to neurodegeneration. As such, it is essential to use animal models to understand which of these factors are most relevant, and to test possible treatment options.

We work extensively with cell culture systems to understand the behavior of individual cell types that contribute to metabolic and neurodegenerative disease. However, due to the complexity of the brain and the lack of culture systems that can fully mimic this complexity, animals remain irreplaceable. Furthermore, animals provide insight into the clinical, behavioral, physiological and neuropathological outcomes that can lead to development of better therapies.

What was your strategy for searching for non-animal alternatives?

The proposed work cannot be readily replaced with non-animal alternatives, however:

- wherever practical, we will use our cell culture systems to prioritize drugs that act on specific brain cells before carrying out targeted animal studies
- wherever practical, we will use our cell culture systems to prioritize genes that act on specific brain cells before carrying out targeted animal studies
- where possible, we will use human tissue samples to confirm the significance of key target genes in human neurodegenerative disease and obesity

Why were they not suitable?

Although brain cell culture systems provide useful insights into obesity and neurodegeneration, they cannot completely replace the need for animal studies. Specifically, cell culture models do not mimic complex interactions between cell types and body systems that likely contribute to human disease. They also do not allow measurement of behaviors or physiological outputs relevant to disease, making it difficult to predict how results obtained from cell culture systems will be relevant to human disease progression or treatment. Therefore, we will conduct both cell culture and animal experiments to identify the most promising strategies for treating obesity and neurodegenerative disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use the minimum number of mice needed in all experiments for reproducible results and statistical validity in line with the ARRIVE guidelines www.nc3rs.org.uk/ARRIVE. We will maximize the use of each experimental animal by maximizing the readouts obtained from each animal thereby reducing the number of animals needed. For most of the quantitative experiments, we will determine the sample size required based on relevant literature. Otherwise, statistical power analysis will used to set sample sizes (significance level of 5%, power of 80%).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have referred to the PREPARE guidelines (https://norecopa.no/prepare) and the NC3RS Experimental design assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) to help plan and design our experiments. We have considered the number of independent experiments that will be performed when calculating total animal numbers and have consulted the “Guiding Principles for Behavioral Laboratory Animal Science” paper to ensure that our experimental design incorporates the most appropriate tests.

What other measures apart from good experimental design will you use to minimise numbers?

The following steps will be taken to ensure best breeding practice to efficiently supply mice for research while minimizing animal wastage:

- We will ensure high standards of animal care and welfare and the breeding of animals will be conducted according to the best practice.

- Dosage and safety of all drugs and drug combinations will be validated by a pilot study.
- Where possible, we will use published data to inform safe dosing limits and adverse effects of drugs, thereby reducing the number of animals needed for screening and testing.
- We will use cell culture systems to prioritize and select drugs and genes that act on specific brain cell populations of interest before carrying out targeted animal studies.
- Mice will be grouped into experimental cohorts large enough to allow sufficient numbers for sampling at regular intervals.
- We will randomly assign mice to experimental groups and where possible, we will conduct blinded studies to minimize bias.
- Suitable experimental controls will be used for each study, based on the study design and specific aims.
- We will maintain minimum colony sizes that are required to meet the demands of our research experiments and avoid overproduction.
- Detailed breeding records will be kept, enabling the selection of the most appropriate breeding stock.
- Where appropriate, genetically altered animals will be used to reduce the number of animals required to achieve specific aims.
- Cryopreservation of genetically altered mouse lines will reduce animal wastage and costs associated with mouse colony maintenance.
- We will ensure that researchers and technicians working on this project are appropriately trained and competent to maximize the success rate of experiments and thus minimize the number of animals used.
- Detailed study plans describing the aims and objective of each experiment along with the experimental steps, treatment groups and sizes and methods for data analysis will be written down to guide our work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Models:

- Mouse models of prion disease are superior to those available for other human neurodegenerative diseases since they show many of the same features of human prion disease, including the loss of brain cells that are not seen in other mouse models. Prions are essentially infectious proteins. They have a particular three-dimensional structure and can cause normal proteins in the brain to fold into that same structure, causing a “chain reaction” of misfolded protein. Therefore, injecting normal mice (e.g. C57Bl/6J) with prions from mouse causes misfolded proteins to spread throughout the brain leading to brain cell damage and loss. Injected mice develop clinical signs of prion disease (ruffled fur, rigid tail, hunched posture, loss of coordination and balance) after about 4-5-months in a manner that has been described in detail and that is very consistent between individual animals. This model aids better understanding of the how neurodegenerative disease progresses, and how treatments might delay or slow disease progression.

- Genetically altered REDACTED will enable us to more easily count connections between brain cells to determine how they change with metabolic or neurodegenerative disease. Similarly, genetically altered REDACTED will be used to facilitate change in gene expression in specific brain cell populations and evaluate the gene function with respect to metabolic and/or neurodegenerative disease.

- We may use genetically altered mouse models of obesity (and/or other metabolic diseases associated conditions such as type 2 diabetes) or models that are resistant to obesity (and/or other metabolic diseases associated conditions such as type 2 diabetes), typically on a C57BL/6J genetic background. For e.g. we may use Melanocortin-4 receptor (MC4R) knockout mouse model that exhibits obesity, hyperphagia, hyperglycaemia (excessive levels of blood glucose) and hyperinsulinemia (excessive levels of blood insulin). These models will enable us to identify the effects of metabolic associated genes on neurodegenerative disease progressions and/or therapeutic interventions.

- Diet-induced models of obesity and metabolic disease are well-established in the field, and complement existing and emerging genetic models. Specifically, the time-course of diet-induced obesity in C57BL/6J mice and the accompanying changes we intend to measure (e.g. body weight, body composition, food intake, energy expenditure, hormone levels, and glucose homeostasis) are all well-described in the literature. These mice serve as useful tools in evaluating the effects of anti-obesity compounds and therapies. We will also use them in combination with prion infection to study the links between metabolic disease (and substances used to treat metabolic disease) on neurodegenerative disease progression.

In drug-treated diet-induced obese mice with or without prion infection, we hope to see reduction in body weight and related symptoms, but it is possible that there may be unintended side effects such as anxiety or difficulty moving. We will therefore monitor mice regularly for potential adverse effects. We will use body-condition scoring charts following published standard criteria rather than solely relying on weight changes, since weight loss in an obese mouse may actually indicate improved health rather

than deteriorating health. Implementation of body condition scoring, regular body weight measurements, and observation charts for neurological signs and general welfare will allow us to accurately monitor the neurodegenerative process and define humane endpoints to reduce suffering.

Humane endpoints have been chosen to ensure that animal suffering is minimised whilst obtaining the most valid scientific output. Most prion-infected mice will be killed at early time points during disease progression, well before they develop prion disease. Tissue collected at these time points will be analysed for histological and biochemical readouts of the disease state; such as neuronal loss, detection of PrPSc (disease-associated form of the prion protein) and markers of inflammation. However, a cohort of mice will be allowed to develop clinical signs of prion disease to assess how metabolic disease and therapeutic interventions affect the later stages of neurodegenerative disease progression. In rare cases (estimated < 5%), mice left to develop clinical signs of prion disease may exhibit rapid disease progression. However, this is very unlikely since prion disease can be confidently diagnosed at relatively early stages by the appearance of early indicators such as decreased motility and tail rigidity, and confirmatory signs such as ataxia and loss of righting reflex. Therefore, suffering is limited by the daily observation and monitoring of these signs.

Methods:

All procedures (breeding transgenic mice, prion inoculation, and administration of drugs, behavioral and physiological analyses, and guided viral injections) will be conducted based on previous publications.

Animal suffering will be minimised by:

- performing all surgical procedures (prion inoculation, osmotic pump implantation and guided brain injections) under general anaesthesia and providing analgesia (painkillers) before and/or after surgery.

- minimizing the number of surgical interventions: most animals will receive prion inoculation followed by one or two osmotic fusion pump implantations (with at least 4 weeks in between subsequent surgeries). Surgical implantation of telemetry device will be carried out at the same time as osmotic fusion pump implantation. In other experiments, mice will receive one set of brain injections on either side of the head (at most two injections, one on each side of the head) on a double transgenic background. For embryo transfer, preference will be given to non-surgical method whenever possible.

- giving mice pain relievers where appropriate and administering substances (e.g. drugs) via the least invasive route that is practical. All administration protocols adhere to published guidelines, LASA Good Practice Guidelines, and as advised by the NC3Rs. For most drugs, daily dosing will be required for a period of 50-60 days, corresponding to the onset of clinical signs or defined endpoints. Wherever practical, mice will be given these drugs via implanted osmotic fusion mini-pumps rather than daily injections. In case of daily injections, mice will be monitored for adverse reactions and body condition (as standard for all dosing studies). Pain relief may be given as recommended by a Named Veterinary Surgeon (NVS)/ Named Animal Care and Welfare Officer (NACWO) if mild signs of discomfort are noted. Dosing will be stopped and the NACWO/ NVS/ Home Office Inspector (HOI) contacted if moderate signs develop.

- using the most refined compounds identified from the literature, our cell culture work, or from drug libraries. After identifying the dosage routes, frequency and concentration, the minimal likely effective dose will be used. In case of new compounds or combinations, small pilot studies will be conducted in mice to provide this information.

- using ultra-fine needle syringes, such as Hamilton NeurosTM syringes for stereotaxic injections, therefore reducing injection site damage.

- group housing mice with enriched environments as much as is practical.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We are unable to use animals that are at a more immature life stage/less sentient/ terminally anaesthetised due to the following reasons:

- To study the complex interrelation and course of disease progression (obesity and/or neurodegeneration), a multi-organ living organism with a developed brain that can closely mimic human disease needs to be utilized as an appropriate model.

- In order to understand the mechanism of disease progression and identify therapeutic strategies, we need to analyse brain structure and animal behavior that cannot be obtained from immature or terminally anaesthetised mice.

- Less sentient species cannot provide accurate insight into the human disease progression as they lack sufficient similarity to humans.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

- Where permissible by the experimental strategy, mice will be group housed in small numbers (3-4 per cage) and will be provided with environmental enrichment wherever practical. Male mice may exhibit aggression and therefore will be regularly monitored for the presence of fight wounds. Any mice with evidence of fighting will be closely monitored and animals may be separated if fighting continues. The NACWO/NVS will be informed and analgesia may be given as directed by the NVS. If an animal sustains injuries from fighting that are noted to cause distress and suffering and that cannot be treated with topical or systemic therapy (as directed by the NVS), it will be promptly killed by Schedule 1.

- Post-surgery (Prion inoculation, osmotic mini-pump implantation, guided brain injection), mice will be monitored daily for a minimum of 72 hours and maybe given appropriate care (analgesic for pain, re-closing of uninfected and minimally inflamed wounds).

- For experiments requiring short-term single housing or transfer to a different type of cage (e.g. metabolic cages), mice will be allowed to acclimatize to the individual housing and/or the new cage for minimum period of 24 hours.

- Body weight, body condition scoring, glucose and ketone levels will be measured regularly (daily to weekly) to assess animal health. Mice exhibiting poor tolerance to fasting may be re-fed or given an intra-peritoneal dose of glucose.

- Mice will be regularly (daily/weekly) assessed for any changes in their motor function (e.g., disturbances of gait and abnormal posture or muscle tone), level of arousal (e.g., hyperactivity and lethargy), and psychological status (aggression, biting, licking).

- All prion-inoculated animals will be regularly monitored for onset of early indicators of clinical disease. Once noted, mice will be inspected daily thereafter for clinical confirmatory signs of the disease and twice daily if prion signs are progressing quickly. The general condition of the animal will be assessed with specific attention given to breathing, coordination, posture and gait. All signs will be documented on clinical observation sheets.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the LASA Good Practice Guidelines and PREPARE guidelines to ensure all our experiments are conducted in the most refined way. We will refer to the NC3Rs (https://www.nc3rs.org.uk/3rs-resources) and use our REDACTED biomedical services search tool REDACTED to stay informed and continuously refine our experimental strategies. We will consider the number of independent experiments that will be performed when calculating total animal numbers and have consulted the “Guiding Principles for Behavioural Laboratory Animal Science” paper to ensure that our experimental design incorporates the most appropriate tests.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

During the project, we will regularly follow updates on the NC3Rs and RSPCA websites specially pertaining to the 3Rs and animal welfare. Experimental strategies will be modified to incorporate new technologies and approaches. We will ensure our participation in review meetings held in our establishment to discuss validity and usefulness of our mouse models and review animal wastage. We will stay updated on scientific literature in our field which would enable us to further refine our experimental approach.

Explain the choice ofspecies and the related life stages

We intend to understand how genes, cell types, dietary factors, and drugs contribute to the development (or treatment) of metabolic disease (e.g. obesity) and neurodegeneration. To understand how these contributing factors are related, it is essential to use animals where behaviors related to obesity (e.g.

food intake) and neurodegeneration (e.g. defects in memory) can be studied. Mice serve as the most appropriate species to use for these studies since mice and humans share more genes, cell types, and behaviors than flies, worms, or fish that are commonly used in research. While in theory monkeys would be even more similar to humans, mice have been used more extensively so obesity and neurodegenerative models in mice are very well established. Furthermore, there are many genetically altered mice that will aid our studies to understand the details of how obesity and neurodegeneration is caused, and how these diseases might be treated.

Since obesity and neurodegenerative disease largely affect adult humans, we will perform our studies in adult mice. Specifically, most of our studies will be carried out using young or adult mice (males and/or females) to enable the study of metabolic and/or neurodegenerative disease progression and the effect of interventions (metabolic and environmental factors, agents (e.g. drugs), and genetic). Prion infection in young mice results in the development of clinical signs of prion disease after about 4-5 months. Their disease onset and progression is well-described in scientific articles and is consistent between animals, enabling us to compare the effect of diet or experimental agents (e.g. drugs) on disease progression.

Home Office

NON-TECHNICAL SUMMARY

55. REDACTED

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Horses	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

REDACTED

A retrospective assessment of these aims will be due by 14 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Veterinary surgeons and trainers will be able to make informed decisions about what therapeutic medication to use and when within regulatory rules.

REDACTED

Alternative *in vitro* methods will be developed wherever possible

What outputs do you think you will see at the end of this project?

REDACTED

Publications - frequent peer reviewed journals , information sections on relevant websites- governing bodies and equine veterinary and welfare organisations

REDACTED

Interaction with general public - we are a signatory to the concordat on openness on Animal research

Education of industry stakeholders through presentations, written material on regulatory body website

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

REDACTED

Information will be made available as soon as it is ratified which can be within months of studies being completed and therefore over the five years significant data will be shared.

How will you maximise the outputs of your work?

Collaboration- liaison with other international and european groups to avoid duplication and maximise study output

Dissemination of new knowledge - through peer reviewed publication, presentation at international and european conferences - this would include any anomalous findings

Species and numbers of animals expected to be used

REDACTED

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

REDACTED

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We expect our studies to have extremely low impact on our horses. Adverse effects are expected to be minor and transient.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The level of severity expected in these studies is mild. EDACTED. A more significant (anaphylactic) reaction could involve widespread (systemic) signs such as fever, limb or facial swelling. Anti-inflammatory medication and a specific protocol of veterinary intensive monitoring and care would be used to deal with this. REDACTED To reduce the number of times a needle is used to take a blood

sample , REDACTED
<1% of horses used experience any adverse effects.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 14 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

REDACTED At this time , generation of these data cannot be satisfactorily modelled without the use of animals because metabolism of drugs can be very species specific.
Although in clinical studies there has been some progress in translating ADME data from rodent species to other species (particularly man) it is also recognised that use of a second species (dogs and

non-human primates) is often required to make the translation acceptable and only then because it is not considered ethical to use the target species (man) at this time.

REDACTED Nevertheless in parallell with *in vivo* studies , we continue to explore whether and how data can be extracted from our drug surveillance programmes, from published studies, (non-regulated samples) REDACTED.

What was your strategy for searching for non-animal alternatives?

There is on going research into ADME using *in vitro* equine hepatocytes systems using post mortem samples. This shows some comparison with *in vivo* studies but is not yet at a stage to replace *in vivo* studies.

Why were they not suitable?

REDACTED.

A retrospective assessment of replacement will be due by 14 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

REDACTED

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We use statistical advice based on the close genetic makeup of the TB breed to minimise overall numbers. We take into account the Toutain method as mentioned above. We also conduct pilot studies

to generate appropriate preliminary data to refine and reduce the overall number of horses required.

What other measures apart from good experimental design will you use to minimise numbers?

REDACTED

Re-use of the horses significantly reduces animal use .

A retrospective assessment of reduction will be due by 14 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

REDACTED

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

REDACTED

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

REDACTED

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We adhere to the ARRIVE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We receive the NC3Rs newsletter and refer to the website. We consider the 3Rs for each individual study carried out and also review them at quarterly AWERB meetings.

Explain the choice ofspecies and the related life stages

The purpose of this work is to produce information about how REDACTED; therefore it is deemed appropriate to use this REDACTED to obtain relevant, comparable data and valid results.

A retrospective assessment of refinement will be due by 14 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Insufficient translocation of drugs through the blood-brain barrier (BBB) has been widely recognised as a key component behind the failure of many treatments for brain disorders. Therefore, our aim is to understand the pathophysiological alterations to the BBB and take advantage of that to design novel delivery vehicles that would enhance drug translocation into the brain.

A retrospective assessment of these aims will be due by 16 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lesioned brain disorders (such as stroke, dementia and brain tumours) represent a leading cause of death and disability worldwide yet have very limited therapeutic options available. In the case of thrombotic strokes, for example, recanalization through thrombolysis or intravascular therapy have limited applicability and only being feasible in a low percentage (~10%) of patients. There is no effective therapy available for haemorrhagic strokes. Likewise, no effective treatments currently exist for other cerebrovascular disorders and brain tumours. There is an urgent need, therefore, to bring new ideas and approaches to the field to gain a better understanding of the disease pathophysiology, identify novel targets and develop selective treatment approaches. Insufficient translocation of drugs through the blood-brain barrier (BBB) has been widely recognised as a key component behind the failure of many therapies for brain diseases. Our recent research and that of others has identified that the nature of the BBB is altered in several brain diseases, yet, the underlying cellular and molecular mechanisms and the benefit of that disruption for brain drug delivery remains poorly understood. Current, treatment strategies for brain diseases do not fully address those pathophysiological adaptation of BBB in their design. Thus, there is an urgent need for a smart design of advanced drug delivery systems that take advantage of BBB structural changes after brain disorders.

What outputs do you think you will see at the end of this project?

This programme of work will provide the novel mechanistic insight into the structural and functional alteration of the BBB and other peripheral immune organs following brain lesions. It will define the nature of central and systemic pathological alterations in the early phase after a neurological event and the long-term outcome. By intervening in key pathways (e.g. tight junction protein disassembly) we will be able to define the contribution of specific pathways (e.g. transcellular vs paracellular pathways) to

achieve maximum drug translocation to brain damage in stroke and other neurological conditions. By defining these parameters we will identify the time frame for maximum drug delivery into the brain and help decide on potential novel therapeutic targets that could be translated into treatments for patients.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The immediate benefit from this project will be for basic science by producing world-leading and internationally recognised work that will be published in very high impact journals. Output from this project will be utilised by research field , including preclinical and clinical academics, as well as industrial partners. We will disseminate our results to the public through various outreach activities and also through our work with charities (e.g. The Stroke Association, British Heart Foundation) and patient organisations to inform them of the findings of our research. While Basic science will benefit in the short-term (1-3 years), clinical impact will take longer period to be achieved. The latter will likely be beyond the five-year duration of the programme of work.

How will you maximise the outputs of your work?

The research findings of this project will produce the first comprehensive evidence on the advantages of selective drug delivery to the brain and other peripheral immune organs affected following certain neurological conditions. If the project outcomes proved positive, REDACTED and other translation awards to confirm the results in multi-centre preclinical trials in-line with the step-wise approach recommended by STAIR. This will inform if initiation of clinical study will be considered.

Species and numbers of animals expected to be used

- Mice: 1400
- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

During this project we will develop different models of brain disorders. These include; brain ischaemia by (temporally cutting blood supply to the brain), brain haemorrhage (by inducing a local bleeding in the brain), brain tumour models (e.g. glioblastoma) and Alzheimer's models. Some of these models are

performed by surgical operation during which the animals will be fully anaesthetised and will receive drugs (analgesics) to minimise any pain.

In some cases, we will combine these models with other conditions such as infections, obesity or diabetes to mimic the health conditions in patients who have multiple illnesses.

In the case of brain tumour models and Alzheimer's models we will apply non-invasive ultrasound externally to include transient opening of the blood brain barrier and therefore, improve the penetration of therapeutic substances into the brain and enhance clearance of harmful molecules that accumulate in the brain and exacerbate the disease condition.

Following induction of these models, we will apply some behaviour tests that are routinely used to check any problem with movement or sensation and memory disorders, and these are very similar to what is usually seen in patients with cerebrovascular disorder.
Behavioural tests are not harmful to the animals and last only for few minutes. However, the effect of the model itself such as stroke may result in discomfort to the animal, but the severity kept to minimum to ensure no lasting harm occur. We will undertake all possible measures to reduce unnecessary suffering or pain experienced by the animals and to apply appropriate humane endpoints if an animal shows persistent adverse events.

At the end of the experiment animals will be killed by overdoes of anaesthesia. We will take blood, brain and other organs and tissues that we will analyse to meet the projects aims.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

1. Related to induction of co-morbidity

Infection: Infection dose will be kept minimum so as to induce only mild infection with limited adverse event to the animals.

Metabolic syndrome: Feeding animals a high-calorie e.g. high fat (or carbohydrate) diet for several months will eventually lead to obesity, and along with this the possibility of developing secondary conditions such as insulin insensitivity (as seen in obese humans). The impact this has on the animals will be reduced by limiting the duration of the study (e.g. up to 4 months).

In situations with multiple co-morbidities in the same animal it is possible that the animal might show an enhanced phenotype compared to those with just a single co-morbidity. For example, obese mice may show a more pronounced response to infection, we will therefore modify doses, treatment schedules etc to avoid producing too severe a phenotype, though we do not expect this to happen in the majority of cases.

2. Related to surgical procedures: Heat loss during the procedure and shortly after will be minimised by the use of an under-body heating pad and/or insulating material as required. During recovery from anaesthesia animals will be observed closely until fully conscious, using appropriate materials to

minimise heat loss. When consciousness has been fully regained, they will be returned to their home cage. Animals will receive analgesia and fluids before, during and after surgery.

3. related to focal brain ischaemia: Brain damage due to acute cerebral ischaemia is likely to be associated with behavioural effects on the animals similar to those seen clinically i.e. hemiplegia and muscle weakness of the face, reduction in sensory or vibratory sensation, contralateral paralysis or weakness, loss of appetite and loss of balance or orientation. However, these well-described behavioural changes are generally limited to the first day or two after induction of ischaemia, thereby allowing recovery of animals for long-term longitudinal studies to study functional outcome. The level of impairment, both clinically and in experimental models, is determined by the amount of brain damage, which can vary and be controlled depending on the method used to occlude the MCA. In many studies we will use distal occlusion of the MCA, which produces a modest cortical infarct and therefore only minor behavioural changes.

4. related to intracerebral haemorrhage: Haematoma volume is the key determinant of outcome and therefore the dose of collagenase or volume of blood injected will be at levels sufficient to induce moderate blood loads in the brain but with minimal effect on the animal. The behavioural changes observed on the animal are comparable to those seen in focal brain ischaemia such as hemiplegia and muscle weakness of the face, reduction in sensory or vibratory sensation, contralateral paralysis or weakness, loss of appetite and loss of balance or orientation (though not as potentially severe) and are generally limited to the first day or two after induction of intracerebral haemorrhage.

5. related to brain ultrasound and imaging: No adverse effects are expected apart from those associated rarely with general anaesthesia including death due to anaesthetic accident and dehydration. Appropriate action shall be taken to limit these in that body temperature will be monitored and maintained with a heating element, making hypothermia unlikely. Monitoring of pulse and/or respiration will also be performed to make sure an adequate level of anaesthesia is maintained while hydration will be achieved as required although, as scanning periods are relatively short, dehydration is unlikely.

6. related to brain tumour: the majority (~80%) are expected to grow at a steady rate and will have no significant impact on the animal’s general well-being. There is a possible risk of cerebral oedema (~2%) and / or systemic infection (~5%), arising from the surgery. If either of these are seen, they may be identified due to a rapid onset and deterioration (i.e., within 3 days post-surgery) of the following clinical signs: pilo-erection, lethargy, ataxia and hunched posture. In the event, these signs are observed or weight loss of up to 15%, then the animal will be killed by S1 method.

7. Related to Alzheimer's model: age-related cognitive deficits may be observed such as spatial memory, cognitive deficits which are associated with anxiety, circadian rhythm, and aggression. These symptoms are age related and has been reported before to first observed at 3-6 months and increase with age up to 12-14 months and generally are not expected to produce any major effects on animal wellbeing. The age of the animal at the start of the experiment will be decided based on the experimental design and the scientific question to be answered. No animals will be kept beyond 15 months of age.

8. Related to behavioural testing
: The majority of behavioural tests are painless, stress free and non-invasive and therefore not associated with any adverse effects. No adverse effects of the behavioural paradigms we plan to use are normally seen other than mild anxiety to a new environment which quickly disappears.

The majority of the studies will be done with short time point between few hours to 72h after induction of the models specified above. In some experiments long term functional studies will be performed over longer period of time (e.g 4 weeks) to study long term functional recovery after treatment with novel therapeutics. Clinically post-stroke complications can manifest some weeks after the event and persist for many years. We will therefore in few experiments may monitor animals for up to 15 months post-stroke, though most studies will be completed well within much shorter time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

It is inevitable that a small proportion of animals will show adverse effects, due to the nature of the intervention. The majority of the animals will be performed in mice and only few experiments will be done in rats. From those 43% (of mice and rats) are expected to develop maximum moderate severity which include those used to induce intracerebral haemorrhage model and those tested with brain US. Animal used under Protocol 2 that involves brain damage due to acute cerebral ischaemia will experience a maximum severe severity limit. This constitute approximately 29% of the mice and rats used under this licence. The rest of the animals (28%) will experience either moderate severity limit (sham operated animals) or mild (control animals that do not undergo surgical interventions).

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 16 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studying mechanisms involved in brain diseases such as stroke is extremely complex. Alongside the death of cells in the brains of stroke and dementia patients, these diseases are characterised by profound changes in behaviour, which it is not possible to study in cells in isolation. Moreover, rodents develop complications that are often observed in humans such as post-stroke infections.

What was your strategy for searching for non-animal alternatives?

The proposed animal studies are complementary to a broad programme of work on brain diseases using in vitro 2D and 3D cell culture models, clinical samples and non protective species.

Throughout the project we will seek, review and incorporate alternative methods based NC3Rs recommendations.

Why were they not suitable?

A key point in this project is the need to study the changes to the blood brain barrier after brain diseases. Studying the causes and consequences of blood brain barrier disruption is a challenging research area that requires an understanding of the complex interactions between multiple physiological systems i.e. the nervous and immune systems. Currently, it is not feasible to mimic these complex communications ex vivo, as there are no in vitro models that can replicate the complex structure of the brain and its connection to the immune system. Therefore, our objectives cannot be fully studied in cell culture model alone and thus whole animal in vivo experimentation becomes unavoidable to gain a full understanding of the mechanisms involved.

A retrospective assessment of replacement will be due by 16 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used data from preliminary experiments and previous studies to estimate the means and standard deviation (SD) for key primary and secondary outcomes. We will then perform power calculations for these outcomes to calculate the sample size necessary to detect a difference of at least 20-40% assuming a significance level of 0.05 and power of 80%. Exclusions due to surgical complications and mortality occur in up to 30% of the mice, therefore we correct for that in our final sample sizes.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will ensure that we use the minimum number of animals required to answer the scientific question by performing power calculation studies. We will also apply the NC3Rs experimental design assistant tool for appropriate experimental planning. We will regularly consult qualified statisticians about experimental design and statistical analysis.

What other measures apart from good experimental design will you use to minimise numbers?

We will use the NC3Rs experimental design assistant (EDA) tool for appropriate experimental planning. All experiments using live animals will adhere to the ARRIVE guidelines on design and reporting. Good principles of experimental design will be applied to ensure sufficient group sizes will be used to adequately test the hypothesis. Sample sizes are estimated from pilot studies and previous data using power analysis. Animals will be randomly allocated to the experimental conditions. Treatments will be administered in a blinded manner. Mice and subsequent tissue and blood samples will be labelled in such a way that the of the data analysis and outcome measures will be blinded to the allocation of experimental group.

A retrospective assessment of reduction will be due by 16 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rodents have brain structure comparable to humans and the location of injury and mechanisms of brain damage are also comparable. Moreover, mice develop complications like those seen clinically e.g. spontaneous infections and behavioural changes that are very relevant to study the project.

We will use previously published models of cerebrovascular disease such as ischaemic and hemorrhagic models of stroke, orthotopic brain tumour models and Alzheimer's models that are very well established and widely used in many laboratories throughout the world. The choice of the model will largely depend on the hypothesis being tested. Although there is no ‘perfect’ model for the conditions we will test in this project, the models selected for this project are based on the pathological and behavioural similarities to cerebrovascular disease in humans, which itself is extremely heterogeneous.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The studies proposed in this project could not be undertaken in animals with a lower degree of neurophysiological sensitivity (e.g. drosophila, C.elegans) because those models don't show comparable complications seen in humans. Similarly, in vitro experiments would not permit testing the interaction between different body systems.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All animals will be very closely monitored for any unwanted effects. We will follow the very recent guidelines published by the stroke community in collaboration with NC3Rs to minimise these. Examples on that include; enhanced monitoring during the critical 24h period after stroke surgery, use of analgesia, use of aseptic technique and post-operative care refinements. We will ensure that initial animal health is established and will be maintained to minimise any risk of infection through environment management and applying principles of biosecurity barrier. Whenever required environmental enrichment strategies will be considered and advice will be taken from NVS/NACWO as appropriate.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

In all our procedure we will refer to published guidance (e.g. IMPROVE guidelines, Workman guidelines) to make sure we apply the best current practice starting from the correct handling methods and applying the minimal invasive techniques in choosing the route of administration, volume size, administration frequency and needle sizes to induce the least harm possible to the animals. We will apply repeated animal observations and objective measurements to identify and define any adverse effects and to ensure humane endpoints are applied to minimise any harms. We will ensure that our team are well trained and have the expertise and experience required to perform the work at high standards.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Throughout the project we will continually review the literature and engage with colleagues/collaborators to learn of any new refinements to the protocols that could be implemented. We will also adhere to the ‘The IMPROVE Guidelines that are published recently in the Journal of Cerebral Blood Flow by NC3Rs working group on stroke.

Explain the choice ofspecies and the related life stages

Most of our experimental procedures will be done in mice and in some experiments will use rats. Rodents have similar cerebral and cerebrovascular anatomy to humans and the location of injury and mechanisms of brain damage are also comparable. Moreover, mice develop post-stroke complications

like those seen clinically e.g. spontaneous infections and behavioural changes that are very relevant to study the objectives of this project. Factors such as age and sex are well-known to impact the outcomes of the study. Therefore, at this stage of our project we will reduce unwanted variabilities by conducting our studies in adult male rodents to improve signal to noise ratio and increase the power of the experiments.

A retrospective assessment of refinement will be due by 16 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

57. Drug discovery in neurodegenerative diseases

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

dementia

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Neurodegeneration leading to dementia is a major unmet medical need and patient numbers are expected to increase with the increase in the aging population. Currently no therapies can slow or reverse the disease process. This work will advance the discovery of new therapies, by providing

support for evaluation of the uptake, metabolism and efficacy of novel potential drug candidates in rodents.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The benefits to humans are the potential identification of new molecules which may become clinical candidates for the treatment of neurodegenerative diseases. This work will also advance science; testing of selective drug molecules targeting specific proteins thought to be involved in the disease process will allow researchers to understand better the role of these proteins in the disease state.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Over the course of these 5 years, we will use both mice and rats. We anticipate using a maximum of 7000 mice (adults and neonates) and 1500 adult rats.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The likely maximum level of severity is moderate and most procedures will be mild.

- Following surgical procedures most animals will experience moderate pain and distress. Anaesthesia and analgesia will be established and maintained at sufficient level for the animal not to feel pain throughout the entire procedure.
- Following injections, animals will experience transient mild pain

All animals will be observed by trained staff to check for sign of distress such as:

- appearance
- behavioural abnormality or distress
- weight loss
- alteration in their natural behaviour and interaction with other animals

Appropriate remedial action will be taken and the following endpoints used when necessary to limit suffering: where anaesthesia is required, animals will be monitored and housed separately from others until fully recovered; more frequent monitoring; placing on a heated blanket; if the condition deteriorates and/or the severity is likely to exceed moderate, animals will be culled by a Schedule I method.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

For all work, animal use will be replaced where possible with in vitro alternatives – this will include the use of cell culture models (primary and stem cell derived) and in vitro models of drug metabolism. Only compounds with an acceptable profile in the in vitro assays will be taken into in vivo models.

For drug uptake and metabolism (pharmacokinetic) studies, animal use is essential as it is important to measure drug exposure in an intact system.

For in vivo efficacy studies, we will measure activity on biomarkers and disease progression. For both of these measures, we require the use of animals. Many processes are involved in neurodegeneration, and to ensure that drugs tested are likely to be of benefit we need to determine the efficacy of the potential therapy in the complex disease state rather than a simplified culture model.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Prior to the use of animals, we will test all potential drug candidates in cell culture assays. These will include assays to determine the potency of the drug compound at its molecular target and the selectivity of the compound for the target. We will use biochemical and cell assays to determine that the compound is stable and likely to enter the brain before dosing to live animals to ensure the compound is likely to reach sufficient concentration to have an effect, but not so high as to cause adverse events. We will also test the compound in cell culture models of neurodegeneration prior to use in animals.

Experiments will be designed in consultation with a statistician to minimize the number of animals required. Sample size will be predetermined based on a high statistical power and based on previous experience. Together these measures will decrease the numbers of animals used, by ensuring that only those compounds most likely to test the hypothesis are selected for in vivo work, minimising the need to repeat experiments.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our work will predominantly take place in mice. The majority of animal models of neurodegeneration are based on genetically modified mouse models; the refinement and understanding of these models has advanced in recent years. For each potential drug target, we will select the most appropriate genetically modified model based on the literature, and will select the timepoint for dosing based on biomarkers of disease.

NON-TECHNICAL SUMMARY

58. Effects of radiotherapy on lung injury

Project duration

2 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

pneumonitis, radiotherapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim is to test whether low doses of radiotherapy to the lungs can reduce the severity of lung injury by reducing the immune response to lung damage.

The immediate aim of the project is to generate laboratory data that is urgently required to help design clinical trials of low dose lung radiotherapy in patients with severe COVID-19 infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The COVID-19 pandemic has directly affected over 1 million people to date and the number of deaths is rising rapidly. A subset of COVID-19 patients experience severe acute respiratory distress syndrome (ARDS) which appears to be caused by an intense immune and inflammatory response to the primary lung infection. There are currently no effective treatments for this phase of the disease and 50% of patients requiring ventilation will die. Low dose radiotherapy to the lungs has historically been used as an effective treatment for pneumonia, and the immune-mediated nature of COVID-19 related ARDS indicates that it might have value in this disease. However, the optimum dosing and scheduling are unknown, and the immune mechanisms involved are unclear. The clinical community is developing a clinical trial of low dose radiotherapy for severe COVID-19 and has urgently requested pre-clinical data to help decide how best to give the radiotherapy - what dose, how often - and to help identify which patients would benefit.

The proposed work will provide unique and urgently needed information that will increase the likelihood of developing an effective new treatment for COVID-19.

The project will also generate new understanding of the impact of low dose radiotherapy on immune processes within the lung, which may provide benefits for patients with a wide range of inflammatory lung diseases.

What outputs do you think you will see at the end of this project?

We will generate:

- new understanding of how low dose radiotherapy modifies immune responses in the lungs

- new information on the best way to deliver radiotherapy to the lungs to reduce the severity of lung injury caused by bleomycin (for example: when to treat, how often, what dose to give, which organs to treat)

- this information will be published in peer-reviewed journals and made available to the international scientific and clinical communities

- our findings will be used in real time to influence the design and delivery of clinical trials testing the use of low dose lung radiotherapy for severe COVID-19 illness

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

We are optimistic that the following groups of people will benefit from our findings in the timescales shown:

- patients with severe COVID-19 infection; within 3 - 6 months

- clinicians developing clinical trials for severe COVID-19 infection; within 3 - 6 months

- scientists and clinicians researching and treating acute respiratory distress syndrome caused by other infections or exposures; within 6 - 12 months

How will you maximise the outputs of your work?

I am already part of a highly active international consortium of radiation oncologists and radiation biologists who are working together to develop clinical trials and increase our understanding of the effects of low dose radiotherapy on acute respiratory distress syndrome. I will share our new knowledge with this community, making use of fast-track publication systems such as bioRxiv. The consortium will also provide timely, expert advice and objective criticism of our experiments and data. With the suspension of the national and international conferences that would usually be used as a forum for dissemination of data, we will utilise webinars and other remote communication platforms to present and share data.

Species and numbers of animals expected to be used

- Mice: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will typically inhale bleomycin through their nostrils while under brief general anaesthetic. Some mice will experience rapid breathing after this, but only for a short period of time. Some mice experience lethargy after the treatment but this usually lasts for less than 2 days, after which time they recover and show normal behaviour.

Some of the mice will receive targeted low dose radiotherapy to their lungs and other organs including the spleen. This treatment is given while the mice are under general anaesthetic and the radiotherapy

doses are extremely low, so we don't expect the mice to experience any side-effects from this treatment. Most mice will receive a single radiotherapy treatment but some may receive up to three treatments, to enable us to see if repeated treatments are more effective. The total dose of radiotherapy is still extremely low so we don't expect any side-effects from multiple treatments.

At various times during the experiment we may perform CT scans or MRI scans of the mice to see whether the lungs are inflamed. These tests will be done with the mice under general anaesthetic and will not cause any side-effects.

We will take small blood samples from mice every few days, typically four times and up to a maximum of eight times. These will cause very brief and mild pain but will not have any lasting side-effects.

About two weeks after the bleomycin treatment, the damage to their lungs may cause some mice to lose weight and show signs or lethargy. Any mice losing more than 25% of their bodyweight will be killed humanely to avoid suffering.

All our experiments will last a maximum of 28 days. At this time, any mice who are still alive will be killed humanely and their blood, lungs and other tissues analysed in detail so we get as much information as possible from every mouse in the study.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The initial increase in breathing rate can last up to one hour.

The early symptoms of lethargy can last up to 48 hours.

Pain caused by blood tests will last a few seconds.

Weight loss and lethargy caused by lung inflammation can be progressive over several days.

Increased breathing rate may be progressive over several days.

Mice may be subjected to repeated anaesthesia over the course of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Based on published data, we anticipate 50% of bleomycin-treated mice to develop more than 25% weight loss within the 28 day experimental period. These mice will be humanely killed.

Increased breathing rate occurs transiently after bleomycin administration in 90-100% of mice but usually resolves within one hour. Increased breathing rate may also be observed in some mice at later stages but this is not a common feature of the model and weight loss tends to occur before breathing is affected.

Similarly, lethargy and reduced interactions with other mice may occur in some mice but this is not a common feature and weight loss tends to occur before these symptoms become apparent.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

An international consortium of radiation oncologists is planning an urgent clinical trial to test whether low dose radiotherapy to the lungs can improve outcomes for patients with severe COVID-19 infection. The consortium has requested information on how best to give the radiotherapy - what dose, how often, at what stage of the disease, and to which patients. It is only possible to get this information by testing the effects of different doses and schedules of radiotherapy on mice with acute lung injury.

What was your strategy for searching for non-animal alternatives?

We will be doing additional laboratory experiments on immune cells taken from human subjects and grown in the laboratory, but these will not be able to provide the critical information needed for the clinical trial.

We are optimistic that clinical trials of low dose lung radiotherapy for COVID-19 lung disease will be up and running within the timecourse of our project. I am part of the consortium overseeing these studies and will have access to early results. If appropriate, we will use emerging clinical data to refine the research questions we are asking in our animal studies. This may reduce the number of experiments required, and will make our results more relevant to the clinical questions.

Because acute lung injury is a complex and dynamic process involving multiple tissues and cell types, it is difficult to replicate it with a non-animal alternative. However some research groups are developing non-animal models that use lung slices; these are showing some promise so we have considered whether we could use them.

Why were they not suitable?

As well as lung injury involving multiple cell types, the effects of low dose radiotherapy on the immune response involve effects on multiple tissues and cell types including lung tissue, circulating blood cells, lymph nodes and spleen. The effects of radiotherapy on lung slices would therefore not be representative of the effects of whole lung radiotherapy. We therefore believe that experiments in live mice are required for us to properly test whether low dose radiotherapy can reduce inflammatory lung injury.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate needing to use approximately 30 mice in each experiment so that we can have confidence in the results. We estimate needing to perform about 20 experiments in order to test all the different radiotherapy doses and schedules as well as the testing whether giving radiotherapy to the spleen and the heart affects outcomes.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will perform two pilot studies: the first will establish the best dose of bleomycin to use to cause lung injury that resembles severe COVID-19 infection. The second will determine how consistent the effects of bleomycin and radiotherapy are on lung inflammation in mice. The results will tell us how many mice we will need to include in all the subsequent experiments in order to give us reliable results.

If we find that mice treated with bleomycin and no radiotherapy all behave in a very similar way, we will use the results of the first experiments as a comparison for the all the subsequent experiments (with different radiotherapy doses, for example).

We will keep abreast of early outcomes of clinical trials testing low dose radiotherapy in COVID-19 patients and if appropriate will adapt our experiments in order to ask the most important research questions or to take account of new clinical information. This may reduce the number of experiments needed to answer the key research questions and hence reduce the number of animals used.

What other measures apart from good experimental design will you use to minimise numbers?

By taking blood samples at regular intervals and undertaking CT or MRI scans of the mouse lungs, we will obtain multiple pieces of information from every mouse. This will increase the data generated by each experiment, which may enable us to reduce the number of mice used. Also by obtaining and analysing multiple samples from each mouse at the end of the experiment (lungs, blood, fluid from the lungs) we will increase the amount of information for each mouse which may enable us to reduce the number used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will treat healthy mice with a chemical called bleomycin that causes inflammation and injury to the lungs, which is very similar to the lung injury seen in patients with severe COVID-19 infection. Mice treated with bleomycin experience minimal side-effects in the first two weeks after treatment, and then may start to lose weight and become tired as their lungs become scarred. We will humanely kill any mice that start to develop these symptoms in order to cause the least suffering possible. This method will enable us to test whether low dose radiotherapy reduces the severity of lung injury caused by bleomycin, without causing distress or lasting harm to the animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We need to use adult mice because the effects of bleomycin on the developing lungs of less sentient animals are very different from the effects on adult lungs. We can't do these experiments on mice who have been terminally anaesthetised because it takes two to four weeks for the effects of bleomycin to be seen.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Mice will be housed in group cages (five per cage) to enable social interaction. Because we anticipate weight loss, mice will be introduced to a soft diet prior to starting experiments so that they become accustomed to it and will find it easier to eat at later timepoints.

Most of the procedures will be done under general anaesthetic in order to minimise harm and suffering.

Mice will be monitored and weighed on a daily basis from the start of the experiment, and a structured checklist will be used to look for the expected symptoms and signs of the bleomycin model as well as signs of general wellbeing. If mice start to display signs of severe lung injury (weight loss, lethargy) they will be humanely killed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our project has been designed in accordance with the PREPARE guidelines and we will use the NC3R's Experimental Design Assistant (EDA) to optimise our experiments. We have sought advice from internal and external experts in the field of inflammatory lung injury to ensure our specific experiments are as refined as possible. We are active participants in REDACTED and are constantly updating our radiotherapy protocols and quality assurance practices to ensure that radiotherapy is delivered as accurately as possible in order to avoid harm.

The results of our experiments will be reported according to the ARRIVE guidelines.

In the conduct of our experiments we will adhere to the Institution's Animal Research Policy.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are continuously updating our research practice through reading the scientific literature, attending seminars and webinars and submitting our research findings and proposals for critical expert review. The work proposed in this application will undergo detailed critical and ethical review when we submit it for funding.

We will monitor ongoing developments in the use of lung sections as models of lung injury and will seek to collaborate with researchers who are using and developing them if this will improve the quality of our research and reduce the number of animal experiments required.

We regularly consult the NC3Rs website and have used it to access the PREPARE and ARRIVE guidelines and the Experimental Design Assistant (EDA). These tools have been used to design and enhance our project, as described below.

Explain the choice ofspecies and the related life stages

We are using adult mice for these experiments because we know how they will respond to the bleomycin treatment and we know that the effects of bleomycin on the lungs of these mice are similar to the effects of severe COVID-19 infection in patients.

Home Office

NON-TECHNICAL SUMMARY

59. Elephant endotheliotropic herpesvirus (EEHV) clinical vaccine candidate trial

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Asian elephant (Elephas maximus)	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to determine the safety and efficacy of a candidate vaccine against EEHV.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

EEHV is an important pathogen affecting captive and wild populations of the endangered Asian elephant (Elephas maximus). The virus can cause a highly fatal haemorrhagic disease in juvenile elephants (Long et al., 2015; Zachariah et al., 2007). Treatment of viraemic elephants with antiviral drugs has not proven effective and is compounded by the rapid progression of the disease with death often occurring within hours to days after the first clinical signs are detected (Richman at al., 2012). Thus, this work is important to develop a vaccine candidate and vaccination protocol that can be applied to protect Asian elephants to prevent developing lethal EEHV-HD. A sufficiently protective EEHV vaccine will reduce the mortality in elephant populations. This directly supports animal welfare of the herd (as the loss of infants is highly stressful) and supports the aim to create sustainable populations.

What outputs do you think you will see at the end of this project?

The primary expected benefit is the creation of a vaccine candidate that is safe and efficacious to induce an immune response.

The work is expected to provide information on EEHV vaccine targets.

The findings obtained in the project will be published in peer reviewed journals and presented at scientific conferences and meetings.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Production of an effective vaccine candidate against EEHV will benefit animal welfare by reducing the incidence of clinical disease in Asian elephants. The full benefit is likely to be realised after the end of the project when vaccination can be implemented into veterinary practice.

New insights into the quality and quantity of immune responses elicited by selected vaccine candidate antigens and host-pathogen interaction will be valuable to the scientific community working on Asian elephants and evolutionary related species.

How will you maximise the outputs of your work?

New findings will be presented in peer reviewed journals and at national and international scientific conferences.

Species and numbers of animals expected to be used

- : 6

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be vaccinated up to four times and in this context and around one week thereafter blood samples will be drawn for laboratory analysis of the effects the vaccine induces.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The vast majority of animals will show no adverse side effects. A small number of animals might display mild and transient adverse effects, such as local swelling. These will be addressed with husbandry and veterinary support and will not lead to a lasting effect

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All animals are likely to experience only mild levels of severity.

What will happen to the animals at the end of the study?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due the specific nature of EEHV infections no alternative models are available.

What was your strategy for searching for non-animal alternatives?

Non-animal/in vitro models are not available.

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experiments are designed to ensure the appropriate number of animals are used: the numbers selected reflect the minimum that enable robust experimental design compatible with obtaining reliable and meaningful results.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have sought advice from local statisticians, but also consulted the regulatory authorities for licensing vaccines and veterinarians with experience in early clinical studies.

What other measures apart from good experimental design will you use to minimise numbers?

This is itself a pilot clinical study and materials obtained and left after analysis will be stored for further analysis if required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The approach selected uses established vaccines approaches that do not show lasting suffering or in any tested mammalian species. The procedures to apply the vaccine and sample blood are equally well established and cause minimal suffering and distress only.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There are no model species that could be used, nor are there life stages less sentinent that would apply to be used.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The animals will be trained for the application of vaccines and blood withdrawal. The animals will be closely monitored after all treatments and if required pain management against local swelling will be provided.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

OIE (World Organisation for Animal Health) Manual of Diagnostic Tests and Vaccines for Terrestrial Animals

Home Office The Harm–Benefit Analysis Process _Advice note

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are in constant exchange with other groups working on EEHV and stakeholders so that we will hear about advances regarding the particular disease and impact this can have on our approach. We are also constantly reviewing progress in vaccination to inform us how we can improve procedures.

Explain the choice ofspecies and the related life stages

The choice of animals is determined by the lack of any in vitro or in vivo model. Adult animals are suitable to determine the safety and efficaciousness of the approach.

Home Office

NON-TECHNICAL SUMMARY

60. Embryonated Eggs for Diagnosis and Research

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project will provide support to work to diagnose, monitor and study viruses causing human infections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Influenza epidemics are associated with high levels of illness and death. Diagnosis of influenza infection provides a public health benefit by providing information on the number of virus infections in the population. This data can also be used to inform how well matched the vaccine is to the virus infecting the population and also how well the vaccine is performing in protecting the population.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Avian eggs

1750 eggs

Five years project duration

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The likely severity is Mild. Expected adverse effects are from microbial contamination during the procedures. This is minimised by ensuring sterility of equipment, careful monitoring of the procedures, quality control and staff training. The embryos are terminated at the end of the procedure and before hatching.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Some viruses will only grow in embryonated eggs. Some diagnostic tests require high concentrations or volumes of virus which can only be achieved by growth in embryonated eggs.

The majority of influenza vaccine viruses are produced in eggs. Diagnostic testing associated with the influenza vaccine must use egg grown viruses to preserve the characteristics of the vaccine virus.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Wherever possible, mammalian tissue culture cells are used instead of embryonated eggs. When eggs are used the number of eggs is carefully selected according to recognised protocols to ensure that the aim of the experiment is achieved without unnecessary wastage. The number of eggs to be used is determined by the use of standard protocols to ensure the quality of the scientific outputs of the work.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Use of eggs is restricted to purposes where they provide a significant benefit which cannot be achieved by the use of mammalian tissue culture cells.

Training and sharing of protocols with other laboratories ensures that methods are updated and refined to achieve the best result.

Careful husbandry is practised to ensure minimum wastage of eggs.

Home Office

NON-TECHNICAL SUMMARY

61. Environmental effects on ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
zebra finch Taenopygia guttata	neonate, juvenile, adult, aged, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to examine how environmental conditions influence the process of ageing in later life, using birds as a model. The project will focus on the effects of exposure to different environments at different life stages, and on the intergenerational effects of parental age on offspring longevity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to understand how environmental conditions, in both early life and in adulthood, influence the pattern of age related deterioration in later life. Exposure to environments that increase stress hormone levels is known to reduce longevity but how this comes about is still relatively poorly understood.

What outputs do you think you will see at the end of this project?

We expect to generate new knowledge related to the biology of ageing and how the pattern and processes are influenced by environmental conditions at different life stages. This knowledge will be communicated via scientific publications and, where appropriate, articles in popular science media.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Exposures to stressful environmental circumstances, and or episodes of poor nutrition, occur in both wild and captive animals, and of course also in humans. Understanding the nature of these effects, their fitness consequences, and the routes by which they occur is important both in understanding how organisms cope with environmental change, and in potentially providing routes whereby such effects can be prevented or alleviated. Circadian rhythm disruption, for example by shift work, international travel or exposure to artificial light at night, has been shown to have adverse health consequences including accelerated ageing, but the molecular processes underlying this are poorly understood. The effect of parental age on offspring longevity is an important topic, and understanding the routes whereby parental age can reduce offspring longevity is important for both animal breeding, understanding the evolution of reproductive schedules, aspects of mate choice, and human reproduction.

This project will advance our understanding of the mechanisms that link environmental conditions in early and later life to long term health. Therefore it is important that we follow through outcomes for individuals over differing time scales and at different life stages. This is beneficial both in terms of advancing the science of ageing and development, and understanding the long term effects of environmental and growth conditions, and stress exposure. This will be beneficial to both humans and other animals. Humans and many other animals can experience early life adversity due to food shortages, inclement weather, poor physical environments, or being a subordinate. The results of this early life experience can persist long after the conditions have been ameliorated, and in some cases

effects may be life long and reduce lifespan. Repeated circadian disruption can also cause long term effects. This project aims to understand the processes whereby these long term affects can occur, and may assist in the development of mitigating treatments.

How will you maximise the outputs of your work?

We will do this by appropriate dissemination of the resulting knowledge, by training young scientists in the techniques in which we have expertise and in educating students

Species and numbers of animals expected to be used

- Other birds: No answer provided
- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mostly, our studies are based on mild environmental manipulations and the taking of very small blood samples, typically no more than six times in the birds' lifetimes, to measure biochemical and molecular parameters. We sometimes also elevate natural hormones, but only within the natural range, and use non-toxic markers. Typically this is done by feeding the substances to the animals, rarely where necessary by injection.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The impacts relate to responses to environmental conditions. Stress sensitivity and metabolic rate may be increased. Increased rate of growth may occur. We expect that parental age at reproduction will increase the ageing rate of offspring, and that this will be evident in the parameters that we will be measuring. We expect this to increase the rate of ageing. Lifespan may be reduced. We do not anticipate the animals experiencing any pain, weight loss or tumours. With respect to the changes in light exposure, there may be changes in activity patterns. These behavioural changes will not persist beyond the experiment itself.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Expected severities are mild for the majority (90%) of animals. For some old animals in captivity (10%) it is possible that the natural ageing process may be considered moderate.

What will happen to the animals at the end of the study?

- Kept alive
- Set free
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying the effects of environmental conditions on fitness traits (longevity and reproductive performance as appropriate) and this needs to involve individual animals. We need measures of the physiological state of the animals, which is generally done from small blood samples. We also, with captive animals, need to control the environmental conditions in order to understand the processes whereby the environment influences ageing parameters. The environmental manipulations that we use are always such as to be as similar as possible to what the animals experience in the wild.

What was your strategy for searching for non-animal alternatives?

None. Not applicable.

Why were they not suitable?

We need whole organism measures of performance, and thus measures taken from cell culture are not appropriate. Our regulated procedures enable us to obtain biological samples in a minimally invasive manner, and also to control the environmental conditions to avoid confounding effects.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on projected experiments over the next five years. Numbers given are maximal.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The number is based on the maximum total number to be used in the overall project. There are different components to the project, and I have endeavoured to use the minimum number likely to be required for robust experiments with adequate control groups. Where possible this is based on previous studies in which we have experience of the level of individual variability and likely effect sizes.

What other measures apart from good experimental design will you use to minimise numbers?

We breed most of our zebra finches in house in large aviaries and do not breed more than the number we require. We obtain quail from registered suppliers. Wild birds are caught at breeding, feeding and roosting sites as appropriate. We have conducted our own pilot studies in the past, or already have relevant experience of all of the protocols that we will use, or have based these on published research by other colleagues. Since we measure a number of parameters in different tissues, we make maximum use of any tissue sampling that we undertake.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use birds because they are most suitable for our projects. We use minimally invasive procedures, mostly involving taking very small blood samples by 'pinprick'. We measure naturally occurring hormones and molecular processes. Any manipulations that we undertake are designed to mimic natural conditions. Where we sample wild birds, this generally involves single blood or feather samples and the birds are immediately released at the capture site.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

These are not appropriate for our studies of long term effects. We use birds because they are easy to sample in the wild, and we can use species that are easy to keep in captivity. Birds are of great interest in ageing studies because of their considerable longevity (on average lifespans are 3 times those of mammals of a similar size).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We are continually monitoring our welfare standards and implementing environmental enrichment. As well as the moral issue, we want our animals to behave as naturally as possible if they are in captivity.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

For our captive species, we use the guidelines produced by the Universities Federation for Animal Welfare. For wild birds, we follow the guidelines of the British Trust for Ornithology for the safe capture and handling of birds. The PI and other colleagues have contributed to outlining best practice for the species that we use.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

From information provided by the REDACTED, the NVS, our Biological Services staff, colleagues in other institutions and by general reading.

Explain the choice ofspecies and the related life stages

We are studying birds because we can relate our laboratory studies to conditions in the wild, birds are recognised as particularly interesting in the context of ageing because of their long lives and repeated breeding. Their egg laying reproductive mode makes it possible to obtain early life stages without invasive procedures being used on the mothers.

Home Office

NON-TECHNICAL SUMMARY

62. EPIGENETIC AND TRANSCRIPTIONAL REGULATION OF GENE EXPRESSION IN NEURONS

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate
Rats	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project will explore how gene expression is regulated in the brain during normal development and in disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding the molecular mechanism that underlies the proper wiring of the mammalian brain represents an essential step to tackle increasingly common neurodegenerative disorders, including Alzheimer's and Parkinson's diseases. A recent study has estimated that the cost of neurodegenerative disorders will reach £112 billions per year, including indirect costs such as lost productivity and absence from work. The laboratory has a long-term interest in employing cutting-edge technology to understand the basic mechanism that regulate gene expression in developing and adult neurons in health and disease. The laboratory has already provided the scientific community with several potential druggable targets that may be further developed into new therapeutic approaches to cure various forms of neurodegeneration.

What outputs do you think you will see at the end of this project?

The discoveries made in the laboratory in the next five years will shed new light on the basic mechanisms of brain functions and how they can be exploited to develop new therapeutic strategies to cure neurodegenerative disorders.

The impact of the findings is potentially very high.

- The work proposed will characterise new basic mechanisms that control neuronal development and functions.

- A wide array of innovative methodology and cutting-edge techniques will be used in neurons, thereby providing the neuroscience community with a number of scientific protocols that will greatly improve our ability to study brain development

- Using a combination of mouse models, the functional significance of these mechanisms will be addressed in brain development and disease.

- The innovative nature of this work should result in high profile publications that are likely to gain the attention of a broad scientific and lay audience. The public has a high level of interest in neuroscience and brain development, so the interest to the public is potentially high. For example, the American Society for Neuroscience conference attracts more than 50,000 scientists and lay people every year, and it is characterised by a number of talks by prominent personalities (e.g. the Dalai Lama)

aimed at disseminating the importance of neuroscience research and its impact on society. Similarly, in the UK, the annual Neuroscience Conference of the British Neuroscience Association is attended by thousands of basic and clinical neuroscientists and many sessions are dedicated to the impact of out discoveries on human health and healthy brain aging.

- Although, the impact on patients affected by autism, amyotrophic lateral sclerosis (ALS) and other neurodevelopment disorders and the public at risk of developing relevant disorders will be long-term and beyond the immediate scope of this proposal, the research will still provide an important step towards understanding, predict, ameliorate and prevent these important neurological disorders. The potential impact of this project for patients is therefore considerable, especially considering the scale of the medical problems, which include long-term disability and loss of productivity.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Academic and scientific community

- The research will be widely disseminated, and the results will be discussed with scientists who are world-renowned experts in the relevant fields and present our research during national and international conferences (years 2-5).

- The results of the research will be all published in high impact scientific journals that reach the wider scientific community as well as the lay public. Publications will be open access and all results will be provided in standard format, or as supplementary on-line appendices to our publications, immediately on publication (years 2-5).

- The techniques developed in the laboratory will be highlighted and shared with collaborators and with other researchers during discussions in informal meetings and in the course of national and international conferences (years 1-4).

- The work will also impact in terms of delivering and training highly skilled researchers, such as research technicians, graduate students and future research leaders in the field of neuroscience.

Economic and societal benefits

To ensure that the public will benefit from the research, a series of initiatives will be taken to maximise the potential impact of the discoveries on human health.

- A significant impact on increasing public awareness and understanding of science will be achieved through press releases, when appropriate, and at open days during the lifespan of the project. in the annual open day for secondary school students, and work placement for students during the summer. This is aimed at introducing young students to state-of-the-art research and encourages them to consider a career in basic research and in academia. The laboratory normally participates in satellite workshops at conferences aimed at a lay audience that includes representatives of the industry, government, press and funding agencies (years 2-5).

- The commercialisation and exploitation of scientific discoveries generated by the research described in this application will be a priority. Molecules and signalling pathways identified that may have relevance for autism or neurodevelopmental disorders will be tested in relevant disease models either in-house orvia collaborations (years 4-5).

How will you maximise the outputs of your work?

As explained above, the research will be disseminated, and the results discussed with scientists who are world-renowned experts in the relevant fields (these include experts in neuroscience and the basic mechanisms of brain development) and the research findings will be presented in national and international conferences on an annual basis.

All publications will be open access and all results will be available to the lay public. Unsuccessful results will be published on open access journal, whenever they are considered to be of potential use to the scientific community and/or the lay public. All genomic data will be made public independently of their publication in mainstream journals and whenever the results are technically sound.

Species and numbers of animals expected to be used

- Mice: 8400
- Rats: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The vast majority of animals (unless otherwise specifically justified) will be bred and subject to the procedures to determine their genotype. A small minority of pregnant animals will be subject to surgery that will be performed under anaesthesia and with the supervision of the veterinarian in the establishment. The surgery will be performed under general anaesthesia and will imply the transfer of genetic material and/or non-toxic substances into the brain of rodent embryos by using a very fine needle. This is necessary in order to perform a detailed analysis of the brain and to understand how lack of proper neuronal development may result in neurologic and psychiatric diseases in the adult, including schizophrenia and autism.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Potential relevant adverse effects are related to the experiment involving surgery. All pregnant females will be monitored carefully after surgical procedures and painkillers will be administered to reduce

suffering whenever animals show signs of discomfort during recovery.

Manipulations of pups can occasionally lead to rejection and cannibalism. This event will be minimised by using a number of precautions, such as rubbing hands with cage sawdust before handling animals, avoiding overuse of surgical spirits and others. Animals will be monitored closely after being reunited to the mothers and fostered if possible if signs of cannibalism or rejection are evident.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The expected severity of adverse effects in the vast majority of animals is mild, unless otherwise specified as moderate. Animals subject to surgery for analysis of the brain in utero represent less than 5% of the animals and may have adverse effects due to the surgical procedure (infection of the surgical sutures and minor pain after surgery).

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Rodents (rat and mice) represent the best mammalian model to study the brain during development, as well as during adulthood in both normal and disease conditions. Importantly, the mouse is the only mammalian species that can be easily genetically manipulated and for this reason, it is widely used in the international research community for studies of the in vivo functions of mammalian genes. Therefore, in order for the data to have worldwide significance, the mouse is the most appropriate species to use. Importantly, in rodents, nervous system development is for many aspects very similar to humans. Work conducted with this animal model will provide insights into the functioning of the human brain. More generally, anatomy, physiology, genetics of the mouse are similar to humans, and mice represent a very powerful system where to model human biology and disease. Currently, the most effective way of investigating the function of a given gene at the level of the whole animal is through the generation of genetically altered mice. Although it is possible to inactivate genes and proteins of key physiological processes by administration of toxins and drugs to whole animals, in many cases this approach suffers from lack of specificity and gives rise to more wide-ranging adverse effects that cannot be easily controlled. It also does not allow the detailed dissection of the complete network of proteins involved in key developmental or physiological processes, unlike the use of transgenic animals.

What was your strategy for searching for non-animal alternatives?

The laboratory will use cell lines (rat- and mouse-derived), whenever possible. Pheochromocytoma and neuroblastoma cell lines and other neural-derived cell lines will be normally used to optimize protocols and to perform experiments that require very large number of cells (some biochemical purification of proteins for example).

Why were they not suitable?

An alternative of the use of animals is to use cell lines to study neuronal development and degeneration in vitro. Although cell lines are used in the laboratory, the information gained is partial and only marginally helpful. Transformed cell lines do not resemble brain cells and often do not model the brain environment. In addition, the lack of reliable markers to isolate many different cell types that the lab is interested in studying represents a major problem in the field. Finally, the currently available techniques are not totally reliable as culture conditions may change the nature of the cell lines. Thus, it is difficult to model neuronal development and neurodegeneration in a dish and this is mainly due to the complexity of the brain. Intact tissues with their full complement of specialised cells represents the only system in which mechanisms can be fully tested and therapies accurately evaluated. In particular, this applies to the brain, for which insufficient information exists to generate accurate computer models, which can predict the complex responses of neuronal tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used for each experiment has been calculated by using statistical calculations that take into account the statistical tests that will be used to analyse the results. All experiments will follow the guidelines indicated by UK research councils in order to ensure that the data are solid and reproducible by other laboratories.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Before embarking upon any in vivo experiments, hypotheses will be tested using in vitro models, including neuron-derived cell lines and primary neurons. When in vivo experiments are appropriate, small pilot studies will be carried out to estimate the variability of the experimental data so appropriate statistical analysis can be used to minimise the numbers of animals required for a validated result.

For all experiments, the smallest possible number of animals to obtain statistically significant differences between groups will be used, taking into account a certain degree of variability of what will

be analysed.

What other measures apart from good experimental design will you use to minimise numbers?

To minimise animal usage, prevent the unnecessary production of animals showing adverse effect and to ensure that animal breeding is inextricably linked to research requirement, the project licence holder will:

- Ensure high standards of animal care, welfare and utilise the most appropriate breeding methods.

- Ensure that colony sizes are monitored and adjusted within a formal forecasting system to meet the requirements of the research programme(s). Transgenic REDACTED that are not expected to be used in the next 6 months will be archived and embryos will be frozen for future use

- Ensure that breeding colonies are always kept to their minimum size so as not to over produce. Detailed breeding records will be kept enabling the selection of the most appropriate breeding stock.

- Verify that before setting up or creating new transgenic lines a full search is carried out to ascertain that there is no other worldwide availability.

- Ensure that all people working on this project are appropriately trained and suitably competent to enable a high success rate to be achieved and thus minimise the number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The laboratory will use wild type rats and mice carrying genetic modifications, as they are the most effective way of investigating the function of a gene in the brain. Although it is possible to inactivate genes and proteins during key physiological or developmental processes by administration of toxins and drugs, in many cases this approach suffers from lack of specificity and gives rise to wide-ranging adverse effects that cannot be easily controlled. Moreover, unlike the use of transgenics, it does not allow the detailed dissection of the key developmental or physiological processes. All personnel in the lab has extensive experience in all the regulated procedures in this licence and will use their experience to ensure that suffering is minimal.

Procedures to be used:

- Genetic modifications by crossing REDACTED – Models described in the project details section present only a mild form in the brain (delayed cortical formation, lower number of peripheral neurons). Although adverse effects are not expected, mice will be monitored daily and will be culled if they show signs of illness.

- Genetic modifications by basic techniques. Potential adverse effects will be minimised by using state of the art facilities for surgical procedures available at the designated establishment and fully trained staff. Animals will be closely monitored after the procedure for any signs of illness or discomfort. Pain killers will be administered during the recovery phase to alleviate the discomfort.

- Injections of substances needed to trace nerve cells may lead to infections in a small percentage of cases. If animals show any sign of infection, they will be euthanized immediately.

Adverse effects are expected to be rare and minor in extent.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rats represent a very powerful model system to study the mammalian central and peripheral nervous system and they are extensively used for experiments aimed at testing the effects of environmental conditions on neuronal functions. Moreover, peripheral neurons, such as the sensory neurons found in the sciatic nerve, have been extensively characterised in rats, and this allows to use published data related to gene expression and sequencing, thereby reducing the number of experiments that will be required to test the hypothesis described in this proposal.

The mouse represents the most appropriate species to study in order to obtain data with high significance, as this model system is used extensively world-wide. Importantly, in rodents, brain development is for many aspects very similar to humans. Thus, work conducted with mouse model systems will provide insights into the diseases of the human nervous system. More generally, the anatomy, physiology and genetics of the mouse are similar to humans, and mice represent a very powerful system where to model human biology and disease.

Less sentient species such as the fly *Drosophila melanogaster*, the fish zebrafish, and the worm *C. elegans* are used to study some aspects of the nervous system functions and are considered appealing as they can be genetically manipulated very easily. However, it should be noted that the brain of these species is extremely different compared to human or mouse as they contain only 135,000 neurons in *drosophila*, 10 millions in zebrafish and only 302 in *C.elegans* (as a comparison, the mouse brain has about 100 millions neurons and a similar number of non-neuronal cells, whereas the rat has more than 200 millions neurons). Therefore, the number of connections between cells and the structure of the brain is very different in these species when compared to rodents and humans, and this is due to the distinct set of behaviours that the brain must control in non mammalian species. Importantly, our research is based on the discovery of new genes and new gene functions that may play a fundamental role in regulating the mammalian brain in health in and disease. In the past decade, extensive sequencing of most genomes has shown that many genes expressed in rodents and humans are not found in lower species. Thus it would be impossible for us to investigate for example, the mechanisms

that regulate the formation of the brain and the cause of neurodegenerative and psychiatric disorders observed in the adults using species that are so genetically distant from humans.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The Biological Services at the institution run a comprehensive health-monitoring programme. Animal health and welfare records are maintained to include any adverse effects that may develop, particularly in genetically altered and spontaneous mutant strains. Signs consistently associated with a particular strain will be recorded on the respective “information sheet” in the breeding area (see above). The animals will be maintained under conditions where their health status can be protected as far as is reasonably practicable.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The project holder will follow published guidelines issued by Laboratory Animal Science Association (LASA), (National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and Royal Society for the Prevention of Cruelty to Animals (RSPCA).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

All associated staff in the lab has extensive training in all the regulated procedures in this licence, and will use their experience to ensure suffering is minimal. The staff will attend all recommended courses organized by the Biological Services at the institution to maintain best practice and to keep our knowledge of animal welfare up to date with the Home Office guidelines.

Explain the choice of species and the related life stages

The laboratory uses rodents (mice and rats), as they provide an ideal model system to study the brain in both normal conditions and in disease. Rats and mice share many of the anatomical and physiological features with humans and represents faithful model systems to study nerve development, maintenance and regeneration in health and disease. The aim of my research is to study the mechanisms underlying brain development and disease and the use of rodents will allow me to meet my scientific objectives and accrue benefit.

Home Office

NON-TECHNICAL SUMMARY

63. Evaluation of fish vaccine potency and interaction with other disease control factors

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
rainbow trout	juvenile
Zebra fish	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To evaluate potency of established fish vaccines against vibriosis, photobacteriosis and enteric redmouth (ERM), as well as to discover, develop and test methods for prevention of fish diseases important to the aquaculture industry.

A retrospective assessment of these aims will be due by 24 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fish disease is the main constraint on the expansion of aquaculture. Since wild fish production is not increasing, but human population is, aquaculture must increase to maintain global food security in the coming decades. Prevention and control of fish diseases are critical to allowing the aquaculture expansion necessary to feed the human population in future. Development of disease prevention measures such as vaccines and in-feed immunostimulants reduces the need for chemical and antibiotic treatments, which in turn reduces release of these harmful compounds to the environment. They also reduce disease incidence in farm facilities, so reducing the opportunity for transfer to wild fish populations. These effects aid protection of the natural environment.

What outputs do you think you will see at the end of this project?

It is anticipated that 50 - 100 batches of vaccines will be released to market as a result of work under this licence application

New information: increased insight into virulence and control of Vibriosis, which will be disseminated through peer-review publications. Refinement of vaccination procedures through improvement of oral vaccine efficacy and expansion of orally administered vaccines.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Aquaculture industry will benefit immediately vaccines are successfully tested (potentially within 2 months of start of project).

European consumers will benefit from availability of food fish supply.

Research community will benefit from new information disseminated through peer reviewed publications.

How will you maximise the outputs of your work?

Dissemination of new information through publications, meetings of learned societies and local knowledge exchange groups

Publication of evaluation of testing regimes and changes in characteristics of pathogenic bacteria

Collaboration with industry partners and Innovation Centres to maximise the communication and uptake of new findings.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A typical animal will be immunized (one of three routes - injection; immersion in vaccine solution or administration of vaccine in food), before a holding period (4 weeks) to allow immunity to develop. After this, the fish would be injected in the abdominal cavity with 0.1 ml of bacterial pathogen. The fish would then be held for 3 weeks to check for development of disease (if the vaccine is effective, little or no disease signs should be evident; sham vaccinated controls will develop disease). At the end of this period, all remaining fish would be euthenised. Thus, most fish would experience 2 procedures (immunization and pathogen injection).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Impacts as a result of disease development can include abnormal behaviour over a period of 0.5 - 1.5 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Severe - 33 %

Moderate - 5 %

Mild - 62 %

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 24 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Potency testing of fish vaccines requires in vivo testing as stipulated in the European Pharmacopoeia 10th edn. (2019), overseen in the UK by the Veterinary Medicines Directorate. At present no alternatives are available, as fish immunity is largely dependent on cellular immunity, which is multifacetted and for which there is no available proxy or in vitro assay (unlike antibody production which can be used in mammals over a short timescale). Antibodies are produced in fish, but often beyond the timescale required for vaccine testing (1-3 months). Longer potency tests are not practical owing to constraints on vaccine shelf-life and the likelihood of natural fish mortality over longer timescales, which make a shorter, whole animal-based test most appropriate.

Investigating interaction of feed additives and vaccines with the immune system requires animal use, as the physiological systems involved are too complex to replicate in vitro at present.

What was your strategy for searching for non-animal alternatives?

Isolated organ culture (such as gills) and cell culture, which may provide alternatives to in vivo testing in the future, but at present are insufficiently well developed or characterised to replicate the complex interactions contributing to an efective immune response in vivo. Consequently, such methods do not yet reach the level of rigour necessary for regulatory approvals.

Consequently, vaccine potency testing needs to continue using whole animal tests at the moment, as this is the only way currently available of encapsulating the complex interactions of the vaccine with the fish immune system and the consequent development of effective immunity.

Why were they not suitable?

Isolated organs cannot be kept viable long enough to investigate disease effect, and do not replicate interactions between organ systems.

Cell cultures only represent single cell types and cannot replicate organ system interactions as seen in whole animals.

A retrospective assessment of replacement will be due by 24 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Trout numbers estimated from numbers used in previous years' testing - group sizes (20-30 per group; 5-10 for controls) specified in regulatory protocols (European Pharmacopoeia, (2019) 10th edn.).

Salmon - power analysis indicates sample sizes of 16-20 per group for effect sizes of ~10-15% (e.g. cell counts)

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Online tools, including power analysis calculator and NC3Rs experimental design assistant. Vaccine work determined by regulatory requirements

What other measures apart from good experimental design will you use to minimise numbers?

Use of pilot studies to explore effect sizes and to ensure appropriate disease challenge doses. Sharing of tissue samples across projects to maximise analysis and output. Sharing control groups between batches to minimise control (unvaccinated) numbers.

A retrospective assessment of reduction will be due by 24 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In studying disease, it is necessary to induce disease. The methods are aimed at combating disease, so the treatments (vaccines, additives) should reduce suffering and distress. In order to evaluate these treatments effectively it is necessary to have untreated controls which develop disease. These are monitored to allow as rapid intervention as possible with onset of disease symptoms, to reduce suffering as much as possible.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Vaccine testing regulations specify the stage and size of animals to be used, which cannot be varied. For characterisation of disease and analysis of factors affecting this, the interplay of organ systems in vivo is crucial to understanding the disease, and using less sentient individuals would not allow relevant life stages to be used (in the case of more immature stages) or long enough maintenence to see disease progression (in the case of anaesthetised animals).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The intended end-point is morbidity (development of disease signs) with intervention and euthenasia before death. Onset of disease is usually recognised by altered equilibrium (uneven swimming) and discoloration of the skin. When these signs are observed, fish will be euthenised using a Schedule 1

method. To achieve the intended end-point, increased monitoring (3 to 6 hours, depending on the pathogen; more frequent monitoring risks accelerating disease progression owing to increased disturbance of the animals) will be performed during critical stages of disease development (usually 2 - 6 days post infection). Observed decrease in morbidity rate will be used to evaluate when increased monitoring can be relaxed, on a test-by-test basis, given inherent variability of the interaction between individual pathogen cultures and different stocks of fish.

Anaesthesia (pain management) will be used to avoid additional stress or injury during handling and injection.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

NC3Rs guidance

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Regular survey of relevant peer review journals.

Regular review of the NC3Rs website.

6 monthly meeting with NACWO on fish welfare issues and implementation plans.

Explain the choice ofspecies and the related life stages

For vaccine testing, the types and life stages used are specified in regulatory protocols as being the most relevant to commercial application of the vaccines.

For basic research the types and sizes of animals used are determined by relevance to future application of the findings.

A retrospective assessment of refinement will be due by 24 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

64. Evolutionary ecology of malaria parasites

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, embryo, juvenile, pregnant, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To understand the strategies that parasites have evolved to cope with the challenges of their lifestyle and to exploit the opportunities it brings. To identify the evolutionary limits on how parasites maximize their fitness, in terms of their ability to survive in the host they infect and to transmit between hosts. Our work involves assessing how parasites interact with each other and respond to the changing environments they experience inside hosts and the vectors, such as mosquitoes, that transmit them.

A retrospective assessment of these aims will be due by 01 November 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Malaria parasites and their Apicomplexan relatives are responsible for some of the most serious diseases of humans (e.g., malaria), livestock (e.g., coccidiosis), companion animals (e.g., toxoplasmosis) and wildlife (e.g., avian malaria). For example, almost half the world’s population are at risk from malaria; it kills approx. half a million people each year, mostly children under 5, and several hundred million cases occur annually. Resistance to all antimalarial drugs has evolved and no vaccine has been licensed for widespread use. New interventions are needed as well as insight into strategies that make the best use of existing tools. Therefore, our research and results are relevant to applied medical and veterinary science.

More broadly, some of the biggest problems facing disease control are a consequence of evolution. Explaining the evolutionary trajectories of hosts and parasites and how they interact to determine infection outcomes and patterns of spread are challenging but central to developing sustainable medical and veterinary interventions. Demonstrating that evolutionary theory can explain the traits, behaviours and strategies involved in host-parasite-vector interactions will inform the development of new drugs and vaccines as well as deployment policies
.

What outputs do you think you will see at the end of this project?

Our research focuses on malaria (Plasmodium) parasites, which cause some of the most serious infectious diseases of humans, livestock, companion animals and wildlife all over the world. These parasites remain ahead of biomedical science, despite extensive research into their immunology, cell and molecular biology. Few new treatments or control measures have been discovered in the last decade. A different approach, using a whole-organism (evolutionary) perspective to understand how parasites behave has been neglected but is increasingly being recognised as central to advance

disease control. Using an evolutionary approach provides a unique opportunity to understand parasite behaviours at all levels - from genes, to behaviour, to population patterns.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The scientific community benefits from my expertise in the evolution and ecology of parasites, which is internationally recognized. This is demonstrated by continuous applications from British, European, and North American candidates to join the lab, and >10 invitations per year to give seminars or keynote talks at conferences and in departments focused on evolutionary biology and ecology, or medicine and parasitology, or chronobiology, and by the >20 publications stemming from work on the current PPL (despite maternity leave and part time working).

My lab is also very active in public engagement. Our focus is developing and deploying activities for children of all ages, including a dedicated grant to carry out school visits and regular (3x year) stands at open days and science festivals.

Malaria parasites have high medical importance and the development of new control strategies requires a better understanding of their evolutionary biology. We will contribute to this understanding and the development of control/treatment strategies.

How will you maximise the outputs of your work?

My lab collaborates widely (e.g. with researchers in the UK, North America, Canada, Saudi Arabia, several European countries). We publish findings as soon as possible in Open Access journals and also post to pre-print servers as soon as manuscripts are ready for submission. Our publications are often the topic of articles in the lay press and attract diverse media attention. In addition, I am integrating evolutionary thinking into parasitology and medicine through international interdisciplinary consortia and symposia that set the directions for emerging topics in evolutionary parasitology and chronobiology.

Species and numbers of animals expected to be used

- Mice: Total = 10000 [P1 = 4000; P2 = 3000; P3 = 2000; P4 = 1000]

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Our experiments require monitoring parasites and hosts during infections and examining parasite behaviours, physiology and genetics. Infected animals are monitored at least once a day (but often round-the-clock occurs) and in some experiments, they do not show any clinical symptoms. When infections need to be monitored throughout their natural course, animals experience weight loss and anaemia, and almost all recover fully. We euthanize any that are at risk of not making a full recovery. We take small blood samples to collect our data and to monitor the health of animals. Mosquitoes feed on mice that have been anaesthetised and they only take very small quantities of blood. All animals are euthanized at the end of experiments.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Infected mice in some experiments will not show many clinical symptoms beyond mild piloerection.

In experiments where parasites are monitored throughout infections, mice can become inactive and anorexic for 2-4 days, experiencing weight loss and anaemia at the peak of infections. After this time, >90% mice control their infections and fully recover.

Mice are sampled daily from their tail vein when <20ul blood is usually collected for red blood cell counts and quantification of parasite stages and to monitor the health of animals.

For mosquito blood feeds, mice are lightly anaesthetised and exposure only lasts for 30-60 minutes.

Parasites and most drugs are administered using IP or IV injections. ID tags are administered subcutaneously.

All mice are under general anaesthetic when large numbers of parasites are collected.

No infection results from using mice to maintain the mosquito colony and anaesthesia is always given.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild 57.5%, includes animals used for:

- Maintaining mosquito colony

- Short term infections

- Generating parasite material for culture/preservation

- Behavioural experiments using uninfected mice

- Breeding colony for GAstrain

Moderate 30%, includes animals used for:

- Infections terminated at the end of the growth phase of infections, before severe anaemia/anorexia occur

- Entire-infection experiments with avirulent parasite strains/species

- Experiments in which interventions (e.g. antimalarials) are used that reduce parasite replication

Severe 12.5%, includes animals used for:

- Entire-infection experiments with virulent parasite strains/species

- Experiments with novel combinations of host/parasite strains or perturbations

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 01 November 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To understand how parasites and hosts interact and their co-evolution, both parties are required. Ethically, it is not appropriate to use human malaria. Therefore, experiments are only possible with animal models. In vitro methods cannot capture the complexity and biological context of real infections.

What was your strategy for searching for non-animal alternatives?

We employ mathematical modeling approaches where possible to form and refine hypotheses but ultimately, we need to use animals to formally test our scientific hypotheses.

We continually harness new technical advances from the fields of evolutionary, molecular and cell biology and immunology to reduce numbers. We have been instrumental in developing some of the in vitro methods we use. We can now reliably culture several parasite strains throughout a single development cycle (24 hours), but longer-term culture eludes us because it has proved impossible to achieve sufficient re-invasion of RBC of the next developmental cycle. Other developments include the discovery that replenishing media post fertilization significantly enhances yields of parasite offspring.

We also use the most powerful statistical analysis methods available for data analysis as this maximises the amount and quality of information obtained from each animal. We use our data to answer multiple research questions, reducing the need for multiple experiments.

Parasites are stored in liquid nitrogen, reducing the number of animals needed to maintain them.

Why were they not suitable?

In vitro methods cannot be used for the entire parasite lifecycle. Neither culture or mathematical models can capture the complexity and ecological context of real infections.

A retrospective assessment of replacement will be due by 01 November 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are estimated based on our current usage, and the anticipated number of researchers involved.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

With the substantial effort and expense of the experiments, developments to improve science quality and reduce animal usage are simultaneously achieved. For example, we:

• Have developed in vitro methods to estimate the mating success of several malaria parasite species, reducing the need to blood-feed mosquitoes on infected animals.

• Have developed in vitro methods to culture asexual parasites throughout a cell cycle. This enables us to produce large numbers of mature parasites from fewer mice and to examine cell cycle transitions.

• Have established membrane feeding for mosquitoes, reducing the need to expose animals to mosquito bites.

• Use data from each experiment up to answer multiple research questions, reducing the need for multiple experiments.

• Parasites are stored in liquid nitrogen, which saves continually maintaining them in mice and prevents virulence from increasing.

Compared to the current PPL, we are able to reduce animal numbers by >40%, and entirely remove 1 species.

What other measures apart from good experimental design will you use to minimise numbers?

We primarily use the excess generated from breeding colonies to maintain our mosquito colony, minimising the number of animals specifically bred for this purpose.

We use both male and female mice in our experiments, and do not restrict usage to a narrow age range. This ensures no excess animals are produced by our breeding colony and minimises the excess in the colonies of the suppliers of the other REDACTED we use.

We closely monitor the production of our mouse breeding colony, moving animals from breeding to experiments efficiently and contracting the colony whenever possible. Likewise, we run a skeleton mosquito colony whenever possible which reduces animal usage by 50% compared to that required to produce mosquitoes for experiments.

A retrospective assessment of reduction will be due by 01 November 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Our research involves malaria parasites that infect rodents in nature. Our experiments require monitoring parasites and hosts during infections and examining host and parasite behaviours, physiology and genetics. We infect animals either from mosquito bites or by injecting parasites. We then take small blood samples to collect our data and to monitor the health of animals throughout infections. Some animals are not sampled but are given RFID tags to monitor their activity patterns and body temperature without disturbance. When large numbers of parasites are collected, animals are under terminal anaesthesia. Our procedures for inducing perturbations and sampling are generally expected to cause no more than transient discomfort and/or slight changes in behavior.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

By definition, the study of the ecology of infections requires allowing infections to play out in as realistic a context as possible. Infections are usually studied for between 5-15 days and so, animals cannot be under sedation for so long.

Malaria parasites only infect terrestrial vertebrates and so, less sentient species are not suitable hosts.

Infection of juvenile animals would result in far more severe infections and the smaller blood volume of juveniles would reduce the amount of information available from samples.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Over the last 15 years our work has been refined. For example, the majority of animals will be euthanized before showing clinical disease symptoms, less virulent parasite strains feature more frequently in our experiments, we have improved the ways that we administer drugs and blood sample infected animals, and we avoid single-housing mice so they can benefit from huddling and social interactions.

We are continually refining our endpoints as we gain more experience with different host-parasite strain/species combinations and experimental perturbations. Infected animals are monitored at least daily and often around-the-clock during symptomatic periods, so that measures can be taken to facilitate their recovery. If animals show signs of sickness they are given supportive nursing measures (e.g. mash, transgel). We are also investigating whether surface body temperature is an informative endpoint and whether gentle warmth from heatpads is another useful supportive nursing measure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Local guidelines for blood sampling.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The REDACTED communicates advances and development opportunities regularly. During the current PPL we have implemented procedures to communicate more closely with animal care technicians to inform the monitoring of animals and how to make interventions more effective. We will continue to foster these lines of communication.

Explain the choice ofspecies and the related life stages

Mice are used as hosts for experimental malaria infections to study infection dynamics, parasite phenotypes (e.g. developmental rhythms), and host responses to infection. Mice are also used to maintain a colony of mosquitoes for studying parasite transmission and maintaining the wild type phenotype of parasite isolates.

To understand how parasites and hosts interact, both parties are required. The aims cannot be met using field-based research with human malaria infections. For ethical reasons, it is not possible to have the necessary untreated control groups, provide sub-curative drug treatment, or prolong infections for research purposes. We use in vitro methods where possible (for some estimates of transmission potential, generation of parasites for transfection, and some cell cycle studies), but in vitro methods cannot capture the complexity and biological context of real infections.

Rodent malarias are an excellent model for human malarias and have been successfully used in lab experiments for over 50years. Much of what is known about the genetics, cell and molecular biology of malaria parasites, the evolution of anti-malarial drug resistance, and immune defence against malaria come from the extensive body of work using rodent malaria model systems. This has been achieved thanks to the uniquely well-characterized biology (e.g. immunity and physiology) of lab mice. Murine immune responses and their circadian clocks are well defined and the technology enabling sophisticated manipulations of the haematopoietic and immune system is highly developed.

A retrospective assessment of refinement will be due by 01 November 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

65. Expression of cardiac mutations in Zebra Fish

Project duration

5 years 0 months

Project purpose

None selected

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To determine the role of specific gene mutations found in the Egyptian population on heart function

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Understanding the genetic basis of heart failure to improve detection and treatment of this condition

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use up to 25,000 fish over a 5 year period

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Some fish may develop impaired cardiac function, of a mild to moderate severity. At the end of the end of the experiments the fish will be euthanised.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Cardiac function can only partially be modelled using cell culture models. Expression of gene mutations in isolated cells and assessment of the function of the cells would not give a full assessment of the phenotype and function of a whole organ, Such experiments cannot substitute research in animals.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We shall only use a minimum number of animals in our experiments. Breeding strategies are performed by qualified personnel and aimed to avoid unnecessary animal generation. Results will be published according to the ARRIVE Guidelines.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The zebrafish model is an excellent model organism, which due to its transparency of the embryo, its high fecundity, its rapid development and the availability of sophisticated genetic tools provides vast opportunities to model the genetic basis of cardiovascular and skeletal muscle disease. We will be using the zebrafish to introduce mutations found in the Egyptian population to ascertain the functional impact these mutations have on the heart. The phenotypes often become first apparent during embryonic development and thus suffering of the animals will be minimised due to the short period until the cardiovascular and muscle pathologies become apparent. Any fish undergoing treatments will be monitored for infection, poor healing or altered schooling behaviour and killed using a humane method to minimise suffering if necessary.

NON-TECHNICAL SUMMARY

66. Fish behaviour and welfare

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult
Teleost fishes	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To understand how fish behaviour and welfare is influenced by environmental factors in both artificial (e.g. aquaculture, ornamental fish trade) and natural contexts.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to determine the best ways to protect fish welfare under commercial settings and to protect natural populations against environmental change, there is a need to understand how changes in their environment affect fish behaviour and physiology (Objective 1 of this project). For example, changes in water quality during transport of fishes for aquaculture can lead to increased stress levels and decreased welfare. Within the natural environment, low levels of contaminants can cause subtle changes in fish behaviour that can have serious implications at the population level if they interfere with the ability of fishes to catch prey or avoid predation. In addition, we need to understand how environmental changes affect the early life stages of fishes; small effects at these sensitive stages can have knock-on effects throughout the life cycle. It is also becoming clear that the environmental conditions experienced by parents can affect the behaviour and welfare of subsequent offspring. Thus this project aims to further our understanding of how fish behaviour and welfare is influenced by environmental factors. Traditionally, monitoring the way fishes respond to environmental change has utilised invasive or terminal sampling; therefore alongside this fundamental knowledge there is a need to develop robust non-invasive, or minimally-invasive, measures of stress in fishes (Objective 2 of this project).
The benefits of this research are discussed in detail below.

What outputs do you think you will see at the end of this project?

Outputs from this project will include new information on the factors which affect physiology and behaviour of fishes, crucial for determining the best ways to protect their welfare and protecting natural populations. New information will be made available primarily through peer-reviewed publications, industry reports, scientific conferences and public presentations.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

From a welfare perspective, these outputs will be of benefit for the welfare of fishes held both within the ornamental trade and aquaculture and can be used by these industries to improve best practice. The ornamental trade represents a multi-million pound industry where millions of fishes are transported and held as pets. Ornamental ‘pet’ fishes (e.g. guppies, zebrafish, neon tetras) lead very different lives to

fishes such as salmon and trout held in aquaculture, and yet much of our understanding of ornamental fish requirements (e.g. diet, water quality), is based on information available for large aquaculture fishes. Very little research has looked at nutrition, husbandry, stocking and transport of ornamental fishes in terms of their welfare. This project looks at ways of improving fish welfare by increasing our understanding of fish behaviour and physiology and how non-invasive methods can be applied to assess fish welfare (e.g. observing behaviour, measuring hormones released into the water and taking mucus samples). Within the food-fish aquaculture industry there is also an increasing desire to improve welfare through the use of more behavioural and non-invasive monitoring. Therefore, this project has the potential to improve fish welfare across a wide range of settings.

Understanding the interactions between behaviour and physiology in fishes is also important for conserving natural populations. In making decisions about protecting our natural environment, often shifts in fish behaviour induced by environmental change have been over-looked or deemed insignificant. Yet small, seemingly unimportant, changes in behaviour can have serious implications for a population if they limit a fish's ability to feed or to escape predation. In this context it is also important to develop non-invasive measures of fish health to allow monitoring of natural populations with minimal disruption.

How will you maximise the outputs of your work?

Our research group works closely with industry (for example with wholesalers and retailers of ornamental fishes and food fish aquaculture companies) and therefore can ensure that results are disseminated in a timely fashion, often considerably prior to publication in the peer-reviewed literature. Unsuccessful approaches are also discussed with our industrial partners so that refinement of approaches, and consideration of ‘non-significant’ effects occurs.

Species and numbers of animals expected to be used

- Other fish: No answer provided
- Zebra fish: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, fishes will first be exposed to a change in environment which may be procedural as it has the potential to cause an adverse effect (e.g. provision of a diet with a lower than normal level of protein, experience of a transport stress) or non-procedural (e.g. addition of environmental enrichment).

Following this fishes will be monitored for changes in behaviour and physiology. Behavioural measurements may include: ability to perform in a maze environment (procedural), to compete/socially interact with other individuals (procedural), and other non-procedural measures including activity, feeding, interaction with enrichment. Physiological measurements could include: mucus sampling (procedural), blood sampling (procedural), respirometry and/or swimming ability (procedural) and other non-procedural measures including water-borne hormone levels, body colouration.

At the end of an experiment, fishes may be released from the act if they are not suffering, or likely to suffer, any adverse effects of regulated procedures. This will be determined by a veterinary surgeon or a competent person using criteria agreed with the named veterinary surgeon in line with standard project licence conditions.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Potential (rather than expected) adverse effects from this project could include adverse changes in behaviour (e.g. lack of feeding, loss of equilibrium/swimming ability, laboured respiration) and skin abrasions. Any fish showing signs of these adverse changes will be immediately removed from the experiment and euthanised by a Schedule 1 method if recovery is unlikely, thus the duration of these effects would be minimal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

With the exception of fishes exposed to aquatic toxicants (5%) the expected severity of procedures is mild. The work involves exposing fishes to mild stresses that they would naturally encounter in the wild or in an artificial environment (e.g. in aquaculture or as pets). For those fishes exposed to aquatic toxicants, very low levels of contaminants are used to look for subtle changes in behaviour and physiology, therefore it is unlikely that adverse effects will be seen. However, due to the nature of these experiments they are classified as moderate. It is anticipated that the majority (95%) of fishes from this project that have only been exposed to mild stresses will be released from the act either to stock or re-homed as companion animals where possible.

What will happen to the animals at the end of the study?

- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently there are no *in vitro* or computer-based alternatives for this type of research. We have used the www.frame.org.uk website and associated links to look for alternatives and can find none documented but will continue to monitor both this website and the scientific literature to look for alternatives. Where possible we use non-invasive measures (e.g. behavioural observations of fishes during commercial practice) to address our objectives.

What was your strategy for searching for non-animal alternatives?

There are no *in vitro* or computer-based alternatives for this type of research.

Why were they not suitable?

There are no *in vitro* or computer-based alternatives for this type of research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For all experiments associated with this project, experimental design is based on statistical planning. Careful consideration of existing literature, including our own unpublished and published data is used to inform experimental design. Tank replication has also been considered as there may be variability caused by different social groups within tanks. This allows us to use the minimum number of fishes while ensuring statistical robustness.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Consultation with statisticians (in-house and/or industry based) occurs both during experimental design and of the final experimental design prior to the start of experiments. For research involving industrial partners, additional statistician input to data analysis approaches allows us to continuously refine our experimental designs and to minimise the number of fishes being used.

What other measures apart from good experimental design will you use to minimise numbers?

For work with embryos, many measurements can be made prior to hatch with only ~25% of embryos used being raised to first feeding and becoming licenced fishes. Therefore, some partial replacement occurs. Additionally, we continue to develop non-invasive methods of measuring fish welfare, and to

work with industry to monitor and refine fish welfare under existing commercial practice, thus reducing the need for experimental research on fishes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The species used in this project will be typical teleost fishes (mainly freshwater) that are either considered to be model species for fish behaviour and physiology (e.g. zebrafish and trout) or are important commercial species (both for food-fish aquaculture and the ornamental trade). These will include species from the families Goodeidae and Cichlidae among others.

For each objective and experiment, appropriate fish species will be chosen based on sound scientific reasoning. Many of the research questions posed in this proposal are related to ornamental fish species and in considering social behaviours and responses to husbandry stressors it will be necessary to consider species with a range of life histories, such as live-bearers and egg-laying species.

In the protocols, different methods of carrying out a procedure are given where different species may require different procedures. Where a choice of methods exists, the mildest method to achieve the stated objectives will be chosen.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Our previous work has refined the use of techniques to assess the impact of environmental change on very early life stages, thus reducing the need to raise embryos beyond first feeding. We will continue to use these methods where they can appropriately address the objectives. However, to understand impacts of husbandry and environmental stressors on fish behaviour, it is not possible to use species that have been terminally anaesthetised or are less sentient.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Welfare costs associated with this project are expected to be mild. Fish health and welfare will be monitored on a daily basis by experienced staff (including the NACWO) including feeding behaviour,

swimming behaviour and overall condition of fishes. Water quality parameters are checked on a daily basis.

Protocols 2 and 3 (of 3) are mild and chosen for their sensitivity in detecting differences in physiology and behaviour. Protocol 1 is classed as moderate due to the potential exposure to aquatic toxicants (N.B. this is an optional component of this protocol) but only mild effects of the toxicant on behaviour and physiology are expected due to the aim of the objectives being to understand the effects of sub-lethal doses. There is an extensive body of literature documenting the effects of aquatic contaminants on fishes, particularly with regard to lethal and acutely toxic concentrations. Here the effects of chronic exposure (ideally at the lowest observable effect concentrations) are of interest and suitable concentrations will be calculated by carefully scaling down concentrations known to be acutely toxic. For all protocols, where a choice of methods exists, the mildest method to achieve the stated objectives will be chosen.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We use a variety of practice guidance to ensure refinement of experimental techniques. These include, but are not limited to:

Guidelines for the treatment of animals in behavioural research and teaching (ASAB, 2012, 2018).

Ethical justification for the use and treatment of fishes in research (Journal of Fish Biology, 2006; Metcalfe & Craig, 2011).

Guidelines for the use of fishes in research (AFS, 2014).

ARRIVE (Animal Research: Reporting of In Vivo Experiments) Guidelines (Kilkenny et al., 2010).

PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) Guidelines (Smith et al., 2018).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We regularly consider updates on the NC3Rs website and receive information through AWERB meetings and email communications. Both PI and students have previously and will continue to attend LASA, RSPCA and NC3R events, including those specifically focused on fish research. Where advances in the 3Rs, particularly with regards to refinement of working with fishes occur, we look to implement these within our work.

Explain the choice ofspecies and the related life stages

The fish species used in this project will be mainly freshwater fish species that are either considered to be model species for fish behaviour and physiology (e.g. zebrafish and trout) or are important commercial fish species (both for food-fish aquaculture and the ornamental fish trade). It is important to understand the response of all life stages of fishes to husbandry practices and environmental change;

indeed we know that husbandry conditions of female fishes can affect subsequent behaviour of their offspring. Therefore, all life stages will be considered.

Home Office

NON-TECHNICAL SUMMARY

67. Fish behaviour modification through gear changes

Project duration

5 years 0 months

Project purpose

None selected

Key words

Fish Behaviour, Selectivity, Artificial Light, Gear Modifications

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of the project is to investigate how fish behaviour can be used to make commercial fishing gears more selective through controlled tank experiments. Selectivity of fishing gear is

particularly important in fisheries with a mix of species such as the North Sea. Therefore it is vital fishermen are selective in what they catch and only retain fish of the correct species and size, particularly with the landing obligation now fully implemented meaning fishing vessels can no longer discard unwanted catch back to the sea but must land everything that they catch. A variety of gear components with a range of modifications made to them, such as visual stimulus's like artificial light, different coloured twine etc., will be positioned in the tank to simulate a commercial gear in a series of controlled tank experiments. This is to enable us to get an understanding of how fish will respond to the modifications to the gear and whether any behaviours identified could be utilised in encouraging escape and avoidance behaviour during commercial fishing to improve selectivity. The first gear modification we will be investigating is the use of lights (either laser powered fibre optic cables or LEDs) to encourage or deter fish to pass through the meshes of the gear. If differences in how certain species behave towards the lights or any of the gear modifications tested are found we could potentially use this to increase the selectivity of the gear and target particular species while allowing unwanted species to escape by re-directing them to an escape hole in a different section of the gear. Gear modifications could also potentially encourage the escape of undersized fish while retaining the larger marketable catch by making escape routes more visible with lights and this aspect of the gear modifications will also be investigated. Further work will observe the effects of other gear modifications such as sound, different coloured twine etc. on a range of commercially important fish species.

A retrospective assessment of these aims will be due by 05 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The potential benefits of this work are that it may assist commercial fishing vessels to fish in a more sustainable and environmentally friendly way. It could potentially help to reduce the capture of undersized fish or avoid the capture of unwanted species which would nicely compliment the landing obligation scheme which was fully implemented as of 2019. It could also exploit species specific behaviours to enhance the selectivity of trawls which is particularly useful in a mixed fishery as the North Sea.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will be using a range of marine fish throughout the work.
Approximatley 1500 over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The expected adverse effects will come from the investigations into escape behaviours of the fish when chased or encouraged towards the gear component which may cause moderate stress. During the escape behaviour work a single experiment will consist of the fish only having to swim one length of the seven metre length of the tank two times a day. A set number of trials will be decided through discussions with a statistical consultant and adequate respite between trials will be given to counteract the moderate stress for the short time period experienced by the fish during a single trial. Certain trials will use laser pods to power long lengths of fibre optic cables, the lasers used are class 3B and can be harmful to the naked eye when viewed. All suitable precautions are in place to ensure both personnel working with the lasers and fish are not at risk of viewing the laser beam and the only part of the equipment the fish will see is the fibre optic cable. This includes the set-up of the laser pods out with the experimental tank and locking the fibre optic cable to the laser pod prior to power being supplied means the likely-hood of ever viewing the laser beam is highly unlikely so risk is minimal.

A retrospective assessment of these predicted harms will be due by 05 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

As we will be observing fish behaviour we have to use actual fish to learn what their responses will be to the gear modifications. A computer model would require prior knowledge of how the fish will react and is therefore not currently an option for our study but we will use the data to develop one in the long term if possible.

A retrospective assessment of replacement will be due by 05 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

To minimise the number of fish used throughout our experiments we will carefully plan our experimental design to ensure it is statistically valid with assistance from our statistical consultant. We will ensure we have enough fish to make reasonable conclusions from our work and have enough power to detect any changes when carrying out the statistical analysis of the results. We will also be carrying out small scale observational studies to understand a range of marine fish species reactions to light or sound etc. which will provide us with an insight into how to proceed with the full scale trials involving the gear components towed or moved within the tank.

A retrospective assessment of reduction will be due by 05 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We will be using marine species of commercial interest to help us meet the aims and objectives of this project. It is crucial we use these species because understanding their behaviour is key to the success of this work and to potentially improving the sustainability of these commercially important fish stocks. We need to replicate the stresses and pressures exerted on the fish that they experience during the commercial capture process to enable us to draw reasonable conclusions from the work. By starting with small scale observational trials (~6-8 fish) we will optimise the design of the study to achieve our aims in a timely manner with the least amount of animals being used as possible. We will be using voluntary behaviours or the use of a food reward which is positive non-painful encouragement for the small scale trials However it is known that during commercial fishing fish are stressed and under pressure to make a decision whether to attempt to escape through the gear, hence we will need to exert some level of stress upon the fish to mimic this effect to evoke a reaction in our fish when we proceed to the full scale trials (10+ fish). All fish will be monitored throughout the process and limited to a number of times where they will be used within an experiment with adequate respite in-between.

A retrospective assessment of refinement will be due by 05 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

68. Gene Therapy For Lung, Liver and Other Disorders

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To evaluate the efficiency, duration and efficacy of transgene expression mediated by a variety of gene transfer and gene editing approaches for the treatment of a range of lung, metabolic and systemic diseases.

A retrospective assessment of these aims will be due by 07 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The targeted human diseases are associated with high mortality and/or a high burden of care (daily physiotherapy sessions for certain lung diseases, frequent injections for other diseases) and considerable costs to the NHS (ranging between £15K and £500K per patient). A potent gene therapy for any of these diseases will provide a significant improvement in the quality of life of affected individuals and a reduction in NHS costs.

What outputs do you think you will see at the end of this project?

We anticipate publishing multiple scientific publications as a result of the studies performed under this PPL.

It is hoped that as a result of the studies performed under this PPL, new drugs will eventually become available to treat these and related disease. A major step in making a new drug available, is performing clinical trials - where drugs are tested in small groups of human volunteers. The PPL applicant has a strong track record in translating ideas evaluated in animal studies to clinical trials in patients; and it is anticipated that further clinical trials will result from the studies conducted under this PPL.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short-term (simplistically - throughout the duration of the PPL), scientific publications will benefit scientists working both generally in gene therapy and specifically in the disease areas gene; and, medical doctors looking after patients with CF, chILD, A1AT-deficiency and WD.

In the medium term (simplistically - towards the end of the PPL and within a few years of its completion), conducting early-phase clinical trials tends not to benefit those generous enough to volunteer to be involved, as such studies often focus on drug safety rather than drug efficacy. However, volunteers on late-phase clinical trials (especially those involving long-acting gene therapy drugs) do often experience life-changing improvements in disease symptoms and/or progression.

In the long-term (simplistically - ongoing over next 10-20 years), making new drugs available to treat these disease will impact both the lives of those suffering from them and, the other individuals who support them (e.g. parents, partners, carers). It is anticipated that the developed drugs will ultimately decrease the frequency of engagement with the healthcare system and overall result in a decrease of healthcare costs - improving the health and welfare of society at large.

How will you maximise the outputs of your work?

The applicant is one of the founding members of both the REDACTED. Advances made under this PPL are immediately available to a group of ~50 scientists working on these projects in three UK Universities.
Information sharing happens via weekly telephone calls and an extensive schedule of review meetings. This pooling of scientific results and best practise Informing complimentary in vivo research at these sites conducted under separate PPLs.

Both of these scientific consortium have public engagement activities - host laboratory visits and encouraging outreach activities; including: public lectures (often to groups with an interest in specific diseases) and visits to primary and secondary schools.

Species and numbers of animals expected to be used

- Mice: 14,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The purpose of the PPL is to investigate the use of gene therapy and gene editing as potential new treatments for a range of serious genetic (CF, chILD, A1AT-deficiency, WD) disorders. Over the course of the PPL we are aiming to improve of our gene therapy approaches and thus are typically attempting to develop formulations with increased efficiency and duration of effect.

For the majority of studies we will administer novel gene therapy formulations (e.g. new mixtures of DNA and lipids and/or polymers or safe version of a common virus) to the nose and/or lungs of mice. In

a minority of studies, the same sorts of formulations are administered via an injection into to either a vein, the leg muscle, the peritoneum or under the skin. For most of these administration routes we anaesthetise the animal.

After gene therapy formulation delivery, we typically ask up to three research questions - how efficient was gene delivery, how long does gene expression last and can the gene delivery approach under evaluation correct a physiologic defect associated with one of our target disease. Thus, after gene delivery animals are allowed to recover for a variable period (days to months) after which time we assess transgene expression and/or a physiologic parameter. One common way we measure transgene expression is to use in vivo imaging - where, after anaesthesia, we inject a molecule that can be modified to emit light and then place the animals in a chamber under a highly sensitive camera. The amount of light emitted is a good measure of how efficient the gene therapy formulation under investigation was. In such studies we often measure light output several times with gaps (days to months) between measurements so as to understand the duration of gene expression.

The PPL allows considerable flexibility in the number of gene therapy formulation delivery events, the number of in vivo imaging events and the timing between them. However, the maximum number of general anaesthetic events allowed is ten - as typically one general anaesthetic events is needed for each gene delivery or in vivo imaging session, this also limits the combined number of such events to a maximum of ten.

To assess correction of a physiologic defect, we typically perform the measurements directly on terminally anaesthetised animals or kill the animals by a humane method and measure the physiologic defect in a sampled fluid or tissue using a laboratory test.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Gene therapy formulation delivery and/or in vivo imaging uses conventional administration routes and optionally general anaesthesia that in themselves induce no more than momentary pain or discomfort.

Administration via the nasal route can cause increased respiratory effort or cough but this resolves within a few minutes.

After gene therapy formulation delivery some animals can experience inflammatory responses to the gene therapy formulations - this typically results in "flu-like" symptoms that spontaneously resolve over 1-2 days. Symptoms include reduced movement and lack of grooming.

Several genetically altered animal models are expected to be used:

For the chosen CF, Sftpc, Abca3 an Serpina1 models appear healthy and thrive, however, there are some mild chronic respiratory issues - largely only measurable using sophisticated lung function tests that are conducted under terminal anaesthesia; the chronic nature of these issues dictates that the overall severity experience of such animals is moderate.

The chosen WD model appears healthy and thrives, however, there are some chronic mild liver issues and cognitive issues that relate to a chronic imbalance in copper levels; the chronic nature of these issues dictates that the overall severity experience of such animals is moderate.

For the chosen Sftpb model, there is a failure of the lungs to stay properly inflated - causing severe respiratory issues which if untreated can result in death.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity varies across the protocols to be used.

For **Protocol 1: Breeding And Maintenance Of GA Animals** (5000 animals), 20% are expected to experience no more than mild harm, while 80% are expected to experience moderate harm.

For **Protocol 2: Breeding And Maintenance Of Sftpb GA Animals** (2000 animals), 80% are anticipated to experience no more than mild harm, while 20% are anticipated to experience moderate harm.

For **Protocol 3: In Vivo Gene Delivery** (6000 animals), 80% are anticipated to experience no more than mild harm, while 20% are anticipated to experience moderate harm.

For **Protocol 4: Sftpb Rescue** (1000 animals), 25% are anticipated to experience no more than mild harm, 50% are anticipate to experience moderate harm , while 25% are anticipated to experience severe harm.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 07 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Where possible we use cell culture experiments to evaluate our gene therapy formulations that perform gene transfer or gene editing. However, no cell culture models currently available recreates all aspects of the interaction between the organs we are trying to treat and the gene therapy approaches we are using. In particular, these non animal approaches lack an immune system, which we and others have shown is crucial for understanding how gene therapy might work when tried in humans.

What was your strategy for searching for non-animal alternatives?

We have used portions of human and animal lung, muscle and liver to study gene therapy formulations in the laboratory. Some of these studies have been very helpful as they have allowed us to replace some animal studies we might otherwise have performed with laboratory studies.

One approach is culturing human lung cells in a way that ensure they have air on one side and liquid on the other. This is more similar to the human lung than traditional cell culture methods. We call this approach ALI - short for culturing cells a the air-liquid interface.

A second approach, called ex vivo lung perfusion (EVLP), uses excess donor human lungs that aren't suitable as transplant tissue. We culture these lungs using an oxygenated blood substitute.

A third approach, called precision cut lung slices (PCLS), allows excess human donor tissue or tissue we obtain from other animals to be cultured for long periods of time.

A fourth approach is the creation of mini lungs and mini livers in the test tube (these are often termed organoids) by sophisticated cell culture approaches.

Why were they not suitable?

ALI studies have been highly informative and we routinely use these prior to initiating animal studies.

EVLP studies have been difficult for two reasons: (i) the donor tissue is in high demand and thus we have not been able to perform many studies, and (ii) the tissue is difficult to keep alive.

The PCLS approach has proved useful - particularly at the end of EVLP experiments where we can use this approach to extend the duration of experiments in a way that is just not possible with EVLP itself.

The organoid approach is new to our laboratory but looks a very encouraging approach to reducing the numbers of animal studies we perform.

Crucially, none of these replacement options recreates all aspects of the interaction between the organs we are trying to treat and the gene therapy approaches we are using. In particular, these non animal approaches lack an immune system, which we and others have shown is crucial for understanding how gene therapy might work when tried in humans.

A retrospective assessment of replacement will be due by 07 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We routinely use power calculations to support group size selection. As we typically have large effect sizes, group sizes are typically 10 animals or fewer.

To estimate the numbers of animals used on this PPL we have used historical values from REDACTEDs, and an assessment of the number of studies needed to deliver the project plan to build a mathematical model. For example, one protocol on this PPL is used to support five scientific projects over five years, we anticipate performing 10 studies per year for each project and that each study will include three groups of eight animals. Combining these estimates, allows us to calculate that we may use 6000 animals on this protocol over the duration of the PPL. (5 projects x 5 years x 10 studies per year x 3 groups per study x 8 animals per group = 6000).

We have applied this approach to each of the protocols to make the overall estimate.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The key factor to controlling the number of animals used in this PPL is the group size selected for each study. In the worked example described above, reducing the group size from 10 to 8 results in a total reduction in the numbers of animals used in that protocol by 2,500, when applied to the entire PPL this reduces the estimate of animals used by ~3,500. Thus, the way we estimate group size is of considerable importance.

We use several tools to help estimate group size: G*Power is an open-source, free to use, statistical software package that we have used over many years to help estimate group sizes. More recently, we have also been using the NC3Rs' Experimental Design Assistant to confirm our experimental designs - this tool provides helpful experimental design suggestions (particularly regarding key experimental factors such as randomisation, group blocking and blinding) and a rigorous "sense check" that our design and analysis strategy is the most refined available.

In a limited number of studies, we are guided by appropriate health authorities (e.g the UK Medicines & Healthcare Products Regulatory Agency or the US Food & Drug Administration) to apply certain design principles. Such guidance is often more conservative than, for example, current NC3Rs expectations and tends to modestly increase numbers of animals used (e.g. for some studies minimum group sizes of 10 are stipulated).

What other measures apart from good experimental design will you use to minimise numbers?

Wherever possible we aim to be efficient in our studies - maximising the amount of scientific data we are able to generate from each in vivo study. For example when culling animals at the end of a study it is often possible to retain blood and tissues that can act as suitable control samples for unrelated

studies. Before embarking on complex multi-group studies we routinely use historical data and pilot studies to estimate group sizes.

When developing novel traditional chemical drugs, the use of computer modelling is proving to be a helpful tool to replace some animal studies; particularly replacing studies aimed at understanding how long the drug will last. Regrettably, due to the complex biological nature of the drugs we are developing (typically our drugs are a modified virus) and the extended duration of action (months/years rather than hours/days for chemical drugs) computer modelling is not currently a helpful tool to replace in vivo studies.

The PPL includes protocols to support breeding of specific disease-related animal models. Wherever possible, we use refined models that allow highly efficient homozygous breeding strategies to maximise the numbers of animals that may be used on other protocols within the PPL and minimise the breeding of animals that are unused.

A retrospective assessment of reduction will be due by 07 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mice for all of the studies in this PPL. We have considerable experience in the development of gene therapy formulations for use in human clinical trials and have found our mice studies to be highly informative.

During the planned studies we often deliver our gene therapy formulations to the lungs, muscle and blood stream of these mice. The delivery methods we use - sniffing droplets of liquid into the lungs, breathing in aerosols or injections are often used both in animal research and as ways of delivering drugs to humans. These delivery methods cause no more than brief discomfort.

The gene therapy formulations we deliver can cause mild to moderate flu-like symptoms. These symptoms last at most for a few days and the animals spontaneously recover from them.

For the majority of studies under this PPL we will use normal laboratory mice, However, we will also use several animal models of diseases which cause significant harm to humans. The diseases chosen

are genetic diseases that are typically passed on from unsuspecting parents to their children and which either cause an early death or significant health problems in later life.

One of these diseases is Cystic Fibrosis (CF) which causes an early death due to repeated lung infections. We will use an animal model of CF to test if our gene therapy formulations can correct the lung problems caused by CF. In REDACTEDs we have performed related studies - these have led to the development of a gene therapy formulation which has been shown in CF patients to halt lung decline. We anticipate that studies under this PPL will identify an even more potent gene therapy approach which will not only stop the disease getting any worse but will actually improve patient well-being.

Another one of the disease areas is called: Childhood Interstitial Lung Disease (chILD); a collection of disease syndromes that affects the alveoli (air sacs) of the lungs. We may use three animal models of chILD with deficiencies termed SP-B, SP-C or ABCA3. There is variation in the severity of chILD depending on which of these deficiencies a newborn human has inherited from its parents. The animal models of these syndromes mimic this well as the SP-C and ABCA3 models (like their human counterparts) have mild lung problems. We anticipate that studies under this PPL will identify a gene therapy approach which will halt and even improve the problems we see in SP-C/ABCA3 animals models and ultimately patients.

In contrast, the SP-B model is severely affected and dies due to respiratory failure - this is exactly what happens to newborn humans suffering from SP-B disease. Stopping this very severe disease is the aim of our SP-B studies. If we can stop the harm seen in the mouse model, we believe there is a good chance we can stop children who suffer from SP-B disease from dying. Currently there is no humane endpoint that the research community has been able to develop for this animal model - however, we will attempt to develop such endpoint during this PPL so that we and other scientists can cause less distress to such animals when trying to develop treatments for this tragic disease.

Another disease area we are researching is called A1AT-deficiency. Interestingly, A1AT is naturally made in the liver but is exported and makes it way to the lung where it helps to keep the lungs healthy after they suffer from infections. Humans who inherit a defective A1AT gene from their parents have both liver and lung problems. We will use gene therapy formulations than can make extra A1AT in either the lung, liver or muscle to attempt to stop A1AT disease problems. To test this approach we will use A1AT models that have mild lung and liver problems - which we anticipate we can halt with an effective gene therapy.

The final genetic disease area is Wilson's Disease (WD) which causes an imbalance of copper levels in the. Animal models of WD have mild liver and cognition problems which are also seen in the human condition. We will use gene therapy formulations than can alter copper transport by introducing genes into either the liver or muscle, in an attempt to stop WD problems.

Why are we developing treatments for all of these diseases at once? Historically in our laboratory we have developed a series of gene therapy formulations which have been really effective at introducing genes into the lungs of patients with CF. We anticipate that these formulations might also be effective in other lung disorders - hence we are now looking to develop better treatments not just for CF but also other lung diseases such as chILD, and A1AT-deficiency. We have also discovered in the laboratory that our gene therapy formulations are good at delivering genes to liver and muscle cells. Hence we

intend to try these delivery routes for some of the proposed diseases (especially A1AT-disease and WD).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have considerable experience developing gene therapy formulations for the treatment of CF and have translated findings from studies performed on REDACTEDs to multiple clinical trials which have involved hundreds of patients.

During development of these treatments we are continually challenged by both our scientific peers and the government agencies that control the development of new medicines to show that our gene therapy formulations work effectively. This is a pre-requisite for evaluating them in humans. We do use less-sentient and non-sentient model systems in the first stages of our drug development programme, but to-date, we have been unable to identify less sentient model systems than the mice described above that satisfy these demands.

One reason behind this inability to use less sentient systems is that the drugs we are developing are complex biological molecules - for example they frequently contain portions of viruses. Understanding how these complex biological molecules interact with a system (such as an animal) that has an intact immune system. Furthermore, it is highly desirable to understand the duration of any effects caused by our gene therapy formulations; such studies may take many months - such long-term studies cannot readily be achieved in anaesthetised animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The aspect of this PPL that is associated with most harm is the experimental use of the SP-B mouse model which if left untreated, dies due to respiratory failure - this is exactly what happens to newborn humans suffering from SP-B disease. Stopping this very severe disease is the aim of our SP-B studies. Currently there is no humane endpoint that the research community has been able to develop for this animal model. As well as attempting to develop new treatments for SP-B disease, we are also committed to develop a suitable, scientifically sound, humane endpoint for this model. From the scientific literature, we have learnt that this model shows increasing frequency of breathing and other signs of increased respiratory effort -understanding how these symptoms relate to the severity experience by such animals will be our initial focus. Thus while we intend to use only small numbers of such animals, whenever they are used, we will incorporate increased observations to enumerate these symptoms and attempt to build a predictive score that we could use to terminate a study with knowledge that that any given animal was now unable to recover - in that way we hope to minimise suffering whilst retaining sound statistical evidence supporting any correction of the disease phenotype.

Importantly, the vast majority of studies under this PPL are anticipated to induce greatly decreased animal welfare issues. Nevertheless, where we identify (e.g. using distress scoring sheets for each animals and protocol) areas where refinements (e.g. in pain management) we have included sufficient procedural flexibility to immediately introduce steps that address the issue.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Improving quality of science through better animal welfare: the NC3Rs strategy

https://doi.org/10.1038/laban.1217

Guideline on the principles of regulatory acceptance of 3Rs (replacement, reduction, refinement) testing approaches

European Medicines Agency - EMA/CHMP/CVMP/JEG-3Rs/450091/2012

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The team of scientists working on this PPL attend regular meetings organised by our local vet services team to make sure we are aware of general 3Rs improvements.

Under REDACTEDs we have been praised by local ethical review panels for both our responsiveness to 3Rs initiatives and for project-specific 3Rs adaptations we have implemented ourselves - for example our recent focus on ALI, EVLP and PCLS studies along with our uptake of in vivo imaging has resulted in a large drop in animal usage. Going forwards we will continue to strive for self-identified improvements in this area and remain vigilant to identify pertinent advances made by others.

Explain the choice ofspecies and the related life stages

Mice have been selected for the proposed studies as they provide a model replete with the full range mammalian cell biology processes. Of particular importance is that they have an intact immune system; this is critical for understanding how recipients of the gene therapy drugs we are developing (animals in this PPL, people in future clinical trials) will respond.

For many studies, normal laboratory mice will be used. However, we also anticipate using a range of genetically altered mouse models. These will be bred under two protocols in this PPL. Each of the models selected present a disease related physiological defect. Clinical development of a novel gene therapy treatment is greatly facilitated by demonstrating that such defects can be corrected by the proposed treatment approach.

Mice harbouring knockouts/mutations of the murine Cftr gene with genetic correction of the CF intestinal defect will be used for studies relating to the development of therapeutic agents to treat Cystic Fibrosis (CF).

Mice harbouring knockouts/mutations of the murine Sftpb, Sftpc and/or Abca3 genes will be used for studies relating to the development of therapeutic agents to treat Childhood Interstitial Lung Disease (chILD).

Mice harbouring knockouts/mutations of the murine Serpina1 gene will be used for studies relating to the development of therapeutic agents to treat A1AT-deficiency.

Mice harbouring knockouts/mutations of the murine Atp7b gene will be used for studies relating to the development of therapeutic agents to treat Wilson's disease (WD).

Mice harbouring standard laboratory reporter genes and/or additional copies of the human versions of the disease genes listed above will also be used. In particular under this PPL they will be used to assess the ability of gene editing approaches to precisely (or otherwise) correct specific undesirable human sequences.

For breeding, all life stages of animals will be used. This is necessary for effective maintenance and use of the genetically altered mouse models.

Adult mice will be used for the vast majority of studies where assessment of gene therapy formulations is anticipated. In a very small minority of studies gene therapy formulations will be delivered to 1-2 days old mice and/or juvenile mice; such studies are of particular relevance to the development of disorders such as chILD and WD where the human disease develops shortly after birth and the target organ (lung and liver respectively) undergo considerable growth in the neonatal/juvenile period .

A retrospective assessment of refinement will be due by 07 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

69. Gene-Environment Interactions

Project duration

1 years 5 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This program of work aims to better understand the consequences of exposure to environmental pollution on living organisms. We will use a panel of reporter mice to study how environmental pollution activates different toxicity pahtways and causes exhacerbatation of disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Humans are constantly exposed to a complex mixture of deleterious environmental agents including pollutants in air, water and foods; and on occupational and household settings. Epidemiology studies have linked exposures in adulthood and during development to the rising incidence of non-communicable diseases and behavioural deficits. The WHO estimates that 23% of global deaths are attributable to environmental factors such as air (e.g particulate matter, nitric oxide), water (e.g. arsenic, heavy metals) and soil contaminants (e.g. pesticides). Despite these statistics, in most cases we do not understand at a mechanistic level how complex mixtures of pollutants disrupt cellular and physiological homeostasis to exacerbate disease pathogenesis.

Whereas significant progress has been made in the identification of hazardous environmental exposures and their consequences on cell homeostasis, the majority of these conclusions are based on ex vivo studies. Proposed mechanisms include oxidative- and DNA-damage, and Aryl hydrocarbon receptor (AhR) interactions. However, the majority of the current understanding does not take into account the complexities of cell-cell interactions and whole animal physiology.

Our program of work will provide in vivo mechanistic insights on gene environment interactions. We will measure the activation of adaptive stress responses by environmental pollutants using a panel of reporter mice of oxidative- and DNA-damage and AhR-activation. These studies will include the consequences of in utero and trans-lactational exposure. In the future, we will use this information to interrogate how individual genetic variability influence susceptibility to environmental exposure. Finally, the identification of pathways activated by environmental exposure can be used to inform subsequent epidemiological studies and can provide biomarkers to test in human studies.

What outputs do you think you will see at the end of this project?

The immediate outputs of this project will be scientific publications in high quality, peer-reviewed, high impact journals appropriate to the field of research, communication to relevant national & international scientific conferences and press releases disseminating the research findings.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

The public health consequences of environmental contaminants are a major global health priority. Human exposure to a complex mixture of deleterious environmental agents including pollutants in air, water, and foods and occupational and household chemicals has been linked to the rising incidence of non-communicable diseases and behavioural deficits in adulthood in both wealthy and developing countries. Indeed, WHO estimates that 23% of global deaths (36% amongst children under 14), are attributable to environmental factors. In the short term, the project will beneficiate the scientific community to understand the mechanisms of toxicity by environmental exposure. The reporter models used will allow fundamental advances on this research, such as a better understanding of cellular sensitivity to pollution in vivo and avoidance of technical problems associated to current methodology (i.e. lack of cell-specific bimarkers). In the medium term, this information will be used to build up more robust models to interrogate how pollution is linked to initiation and exhacerbation of human diseases. In the long term, the project will benefit the society through an increased understanding of how environmental pollutants lead to disease and, in the longer run, through contributing to improvements to the quality of the environments in which people work and live.

How will you maximise the outputs of your work?

The mounting global concern surrounding the public health consequences of environmental contaminants will ensure the impact of this work. The knowledge and skills acquired will be deployed to understand the consequences of emerging environmental toxicology problems, such as household/indoor pollution, tear and wear of tyres and toxicity of new materials (e.g. microplastics). To maximise the output of this work, we will ensure the continuity of our research lines by extending our current national and international collaborations with leading figures in the field of toxicology .

The stress response models can be applied to a number of toxicological problems. Therefore, we will seek new collaborations with toxicology groups/centres where environmental research is a priority.

The work described in this project will be disseminated through publications in peer review journals and by presentations at scientific meetings.

Species and numbers of animals expected to be used

- Mice: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Animals will be treated with agent(s) associated with environmental pollution (diesel emissions, singularly or in a mixture; naturally occurring pollutants; indoor pollutants, singularly or in a mixture), with all substances and procedures shall be pre-approved locally by the NVS. A typical scenario may be daily po doses of a pollutant for a maximum of 5 consecutive days. Ocasionally, antioxidants can be co-administered in the diet or drinking water. After the exposure period, mice may undergo optical imaging before sacrificed by exsanguination and/or tissue perfusion under terminal anaesthesia [AC(G)] or by a Schedule 1 method.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The main type of impact on animals during this project will be a transient discomfort during the administration of the substances. In rare occasions, animals may develop pain and weight loss. Animals experiencing this type of effects will not be included in our studies and will be killed by a Schedule 1 procedure after consultation with NVS or NACWO as appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mice in protocol 2 will be expected to experience a mild severity. For animals with treatment in drinking water or diet (15%) the severity will be below threshold. In rare occasions, less than 2% cases, animals may experience a moderate effect. For instance, animals may refuse the modified water or food as a consequence of dissolved compounds making it less palatable, with a concomitant weight loss or dehydratation.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The variety of environmental exposure whose links with stress responses we wish to explore affect multiple organs and can only be investigated in an intact organism. Although in an ideal world, some of these studies would be performed ex vivo using human cell lines, these lines are invariably cancerous

in origin and the process of cell transformation alters how cells produce, use and adapt to environmental pollutants; again, this makes this approach unacceptable for our purposes.

What was your strategy for searching for non-animal alternatives?

Potential work is developing technologies for engineering stress-reporters, similar to those described herein, into induced-pluripotent stem (iPSC) cells. In future, this will allow us to replace mice in some experiments with iPSC cells or immune cells derived from exposed individuals. But, for now, mice remain irreplaceable and the organism of choice for our work.

Why were they not suitable?

To understand the consequences of environmental exposure and their role in disease aetiology, there is a need to work at the organism level. iPSC cells will not reflect the complex cell-cell interactions of the whole organisms. Moreover, pollutants often require metabolic activation to reactive species in order to exert their damaging effects. This metabolic activation is often cell-dependent and iPSC cells do not express the required set of metabolic enzymes. Metabolites can also exert their effects in tissues distant from their metabolic activation site. Therefore, for a comprehensive study of pollution toxicity, a whole organism is required at the moment.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals required for this project has been calculated on the basis of previous experience with these lines. We have also estimated the number of pollutants and complex mixtures available for our research and the experiments required to understand their toxicity mechanisms.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experimental design – based on experience and literature review - will be kept as simple as practically possible in order to maximise the information obtained from the minimum number of animals. Advice will be sought as necessary from statistical sources, locally or online, concerning the minimum number of experimental animals required to allow a sufficiently powerful statistical analysis. Experience to date suggests that three mice per experimental group will usually be acceptable. This is the smallest number of animals that could be used consistent with good statistical practice.

What other measures apart from good experimental design will you use to minimise numbers?

The animals required for our experiments are heterozygous for the reporter allele. To ensure an efficient breeding, we will cross wild type animals with homozygous reporters, therefore all the offspring will be amenable for experiments.

As aforementioned, we conducted a comprehensive characterization of pollutants ex vivo before proposing their use in an in vivo study. This approach ensures the animals used for our research are kept to a minimum.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mouse models which are reporters for the activation of the NRF2 pathway (oxidative stress; HOTT, NRF2-KO), p53 pathway (DNA damage; p21), AhR pathway (xenobiotics receptor; CYP1a1_KI_Cre/multireporter) and AP-1 pathway (early stress response; Pyroz). The presence of the reporter has no deleterious effects on the animals. The severity of the methods to be used has been classified as mild.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The regulation of stress pathways can differ between different species. Mice represent a closer step to understand the consequences of environmental exposure on human health.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals that will enter into a study are acclimatized to handling. When animals are in a study plan, we will increase the monitoring of adverse effects.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

There are multiple online resources which are updated with best practice guidance for experiments, e.g. LASA website or the NC3Rs website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will regularly visit the NC3Rs website and others recommended by the local named information officer.

Explain the choice ofspecies and the related life stages

Of the model organisms commonly accepted as surrogates for humans, the mouse is the closest in evolutionary terms to humans. Simpler, more socially-acceptable alternatives, such as the worm species C. elegans, have well-documented differences with humans in how they handle oxidative stress and this makes them unacceptable for this project.

Home Office

NON-TECHNICAL SUMMARY

70. Generation of antibodies in pigs against the SPIKE protein of Wuhan 2019 Corona Virus (SARS-CoV-2)

Project duration

1 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Pigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To generate polyclonal and monoclonal antibodies in pigs to the SARS-CoV-2 spike protein to both enable reagents to be available for treatment and diagnosis and also to be used to map the surface of the virus against which antibodies are produced. Another aim is to assess the effect of route of administration of the human experimental vaccines on the subsequent immune response and kinetics.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work as there are currently little to no reagents readily available to help develop diagnostic tools, in particular antibodies which are used in a variety of diagnostic tests for other infectious diseases. Producing monoclonal antibodies also will allow the portions of the Coronavirus surface which elicit an immune response to be mapped and compared with other animal models in order to select an appropriate model for immunogenicity. The immune responses to experimental human COVID-19 vaccines are essential to define, and this study will use the pig model to determine the detailed immunogenicity of human experimental vaccines, including the effects of different routes of vaccination on the subsequent immune responses.

What outputs do you think you will see at the end of this project?

At the end of this project it is predicted that immunological materials (polyclonal and monoclonal antibodies) will be produced against the Spike protein of SARS-CoV-2. These will help investigate and diagnose the ongoing SARS-CoV-2 epidemic to which there is a paucity of materials available at present. Immune responses of experimental human COVID-19 vaccines administered by differing routes and schedules of immunization will be determined which may help identify the optimal regimens and in doing so allow a more efficient use of the vaccines, thereby increasing the number of potential doses available.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The antibodies produced in this study (both polyclonal and monoclonal) will be made available to our collaborators in the short term. Novel diagnostic tests, as well as mapping the parts of the SARS-CoV-2 to which the immune system creates antibodies (epitopes) will be achievable in the medium term. In the long term, it is envisaged that the reagents created from this work, and associated derived assays, will aid in the creation of countermeasures (such as a vaccine and therapeutic antibodies) to SARS-CoV-2 where the ultimate benefit will be to patients and the global at-risk population as a whole.

Knowing how the pig immune system behaves when the animal is vaccinated with the human COVID-19 experimental vaccines will allow the vaccination approaches in humans to be optimised and understood with much more clarity, especially the potential induction of vaccine induced enhanced disease.

How will you maximise the outputs of your work?

Collaboration with structural biologists in REDACTED will allow the epitopes of the Spike protein to be mapped. This will be helpful in designing or testing novel diagnostic reagents as well as disease countermeasures.

Collaboration with teams having access to human and mouse monoclonal antibodies (mAbs). Compare the pig mAbs with human mAbs to establish if humans or pigs are better in making neutralizing mAbs. If pigs and humans make a similar repertoire of mAbs pigs could be a useful model to test the immunogenicity of SARS-CoV-2 vaccines.

The reagents created in this study will be available to collaborators in the global effort to investigate the immune response, as well as creation of countermeasures to SARS-CoV-2.

Close collaboration with REDACTED, and ongoing sharing of results will allow frictionless information exchange regarding the immunogenicity of the experimental human COVID-19 vaccine.

Species and numbers of animals expected to be used

- Pigs: 66

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, Animals used in this project will injected into the muscle or skin, or administered material into the nose or lungs with SARS-CoV-2 proteins or vectors expressing the proteins to induce an immune response. This will typically be conducted twice. Blood samples and swabs will also be taken to characterize the immune response and to isolate immune cells for further analysis. This will typically be done weekly. After around 56 days animals will then be culled humanely. Some pigs may also require sedation to enable accurate administration of vaccine. After culling, various immune tissues will be collected to further collect immune cells which will then be used for further analysis.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are no adverse effects expected during this project other than the brief discomfort associated with an injection (of the antigen) and blood sampling. The substances inoculated into the pig are not expected to cause any adverse effects themselves.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The maximum severity expected in all pigs is mild, and 100% of pigs used in this study will experience it.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Due to the complex nature of the immune system, it is not currently possible to generate antibodies (or to accurately predict them) to a novel protein without inoculating it into an entire animal.

What was your strategy for searching for non-animal alternatives?

It is not possible to achieve this aim without using animals as above. Cell culture based systems will be used to generate the SARS-CoV-2 proteins.

Why were they not suitable?

No replacements options are available to replace the whole animal at this time as an entire organism, including the immune system, need to be present.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The first study is a pilot study to generate the antibodies to the SARS-CoV-2 virus spike protein. Based on previous work, 3 pigs are sufficient to produce a broad set of monoclonal and polyclonal antibodies. As we will be using two immunogens, we will be using 6 pigs. The subsequent studies will involve development and use of a pig model to examine the immune responses to human experimental COVID19 vaccines. These studies will be able to investigate the optimal dose, regimen, and route of vaccination. Numbers of animals per groups, and number of groups will be determined based on previous data collected by working with a statistician.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Review of the previous studies generating monoclonal antibodies have confirmed that 3 pigs are required. Using statistical approaches it was determined that 6 pigs will be required to determine the effects of route of vaccination on the responses.

What other measures apart from good experimental design will you use to minimise numbers?

The first is a pilot study itself, and the numbers have already been optimised. The second is an immunogenicity study and responses based on recently acquired data in mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will be using pigs because we have previously shown that antibodies generated by pigs recognise similar epitopes to human antibodies, in contrast to antibodies raised in mice, when investigating influenza viruses. The method of isolating and creating antibody secreting cells in pigs has also been validated previously and so will maximise the chances of generating results in this model. The methods used are the minimal number and consist of a vaccination with a needle (and instillation into the nostrils) which is the least pain needed to generate antibodies.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Pigs have been used in this study as there is evidence that the antibody response of pigs to influenza virus proteins is similar to that of humans, and these influenza proteins are similar to the coronavirus spike protein. Furthermore, there is a concurrent mouse pilot study which will compare the antibody responses of the mouse to the pig, to elucidate differential recognition of the SARS-CoV-2 spike protein. Pig monoclonal antibodies are antigenically different from mouse antibodies, and therefore there is less chance of cross reactivity if they are both included in certain diagnostic and research assays.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be housed together with bedding and other items of enrichment. Highly trained animal technicians will monitor these animals throughout the day, ensuring they are comfortable and to maximise their welfare status. We have 24/7 CCTV surveillance which can be used to monitor the animals behaviour over time.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Adherence to the ARRIVE guidelines for reporting these studies, as well as reference to the FELASA guidelines for pig health monitoring to help ensure the most robust health assurance for animals used in this study. FELASA guidelines for administration of substances has been used to limit the maximum volumes for each of the routes.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through continued CPD and frequent review of the CAAT (Center for Alternatives to Animal Testing) I will keep informed about advances in the 3Rs. Included in CPD will be annual attendance at national lab animal science conferences.

Explain the choice ofspecies and the related life stages

Pigs are being used in this study as they have previously been demonstrated to generate an immune response in line with the human responses to influenza antigens (which are similar in configuration to SARS-CoV-2 spike proteins). Pigs are also naturally infected with coronaviruses which may further aid to them being a future model, and therefore another benefit of using them as a model to create reagents. Also, the large size of the pig compared to rodents allows B-cells in the blood to be characterized and isolated, in addition to the large amounts present in the secondary lymphoid tissues. The size and anatomical similarities of pigs make them ideal for assessing the effect that the route of vaccination has on the immune responses.

Home Office

NON-TECHNICAL SUMMARY

71. Glutamate Receptors and Epilepsy

Project duration

5 years 0 months

Project purpose

None selected

Key words

Epilepsy, Glutamate Receptors

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Currently, the processes by which epilepsy is established, and why, in some cases, it becomes resistant to drug treatment, are poorly understood. The aim of this project is to advance understanding of underlying mechanisms within the neuronal circuits of the brain that are responsible for generating and maintaining epileptic activity. The work aims to identify how disruption to neurotransmission alters normal synaptic communication between neurons within local circuits of the brain and triggers epileptic

activity. In doing so, the project’s long-term aim is to identify treatment strategies that could be used to restore normal brain function in patients suffering from drug resistant epilepsy

A retrospective assessment of these aims will be due by 15 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The project will advance fundamental understanding of how these neuronal pathways and neurotransmitter receptors are involved in normal brain function, and how these become altered in epilepsy. The information will be of value to scientists working in the field of neuroscience, and specialist medical practitioners dealing with patients suffering from neurological conditions. In the longer term the information generated in these studies will be of value to the pharmaceutical industry in their quest to develop new medicines for the treatment of epilepsy and other neurological conditions.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The project will run for 5 years. Experiments will be conducted on rats and mice, of which the study is expected to use up to 3850.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The studies will require the induction of epileptic activity in healthy rats and mice. Consequently, whilst some animals will undergo surgical procedures, performed under general anaesthesia, these are not expected to have any long-term detrimental effect on their wellbeing. In order to study the changes in brain function that occur during epileptic activity, suitable models of epilepsy will be used. In all cases we will apply the least severe model and endpoint suitable for the study, such that no animal will be allowed to progress beyond unnecessary stages of the disease. In the event that any animal develops signs of distress or ill health, it will be killed promptly to prevent any undue suffering. At the end of the

experiment all animals will be killed as it would not be legally possible to rehome them under the terms of the Animal Scientific Procedure Act.

A retrospective assessment of these predicted harms will be due by 15 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

It is not currently possible to study how the brain functions in cell culture or using a computer-based models. Consequently. It is essential to use animals for this study. Equally, it is not possible to undertake this work in a non-protected species as these do not have comparable brains to humans.

A retrospective assessment of replacement will be due by 15 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

The experimental group size has been estimated using statistical “Power Analysis calculation” based on date obtained from similar studies conducted previously by my research group.

Animals numbers will be minimised by:

- Defining effective drug concentration using tissue culture or organ preparations prior to the animal experiments.
- Using pairs of independent stimulating and recording electrodes. We will use one pathway as control and the second as the experimental pathway, therefore reducing animals used by approximately 50%.
- Making use of historical data to minimise the number of control animals used.
- Interleaving experimental groups to enable the control animals to serve more than one set of experiments.

A retrospective assessment of reduction will be due by 15 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

In these studies, we will use rat or mouse which will be submitted to one model of epilepsy. These species have been used extensively in neuroscience because their brains share many similarities to that of humans at both an anatomical and molecular level. The epilepsy models used in these studies are all well characterised and have been shown to reproduce specific aspects of the neurological conditions of interest. In all cases the progression of the disease will be carefully monitored, and animals will not be permitted to progress beyond the early stages of the condition.

All surgical preparations will be performed under general anaesthesia using full aseptic precautions. For recordings taken from conscious animals the connection cables allow the animal to use a full range of normal behaviours and does not restrict movement. Animals will be habituated to the recording room/arena and behavioural apparatus. Experience shows that animals rapidly learn the routine of daily recording sessions, and within 2-3 days will become relaxed enough to perform the experiments

A retrospective assessment of refinement will be due by 15 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

72. Homeostasis and disease in multilayered epithelia

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Some tissues, called multilayered epithelia, act as a protective interface between our bodies and our environment, for example in the skin and mouth. The aim of this project is to understand how they function in health and disease, so that we can develop new ways to treat diseases such as cancer and skin inflammation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Multilayered epithelia, such as the epidermis, cervix, oesophagus and oral mucosa, act as a protective interface between our bodies and our environment. In part because of their exposure to environmental carcinogens, and in part because they turn over rapidly, they are frequent targets of neoplastic conversion. Such cancers are a major human health problem. Epidermal basal and squamous cell carcinomas (SCCs) are the most common type of cancer in the UK and although they can normally be cured by surgery SCCs can metastasise (spread) if left untreated. SCCs of the head and neck (HNSCC) are less common than epidermal SCCs but have relatively high mortality: 11,900 people in the UK are diagnosed with HNSCC every year and there are approximately 4,000 deaths. The 5-year survival rate is 28-67%. HNSCC represent an enormous burden to a patient, since surgery and adjuvant therapies are mutilating and have a devastating effect on normal oral function as well as general health and mental wellbeing. New treatments are required that are more effective and less damaging to the patient.

In addition to their importance in cancer, multilayered epithelia are deregulated in a number of common inflammatory conditions such as psoriasis and eczema. All such benign disorders are incompletely understood and are believed to represent an attempt by inflammatory cells to protect the tissue from impaired barrier function.

Multilayered epithelia are maintained throughout adult life by proliferation of a subpopulation of cells known as stem cells. These cells not only self-renew, but also generate all the differentiated cell types of the epithelium such as hair follicles and sweat glands of the skin. Stem cells give rise to tumours when they undergo changes to their DNA and undergo uncontrolled growth. However, it is still unclear what determines tumour type and, in addition, there is evidence that differentiated epidermal cells can influence tumour development in a positive or negative fashion.

In order to study the epithelial stem cell compartment and its contribution to normal differentiation and disease, four important experimental tools are available. First, it is possible to culture cells from normal human and mouse epidermis (and other multilayered epithelia) and to reconstitute the tissue in culture. Secondly, histological sections of normal and diseased tissue can be examined and used to evaluate the significance of the in vitro observations. Third, it is possible to make transgenic and knockout mice in which gene expression is altered either in the stem cells or differentiating cells. Fourth, small pieces of human or mouse tissue, cells isolated from tissue or cultured cells can be grafted into suitable recipient mice to evaluate their growth and differentiation potential. Our observations using the first two approaches inform our decisions to carry out experiments with mice. We also access electronic databases of information to make predictions about how the properties of multilayered epithelia are controlled. Wherever possible my laboratory carries out experiments on cultured cells and human material. However, tissues formed from multilayered epithelia are too complex to be fully recreated in a culture dish and for this reason it is essential to carry out some experiments on mice.

In particular the formation of a tumour depends on different cell types such as blood vessel cells and immune cells and it is possible to control tumour growth by targeting those cells as well as the cells of multi-layered epithelia – these types of interactions are so complex that they need to be analysed in a living mouse.

What outputs do you think you will see at the end of this project?

The major outputs are new information about tissue homeostasis and disease; REDACTED; wide spread dissemination of knowledge through publications and presentations at seminars and conferences; and proof of concept research for clinical applications. A further output is to maximise the value of the mice that we study by sharing tissue with other researchers. This is because the genes we study in tissues with multilayered epithelia are often expressed in other tissues. By making those tissues available to other researchers, mice that are killed for this project can foster research on other disease-relevant tissues, including breast and intestine.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This work is expected to provide novel information about the properties of stem cells of multilayered epithelia, how they communicate with other cell types in the same tissue, the pathways that regulate their differentiation, and the changes that result in benign hyperproliferative disorders and in tumour formation. Tumours of the epidermis, called basal cell carcinomas and squamous cell carcinomas, are the most common tumours in humans. Tumours of other multi-layered epithelia, such as the oral cavity, cervix and oesophagus, are less common but have significant mortality. Benign skin conditions are also a major health problem, with 2% of the world’s population estimated to suffer from psoriasis. New insights into the underlying mechanisms of these diseases will be generated continuously throughout the project. Clinical applications, such as new drugs, will occur over a longer time frame of up to 10 years from completion of the project. Nevertheless, the pace of translation is accelerating, and discoveries made in my lab since 2013 have already attracted interest in new treatments for scarring and in stratifying combinations of drugs for head and neck cancer on the basis of the underlying genetic lesions. The scientific community will benefit throughout the project from sharing data, protocols and

reagents, including any surplus tissue. Staff working on the project will gain training in the use of animals and as a result will have enhanced career opportunities; for example, over 50% of researchers leaving my lab go on to independent academic careers.

How will you maximise the outputs of your work?

In recent years we have increasingly used experimental data generated from mouse models as the basis of collaborations with mathematicians and computational biologists. These collaborations result in a reduction in the number or mice we use, because the computational models make firm predictions about further in vivo experiments. My lab is committed to dissemination of new knowledge through presentations at conferences and conventional peer-reviewed publications. In addition we share unpublished data via pre-print servers such as BioRxiv and the protocol sharing website protocols.io. Through our commitment to maximising the output of our experiments we intend to publish work that yields negative results or is confirmatory via routes such as BioRxiv and ScienceMatters.

Species and numbers of animals expected to be used

- Mice: 45,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice may be subject to procedures such as ear snipping and blood sampling for genotyping and to monitor the immune status of the animal. Mice will typically be subject to topical applications of agents such as Tamoxifen, or receive injections of labelling agents. They may be subject to wounding or UV irradiation to induce skin damage and may be transplanted with cells or tissue fragments - normal or cancerous - either in suspension or in chambers. They may be treated with chemical carcinogens, either in the drinking water or by skin painting in order to stimulate the formation of tumours. They may be treated with potential anti-cancer drugs and their immune system may be altered, for example as a means of potentially slowing cancer progression. They may be anaesthetised and subjected to in vivo imaging. Most experimental observations are complete within 1 week to 3 months.

In this project mice may develop cancers of the skin or oral cavity. Cancer studies typically last 7 to 12 months. Typically tumour development can be evaluated by visual inspection and tumour metastasis is, in our experience very rare (fewer than 5% of tumour bearing animals). However, when tumours form in the oesophagus or forestomach – as a result of 4NQO carcinogenesis - they are not visible and therefore careful monitoring of weight is important, weight loss being indicative of tumour formation.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Expected impacts are the development of benign skin disease and skin and oral tumours. Provided that the mice are showing no other signs of ill health they may experience these effects for several months.

We do not expect any of the following clinical signs: intermittent vocalisation; pallor of eyes, nose, ears and food pads
.

Any weight loss is expected to be transient (up to 3 days), except in the 4NQO protocol, when there may be slow weight loss for the final weeks.

Other phenotypes indicative of a mouse that is in pain or experiencing stress - hunched posture, reduction in food and water consumption, a disheveled coat, subdued behaviour and abnormal breathing - are expected to be rare and transient.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

In protocol 1 the severity limit is 'mild' and it is expected that over 80% of mice have no phenotype at all.

In protocols 2-6 the severity limit is 'moderate' and it is expected that 80% of mice will experience this severity. Moderate phenotypes will include formation of tumours of the skin or oral cavity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The behaviour of keratinocytes, the cells that form multilayered epithelia, in health and disease is profoundly influenced by communication with other cell types, such as skin fibroblasts and bone marrow derived cells. These interactions cannot be adequately recreated in culture.

Furthermore, cancers develop over a period of months and it is not possible to maintain keratinocytes in culture for more than 21 days without subculturing them. We have also found that the way cells behave in culture does not fully recapitulate the way they behave in the body - for example fibroblasts proliferate rapidly in culture but only rarely in undamaged adult skin. Furthermore, the effectiveness of

anti-cancer and anti-inflammatory drugs depends not only on the drug target but also on pharmaco-kinetics and –dynamics, parameters that can only be assessed in vivo.

What was your strategy for searching for non-animal alternatives?

Keratinocytes (the cells of multi-layered epithelia) can be grown in culture and induced to differentiate into interfollicular epidermis and sebaceous gland cells. Histological sections of human epidermis and other multilayered epithelia are available for analysis. Data sets of gene expression and genomics are available and it is possible to run computer simulations of aspects of tissue behaviour, including wound healing.

Why were they not suitable?

Analysis of different datasets and computer simulations is very effective at hypothesis generation, but validation requires mechanistic experiments that can only be carried out in cell culture or in mice. As described above, cell culture cannot mimic the full complexity and extended time course of the interactions between different cell types that influence tissue homeostasis, repair and disease, nor can it mimic the pharmaco-kinetics and –dynamics of drugs that can potentially treat cancer.

The properties of cells change in culture and there is no adequate in vitro model that supports the complete formation of hair follicles.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

My current licence uses an estimated total of 89,500 mice. However, 5 of the protocols in the current licence, which accounted for 4,000 mice, have been removed from the new licence and in practice the total number of mice used in the current licence is lower than estimated. The estimated total number of mice in the new licence is based on the assumption that the number of animal experiments performed by my lab (except for those involving the deleted protocols) will remain the same as in the previous 5 years, since we have used fewer mice than expected.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In order to reduce the number of mice, we keep stocks of frozen sperm and embryos so that if a line of mice is not required for several months we avoid unnecessary breeding.

For chemical carcinogenesis experiments we use the same parental mice for the first and the repeat experiments, starting the repeats before the first experiment has been completed. This reduces the amount of mouse breeding required per experiment.

We encourage labs that have an interest in other tissues to obtain necropsy samples from our mice. This allows other researchers to obtain preliminary data without having to generate their own mice.

Prior to performing an experiment we perform statistical analysis to ensure that we use the minimum number of mice per group that will be informative. We aim to achieve a minimum power of 0.8, assuming statistical significance of $P < 0.05$.

When initiating skin carcinogenesis experiments I obtained advice on statistical analysis fromREDACTED, who has written extensively on the design of animal experiments. I have previously attended a lecture entitled ‘How many mice do I need for my experiment?’ given by a staff member from the Wellcome Trust Sanger Institute. Members of my lab have attended the NC3R's Experimental Design Assistant workshop and their expertise in available. I can also consult our in- house statisticians at REDACTED for advice on experimental design.

Principles of good experimental practice, including randomisation and blinding, are inculcated into the laboratory. When planning experiments involving a new application - such as dosing with an anti-cancer drug - we begin with a pilot experiment before setting up the full experiment.
Although we can minimise the number of mice that undergo experimental procedures, in some cases a large number of animals have to be bred to obtain sufficient animals of the correct genotype. For example, we may need to activate a fluorescent reporter gene (mouse 1) by crossing it with a mouse expressing Cre recombinase in a particular cell type (mouse 2) and a mouse in which we genetically modify cancer susceptibility (mouse 3). In addition, some experiments require age and sex-matched mice, for example because skin tumour formation is influenced by the hair growth cycle and skin androgens. Our strategy in these cases is to use littermates that lack one or more of the transgenes as controls in the experiments.

What other measures apart from good experimental design will you use to minimise numbers?

Efficient breeding, as illustrated above, is an important way to ensure that the number of mice we use is minimised. We also perform pilot studies prior to embarking on a new set of experiments - this was the case when we initiated our current oral cancer studies. Computer modelling can enable us to predict the optimal time points for analysing experimental mice, thereby reducing the number of time points, and thus mice, to be analysed. We encourage sharing of tissue so that spare tissue from mice can be analysed to obviate the need for killing animals for tissue collection. We also have regular meetings of lab mouse users to ensure that lines of animals are not being maintained unnecessarily.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice are the lowest form of mammal that can be used to study normal and diseased skin and other tissues containing multi-layered epithelia. They are the only mammal inwhich transgene and knockout technology works reliably.

When generating transgenic mice we use inducible transgenes whenever possible. This reduces the time window when mice display a phenotype.

The different types of grafting experiment - for example, cells injected into the cheek and cells injected into skin chambers - are well tolerated and the end-points for the cheek injections are chosen to occur before the ability of the mice to eat is impaired. Tumours induced in the skin and oral cavity with chemical carcinogens are well established and again endpoints are chosen to prevent undue suffering.

When a new surgical or sampling procedure is involved, training on dead animals is first carried out.

When a new drug is being tested, an initial experiment is carried out with a small number of mice using the conditions predicted from the literature to be most effective, to ensure that the drug does not result in generalised adverse effects. The data from the first experiment then informs the design of subsequent experiments, which may involve larger numbers of mice.

In the case of administration of agents, the table of maximum dosing volumes and frequencies that is included in each protocol will be used. These are maximum volumes and numbers of injections by different routes that are normally well tolerated, assuming the substance being injected is non-toxic. These are the overall maxima for a single protocol.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The goal of our research is to understand homeostasis, repair and disease in adult tissues, and therefore confining our analysis to embryos is not appropriate. When performing in vivo imaging mice are subject to terminal anaesthesia but for all other experiments the duration extends to weeks and so terminal anaesthesia is not suitable. Mice are the least sentient mammals that are suitable for the proposed experiments.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All of the procedures in the licence are in use in my current licence and the most likely adverse events are not due to the procedures themselves, but to the genetic make up of the mice and the development of inflammatory disease and cancer. Strong communication is important between researchers and REDACTED staff to avoid animals going beyond their end points and to ensure that everyone involved is aware of what stage the animals are at in the study and what additional care is needed. In particular, when the chemical carcinogen used in the oral cancer studies is withdrawn mice can start to deteriorate as invasive tumours develop. The weights and overall condition of the mice is monitored at least twice a week and once any deterioration is seen the mice are monitored and weighed daily. A notice regarding monitoring is prominently displayed in the rooms where mice are kept to remind everyone what is required.

Throughout the period of the licence we will seek, and implement, ways to refine the procedures. For example, we have recently developed a nose cone for mice undergoing inhalation anaesthesia that facilitates examination and photography of the oral cavity and thereby reduces manipulation of the tongue and jaws. In the present licence we will will ensure that animals in a protocol that involves regular handling, such as measuring tumour growth, will be handled prior to the start of the experiment, to ensure that the process does not induce unnecessary anxiety or stress to the animal. Mice being treated with a new compound will be monitored very closely in the early stages to ensure that any unexpected issues are caught rapidly. When performing oral gavage we will use a flexible plastic tube, rather than a metal one, to reduce the likelihood of tissue damage.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow regular updates on the Home Office website guidance on animal testing and research. We will read the specialist literature, such as the UFAW (Universities Federation for Animal Welfare) journal. We will attend events organised by the local AWERB. We will also check the NC3Rs website on a regular basis (nc3rs.org.uk).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I receive regular updates from the staff of the REDACTED in a variety of formats. Home Office recommendations are forwarded and we receive invitations to update meetings on campus. The Home Office Inspector is always very helpful in responding to queries face-to-face or via e-mail. Members of my lab also attend training at the REDACTED and we share best practice through meetings with other scientists who have shared research interests. REDACTED and lab members are kept abreast of the latest updates from NC3Rs.

Explain the choice ofspecies and the related life stages

Mice have been chosen as the lowest form of sentient mammal that is of proven relevance to the pathophysiology of human tissues comprising multi-layered epithelia. The objectives of the project are to study homeostasis and disease in adult tissues and therefore the only experiments involving embryonic animals are either to manipulate gene expression in utero in order to study the effects postnatally (as in lineage tracing of different fibroblast populations) or to trace the origins of an early post-natal phenotype (such as postnatal skin fibroblast quiescence).

Home Office

NON-TECHNICAL SUMMARY

73. Host-symbiont ecology in REDACTEDs

Project duration

5 years 0 months

Project purpose

None selected

Key words

wild, rodent, microbiome, ecology, symbiont

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to improve our understanding of why it is that animals in nature vary so widely in the symbiotic organisms that colonise them – their microbiome. Studies in laboratory animals as well as humans have shown that which microbes are present in the gut, and in what numbers, can have profound impacts on many aspects of animal biology – shaping immune responses, metabolism, and susceptibility to infection. And yet, we still know rather little about what determines the composition of these communities, how they pass from one animal to another, and their ultimate effects on health and

fitness, in nature. In this project, we have three main objectives. First, we will use REDACTEDs to understand how a range of factors - including variable diet, aging and parasite infection - affect the REDACTED. Second, we also aim to understand how commensal gut bacteria, as well as viruses, pass from one rodent to another in the wild. This information is valuable as it may shed light on the pathways by which infectious organisms transmit among other mammals, including humans. It is also relevant for understanding the spread of pathogens infectious to humans that circulate in REDACTEDs (zoonotic organisms). Finally, we aim to explore whether the microbiome is important for animal health outside the laboratory (where most microbiome studies are performed) among REDACTEDs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This study will provide fundamental insight into why the microbiome of mammals is so hugely variable, and it's importance for animal health. It will show how factors relevant to all free-living mammals, such as host genetics, diet and infection with parasites such as worms, impact these key microbial communities. As such, insight gained may ultimately be relevant for improving the health of humans, livestock, domestic animals and endangered animal species. It will also provide new information about why individuals within a population or community share particular bacteria and viruses, and the role that social interactions and space use play in this. This has value for our understanding of the epidemiology of rodent-borne zoonoses. Finally, part of our research focuses on how we can improve the experience of wild small mammals in scientific research, by designing new traps that prevent unnecessary captures and limiting capture time to the minimum required for those that do need to be caught. As such, in the long-run this work will benefit our animal study subjects.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

To do this, we expect to study approximately 1100 wood mice, 200 yellow-necked mice, 500 bank voles and 2000 wild house mice over a five year period.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

It is important for both our scientific goals and ethically that animals involved in this research stay in good condition, and any potential adverse effects are minimised. For most mice and voles, we expect to cause them only transient stress and mild discomfort associated with being trapped and handled,

before they are released back to the wild at their capture site. Some animals will receive a drug treatment to reduce their natural parasite infection levels. If anything, we expect this to improve their health. While most animals will be set free as part of a capture-mark-recapture approach to studying wild animals, a small subset will be humanely euthanised allowing us to validate several of non-invasive measures we take on wild animals. For all animals involved in this study, the procedures we will use should only lead to mild and transient pain, stress or discomfort. Adverse effects should be very rare and we take careful steps to minimize the risk of these arising, through good trapping practice, rapid release of captured pregnant/lactating females, and careful monitoring of all animals in our care.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Since our goal is to understand how elements of an mammal's natural environment affect their microbiome over time, there is no alternative but to capture and sample live animals in their natural habitat.

Reduction

Explain how you will assure the use of minimum numbers of animals.

First, we will carry out careful experimental design including power calculations to estimate what number of animals are required answer the particular scientific questions. We use these estimates and our experience with REDACTED fieldwork to design field experiments that are not excessive, and use only sufficient animals likely to provide the required information.

Second, we will use appropriate and sophisticated statistical methods to analyse the data, that derive as much possible information from our study designs. This will mean we need fewer animals to answer a question than with more basic analyses.

Finally, we are pioneering the use of new technology to study REDACTEDs. This will reduce the number of unnecessary animal captures (by not allowing animals that we do not require for scientific reasons to enter traps), and replace capturing and handling animals with passive monitoring systems wherever possible.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We will use good trapping practice to ensure animals involved in this work experience minimal welfare costs. This includes only setting traps when weather conditions are suitable, for the minimum time

required (so animals cannot be trapped for too long), providing sufficient bedding and food to keep them comfortable and releasing animals in exactly the same location they were captured. We will also limit the frequency of trapping to minimize the potential adverse effects of animals being in traps too often. When animals have been caught and are in our care, we will carefully monitor them for signs of suffering, and react accordingly should this occur. We will choose methods of performing procedures that are as refined as possible. Finally, we have designed and will start using a new "Smart Trap" in this work, that prevents bycatch of non-target species and unnecessary recapture of individuals, and allows us to limit the time animals are held in traps to the minimum required for scientific objectives.

Home Office

NON-TECHNICAL SUMMARY

74. How does inflammation shape the course of disease in arthritis?

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Rheumatoid arthritis, Inflammation, Immune cells, Therapy, Precision medicine

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Lay summary overview – Inflammation is the body's response to infection or injury and contributes to the healing process. In rheumatoid arthritis, appropriate control of inflammation is lost promoting joint disease. Importantly, the pattern of joint inflammation often differs considerably in rheumatoid patients to affect the rate of disease onset, the severity and response to therapy. Studies outlined here will define the mechanisms that account for these clinical differences. 'Inflammatory signatures' that reflect these various forms of joint disease will provide an opportunity to improve patient diagnosis and treatment.

Background to the problem – Cytokines are proteins that regulate inflammation and are considered major drug targets for the treatment of rheumatoid arthritis. These include the anti-TNF blockers. Here, adverse cytokine activities drive joint inflammation and disease progression. However, not all patients respond to these drugs and it is widely accepted that multiple, often independent, mechanisms contribute to joint disease. We propose that cytokine activities influence the type of inflammatory joint disease seen in rheumatoid patients. Thus, experiments aim to understand the inflammatory mechanisms that determine the course of arthritic disease.

Questions we aim to address – We have characterised a cytokine-controlled mechanism that directs the pattern and severity of inflammatory arthritis. To build on these findings we will answer the following questions:

- What are the inflammatory mechanisms that drive chronic joint disease?
- Why do patients with rheumatoid arthritis display different forms of joint inflammation?
- How do the activities of particular cytokines affect the type of joint inflammation observed?
- Can inflammatory signatures that reflect these differences in rheumatoid arthritis improve patient diagnosis, clinical management and response to therapy?

The Experimental approach – Experiments will establish how inflammation promotes the various forms of joint inflammation observed in patients. Here, differences in inflammation refer to the composition and specific organization of infiltrating immune and structural cells within the diseased tissue. We will examine the response of these cells to cytokines. Using cell-based systems, mouse models of arthritis and clinical samples including ultrasound-guided tissue biopsies from rheumatoid arthritis patients, studies will identify response patterns that predict the course of disease. Specific approaches will explore differences in gene expression, the mechanisms that affect these gene changes and the impact of these events on joint inflammation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Our objective is to aid patient diagnosis, treatment and cure by identifying the mechanisms that dictate the course of joint disease and inflammation. Studies will help identify how patients with the same condition display fundamental differences in the presentation of local joint disease. Our aim is to deliver long-term patient benefit by improving the clinical management of disease and potentially enhancing the likelihood of clinical cure. The identification of novel diagnostic tools that predict differences in

disease activity or the presentation of disease will support clinical decisions relating to the selection of the most appropriate therapy for an individual patient group.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice – both wild type mice and genetically manipulated strains that alter the capacity of mice to mount to an immune response.
Experimental Numbers – 4,250 (over 5 years).
Breeding Numbers – It is anticipated that a maximum of 3000 animals will bred under this licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Expected level of severity – Mild to Moderate
Outcome – All animals will be killed
Adverse effects – All animals will be immunised with agents that will either promote arthritis (causing bone and joint damage and inflammation) or alleviate the signs and symptoms of disease. Following the onset of disease this may result in a loss of mobility and some mice may lose their normal exploratory behaviour. These changes are however short lasting and typically go back to normal once the initial joint swelling has reduced. In some instances mice may encounter an adverse response to reagents administered to promote arthritis. This may include mild skin irritations at the site of injections, or more pronounced changes in wellbeing or health (e.g., fever-type responses or changes in normal animal behaviours).

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The immune processes responsible for the development of arthritis likely occur before the presentation of clinical signs and symptoms of joint disease (i.e. when the disease may not be overtly apparent to the patient). These early warning signs will cascade the escalation of inflammatory processes leading to the onset of arthritis – affecting the severity, the rate of disease progression and the response to therapy. Unfortunately, this initial phase of arthritis is difficult to track in humans and remains subjective. At present there is no alternative to using the *in vivo* models described to achieve the experimental objectives outlined in this licence application.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We routinely discuss our research with clinical colleagues to ensure we ask meaningful questions. Our previous research has yielded a large amount of data, and archived samples for training purposes and informed decisions on the best study design (e.g., selecting specific time points within the model). However, our laboratory is now using exciting new methodologies that enable us to generate more information from fewer mice. These include the introduction of next generation sequencing techniques to capture whole genome changes in gene regulation and expression. Moreover, we also use comparable datasets derived from human clinical studies to verify our mouse findings, and this approach often informs new questions that can be tested in our experimental model systems.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Inflammation is a complex process that is determined by a close communication between immune cells and cell resident to the site of disease (e.g., the inflamed joint). Many of these responses are also controlled outside the inflamed joint. This necessitates the need for a model system that can reflect this high degree of complexity. Mice provide an excellent model system in which to study the relationship between the immune system and arthritis development. Mice are well characterised immunologically, and their immune systems closely resemble those of humans. In addition, several genetic modified mice lacking various immune molecules/cells have already been generated and provide an ideal opportunity to perform detailed analyses of immunological function. In this regard, our research has now identified three mouse strains that closely resemble the various forms of joint disease seen in humans. We are therefore uniquely placed to realise the ambitions of this study, and have the capacity to draw upon information derived from both human patients and mouse models.

We (in collaboration with others) have refined these models through discussion with clinical colleagues, and explored new methodologies that enable us to optimise experimental questions. This has been achieved through an increased understanding of the model, with specific regard to how immune cells behave and the time points that immune cell are critical for specific aspects of disease, this ensures that only high value time points are chosen and mice are not subjected to needless procedures at non -relevant time points. The Introduction of new imaging techniques can lead to a number of refinements . For example, previous monitoring protocols have included excessive handling of the mice (e.g., measurement of joint swelling using callipers). This causes distress and anxiety to the mice housed together and will invariably moderate immune effects linked with stress. The use of these alternate imaging techniques means that certain measurements can be conducted only once at the end of the study once the animals have been killed.

In addition the following steps will be utilised as best practice:

We will Ensure that good practice is observed with training, supervision, assessment of competence, Continuing Professional Development and skill refresh on a yearly basis, seeking advice both internally and externally as necessary.
We (in collaboration with others) have refined these models through discussion with clinical colleagues, and explored new methodologies that enable us to optimise experimental questions. This has been achieved through an increased understanding of the model, with specific regard to how immune cells behave and the time points that immune cell are critical for specific aspects of disease, this ensures that only high value time points are chosen and mice are not subjected to needless procedures at non -relevant time points.

NON-TECHNICAL SUMMARY

75. How neuronal activity links sensations, perceptions and actions

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Neuroscience, Sensory coding, Decision making, Somatosensory cortex, Neural circuits

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The world around us is full of temporal structure: things happen in specific sequences and patterns over time, and this information is essential to our ability to make sense of our environment and, ultimately, to survive. The aim of this project is to use wild type and genetically altered mice to record and manipulate neuronal activity while animals carry out a task guided by sensory input, in order to understand how neuronal activity underpins the animal's capacity to sense and identify temporally patterned sensory signals and decide on an action in response.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The project will illuminate how neuronal circuits give rise to sensory-guided behaviour. Progress in this area is central to our understanding of how mental function arises from the healthy brain, and how it is affected by disease. Such an understanding is fundamentally needed to drive improvements in the treatment of neurological disease.

Our understanding of how neuronal activity underpins sensory perception and drives decisions and actions remains limited, particularly in the cerebral cortex, a region that is key to the formation of sensory percepts, decision making and cognition. Sensory processing and its translation into decisions is affected in many pathologies of the cerebral cortex, e.g. developmental disorders such as autism or schizophrenia.

By allowing measurement and interference with neuronal activity while mice perform a task on which they have been trained, we will be able to directly link neuronal activity with task performance, and this will provide a highly powerful experimental framework.

What outputs do you think you will see at the end of this project?

The primary objective of this work is to generate new scientific knowledge. Our research will advance understanding of how neuronal circuits give rise to behaviour, and specifically how brain activity underpins the capacity to reach decisions based on sensory signals. Accordingly, the main scientific output will be in the form of conferences and of publications on this topic in open access peer-reviewed journals.

As part of this work, we will develop experimental protocols allowing the measurement of neuronal activity during the performance of sensory processing and decision making. Insights into procedures for high-data-yield mouse behavioural training will be shared with the academic and industrial research community through an existing NC3Rs working group and the publicly available peer-reviewed publications that will result from it.

Our understanding of information processing at single-neuron resolution in the healthy and diseased brain remains relatively limited, particularly in the cerebral cortex, the region underlying percept formation, decision making and cognition. The outcomes of this project will have implications for basic research beyond improving our fundamental understanding of information processing in cortical neurons. Many devastating and complex diseases of cortical circuitry, such as autism spectrum

disorders or schizophrenia, affect poorly understood aspects of circuit organisation and disrupt higher sensory function, including the processing of sensory sequences and the resulting ability to make decisions based on sensory evidence. Reaching a better understanding of how cortical circuits achieve these functions is important for illuminating how the healthy brain constructs our experience of the world and how the functional consequences of brain disorders can be ameliorated.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term, conference communications and publications will be addressed to academics and other researchers (e.g. in industry), and this will be the earliest form of benefit. Other potential benefits primarily affecting academic and clinical researchers include:

- adoption of procedures refined during the course of this work (short-term);
- adoption of our behavioural tasks as an assay for testing sensory-decision function in the cortex of healthy mice and disease models (medium-term);
- improved understanding of brain function in disease models (medium to longer-term; any potential extensions to human patients would occur long-term).

We will also target public communication as we have done in the past: our group has a very strong track record of public engagement (school visits, lab demonstrations, public conferences, media appearances). This will occur over the short- to medium-term.

How will you maximise the outputs of your work?

- Dissemination of new knowledge through conventional scientific primary publications
- Deposition of data and of software code in public repositories and on journal websites REDACTED
- Collaborative publication of best practices in mouse training, arising from high-yield rodent behavioural experiments working group

Species and numbers of animals expected to be used

- Mice: 2900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice used only on Protocol 1 will only undergo breeding and maintenance. Those will be the majority of animals on this project. Experimental animals used on Protocol 2 will usually undergo behavioural training on a sensory-guided discrimination task, most often including (i) an implant surgery (sometimes including cranial surgery for implantation of devices such as electrodes, cannulas or a cranial window), (ii) daily head fixation using an implanted device, and (iii) a form of water or food control or restriction.

Implant surgeries will last about 1 hr. Daily training sessions will typically last between 30 min and 1 hr, but no more than 2 hr including all associated preparation. Animals will be given opportunities to top up their water intake after the end of the session and will not be left for more than 24 hr without access to water.

After surgery, animals will not be kept alive for more than 8 months. Training on a task will not last longer than 6 months. Training may be combined with recordings involving either electrophysiology or imaging, but not both.

Some animals will undergo anaesthetised recordings at the end of their use. Although experiments under anaesthesia do not allow one to test relationships between neuronal activity and perception, they can help establish fundamental properties of neuronal responses to sensory stimulation. Stimulation is highly controlled thus allowing for greater analytical power and reproducibility.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Pain and discomfort from tissue being taken for biopsy (duration: transient, seconds to minutes). Some genetically modified animals may have the potential to develop a harmful phenotype, e.g. tumours, neurological signs, after a certain age (cannot be fully predicted but all types of mice will be monitored for side effects). Some genetically modified animals may have an altered immune system. Blood loss and hypothermia could occur during surgeries (duration: tens of minutes; monitored in real time during surgery). Pain, physiological adverse effects (inflammation, infections, dehydration, weight loss) or distress could arise during surgery recovery and training, manifested in physiological or behavioural alterations (duration: up to a few days; monitored continuously).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild: approximately 86%.

Moderate: approximately 14%.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no realistic alternative to in vivo data collection for understanding how the brain generates sensory function. We use electrophysiology and optical (two-photon) imaging to record activity in vivo because other techniques cannot provide the resolution needed to analyse the activity of individual neurons. We combine recordings with behaviour because we need to understand how neuronal activity is modulated by brain and behavioural state, and how activity contributes causally to behaviour.

What was your strategy for searching for non-animal alternatives?

Computer simulations: these can help guide predictions based on known data.

In vitro experiments: these can provide basic information about how neurons and synapses work, about neuronal circuit anatomy and connectivity, and about how neuronal activity alters the signals (e.g. fluorescence from genetically encoded calcium indicators) that we use to monitor it.

Reuse of experimental data in repositories: as part of the movement towards open access dissemination of results, a growing amount of neuronal data collected in vivo from animals carrying out sensory-guided tasks is being made publicly available.

Why were they not suitable?

Computer simulations are not sufficiently constrained by experiment and cannot take into account unknown factors crucial for brain function, including changes in brain state or context for a given behaviour: to simulate the brain, we will need much more validated experimental data to generate meaningful output. Thus we cannot yet replace observation with simulations.

In vitro experiments cannot reproduce the behaviour of an intact neuronal circuit. We do use in vitro work to determine neuronal circuit connectivity and to check the expression levels and functioning of the sensors we use to monitor activity (e.g. calcium indicators). This is important to improve interpretation of our in vivo experiments and reduce the need for further such experiments.

Data currently available in repositories do not yet reproduce or approximate the experimental conditions described in this project. However, during the project's lifetime we will monitor openly available data and will reconsider our experimental plans whenever there is the option to reanalyse suitable data rather than generate it anew.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used statistical methods (power analysis) to estimate how many neurons we need to record in order to establish the proportions of neurons that play different roles in the brain when an animal is performing a sensory discrimination task. This gives sample sizes on the order of 400-500 neurons for each tested brain area. From this estimate we have derived experimental mouse numbers by taking into account the number of neurons that we can typically observe in a session, the proportion of neurons that are found experimentally to be responsive in an experiment, and the actual success rates for mice learning the task and allowing us to generate data. The resulting numbers of experimental animals are also consistent with those actually reached empirically in our previous licence.

We have also estimated breeding numbers for maintaining colonies of mice genetically altered to express indicators of neuronal activity, or molecules that allow us to manipulate activity. The majority of offspring with an appropriate expression genotype will be used for the experimental protocols.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Three key aspects of the experimental design are (i) the longitudinal use of animals to record activity at successive sessions during training, leading to a drastic reduction in the number of animals used; (ii) the development of training protocols that can generate several hundreds of trials (repetitions) of performance per session, enhancing statistical power; and (iii) the use of state-of-the-art techniques for neuronal recording and manipulation that allow data collection from many neurons in parallel during task performance. These, coupled to actual calibration of empirical success rates as described in the previous section, have both been taken into account in our estimate of numbers. All estimates involve the use of online tools for power analysis.

What other measures apart from good experimental design will you use to minimise numbers?

- Efficient use of animals bred both under this licence and under the authority of other licences within the establishment that allow for the breeding and maintenance of mice expressing genetically encoded reporters and effectors of neuronal activity. For example, we will avoid ordering additional wild type experimental animals whenever surplus mice can be obtained locally.
- Longitudinal data collection will not only include functional experiments as described above, but will also include tissue collection for histological analysis and any novel reagent testing.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The project requires a valid model for studying neuronal activity in the mammalian brain and how it gives rise to behaviour. Traditionally, this type of research was carried out in primates, the species most closely related to human. However, rats and mice can perform behaviours previously thought to be only within reach of primates. The networks of neurons underlying sensory processing have a fundamental organisation that is remarkably conserved across different mammals, so that rodents can provide a good experimental model for their study. At the same time, rodents have perceived lower sentience than primates and provide a standardised model for laboratory biology. Much knowledge has been built up over the years on basic mouse brain anatomy and neuronal properties, and new work can build on this, avoiding the need to re-establish fundamentals anew in a different species. Tools for genetically based targeting of neurons in mice permit more powerful and precise experiments.

Consideration for welfare of the animals is integral to the project's design. Animals will be given pain killers peri-operatively and closely monitored after surgery for signs of pain or distress. Animals routinely learn to perform the behavioural task without evidence of distress or ill health. We will ensure animals can reach the desired performance by combining incentives (positive food or liquid rewards) with the least severe form of restriction. A training approach in stages will be used to acclimatise animals and minimise stress. Animals will be group-housed wherever possible, with exceptions to this rule being when required for purposes of welfare (e.g. post-operatively) or when a single animal needs to be monitored for water and food intake.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The project's aims interrogate the relationship between neuronal activity and behaviour in the intact, embodied brain of a mammal aware of its sensory environment. This requires animals to undergo training in a sensory-guided task after having undergone an initial implant surgery. The need for a longitudinal period of training implies that implants must be stably mounted on a stably sized skull, hence the need to wait until the animal has reached adult size before starting training procedures.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Multiple refinements to procedures during and after surgery and to mouse training will be incorporated. Animals will be given pain killers and closely monitored after surgery for any signs of pain or distress.

The temporal separation between surgery, training and other procedures has been designed to ensure that any adverse effects can be monitored, that animals recover from any step before undergoing the next, and that accumulation of effects is limited. Training incorporates extensive monitoring and habituation. Animals are given rewards from the outset of training, at the step where they first become familiarised with the experimenter; rewards are combined with the least severe form of restrictions to encourage the animal to learn the task. Animals will have enrichment available in their home cage. These refinements are based on best practices shared by other labs as well as our own experience performing similar experiments under a previous licence.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will continuously refine our training procedures to follow best practice in this area, which is a very active one at the moment; e.g.,

Guo et al (2014) Procedures for behavioral experiments in head-fixed mice. PLoS One 9: e88678.

Burgess et al (2017) High-Yield Methods for Accurate Two-Alternative Visual Psychophysics in Head-Fixed Mice. Cell Reports 20: 2513-2524.

Goltstein et al (2018) Food and water restriction lead to differential learning behaviors in a head-fixed two-choice visual discrimination task for mice. PLoS One 13: e0204066.

Our participation in the NC3Rs working group mentioned elsewhere, through which we will disseminate any refinements throughout the community, also puts us in an excellent position to hear about and adopt any relevant updates to refinements developed by other researchers.

Surgical procedures will be carried out according to the published LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Several avenues:

- Participation in NC3Rs working group on 'high-yield rodent behaviour', through which we share best practice in this area;
- NC3Rs bulletins and newsletters;
- News and information provided by local NACWO/NTCO;
- Scientific meetings with presentations on mouse behaviour and training.

Explain the choice ofspecies and the related life stages

The project requires a valid model for studying neuronal activity in the mammalian brain and how this activity gives rise to behaviour, in an animal interacting with its environment and where the causal contributions of activity to behaviour can be experimentally dissected. Mice can readily learn to perform sophisticated sensory-guided behaviours, and the basic neuronal circuits for sensory processing and decision making are remarkably conserved across mammals. Mouse-based experiments can build on a wealth of knowledge concerning the basics of neuronal circuitry and anatomy, implying that reaching a certain level of insight requires less additional experimentation. Tools for genetically based targeting of neurons are highly developed in mice and permit powerful and highly reproducible experiments measuring and modifying neuronal activity.

Animals typically need to undergo weeks of training after undergoing an initial implant surgery. Thus, before beginning procedures, the mouse must have attained a stable size and behavioural repertoire. The project addresses the functional study of neuronal activity but does not require tracking changes in activity during brain development. For these reasons, the work involves animals that have reached adult size.

Home Office

NON-TECHNICAL SUMMARY

76. Identification of mechanisms that control resource allocation in mammals

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To understand how the baby communicates with the mother during life in the womb and during lactation (milk suckling), to obtain the food and other resources it needs. We want to know how genes (the set of 'instructions' in our cells that that makes us what we are) and what surrounds us (the environment) affect this communication between mother and baby, and how these processes affect our health when we get older.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We know very little about how and when a baby sends signals to the mother to get the food it needs to grow in the womb. The placenta is a specialized organ of the baby, whose function is to exchange food and gases between mother and baby. It is attached, on one side, to the womb through blood vessels and maternal cells, and on the other side, to the umbilical cord - that takes food and gases to all organs of the baby, including the brain. At birth the baby is delivered, followed by the placenta. Remarkably, the baby is somehow able to ask for more or less food by communicating its needs to the mother, through the placenta. Similar communication systems (of the baby to its mother) also exist through the period of breast feeding. We call these systems "resource allocation" systems. We know that genes play a role in this communication, as well as the environment too, but precisely how this occurs is not well known.

Studying resource allocation processes is important for two main reasons:

1- Suboptimal resource allocation is linked to developmental problems, from poor growth in the womb, called fetal growth restriction (FGR), to other pregnancy complications or 'diseases', such as pre-eclampsia - increased blood pressure in the mother- and gestational diabetes - elevated levels of sugar in mother's blood that go away after the baby is born**.** For example, FGR is a serious complication of pregnancy, which can result in the death of the baby in the womb (stillbirth) or soon after birth, and significant disease in early childhood and adulthood. FGR is thought to affect ~10% of all human pregnancies and contribute to about 1 in 4 stillbirths. Furthermore, newborn ill health amongst survivors of FGR pregnancies is significantly increased: 25% to 40% will require prolonged assistance with their breathing, and 4-6% will develop a severe gut disease called necrotizing enterocolitis. Long-term childhood disease for survivors of pregnancies affected by FGR is also increased. A total of 8% of all growth-restricted survivors will have some degree of brain impairment.
Low birth weight is also associated with increased risk of disease in later life (so called development programming of adult disease).

There is no effective treatment for FGR, despite the current clinical, social and economic burden (caring for survivors of an FGR birth in newborn intensive care costs the UK National Health Service at least £420M per year). Early diagnosis can allow intensive monitoring of the affected woman and baby but this only informs the crucial decision about when to deliver the baby (preterm delivery is itself a cause of poor pregnancy, newborn and childhood outcomes). The current REDACTED guidelines on care of pregnant women identified research on FGR as one of five research priorities. There is a considerable lack of drugs available, or even in the pipeline, to deal

with serious pregnancy problems such as FGR: in the last 20 years only one new class of drugs has been licensed for pregnancy applications and no new drug developed primarily for pregnancy applications is currently in clinical trials.

2- In the past few decades, it has become evident that healthy living and aging is determined not only by lifestyle choices but by the interaction of the genetic programme with the environment. Such interactions can occur at any stage of development, from embryonic life to adulthood and affect future generations through effects on developing germ cells (cells that give rise to sperm and eggs). Our understanding of gene-environmental interactions, in particular those related to parental resource allocation to offspring, are poorly understood.

Control of resource allocation is therefore a major component of growth and development in species like us (placental mammals) and is a key underlying cause of programming of adult disease. This work is important as it will address an enormous gap in knowledge in this area of study and will provide unique animal models for the study of effects, over several generations, of environmental cues on development and disease, whilst providing new drugs to treat pregnancy complications and long-term health outcomes (such as diabetes and obesity).

What outputs do you think you will see at the end of this project?

For every 100 human newborns, 10 to 15 do not grow well in the womb. Those babies are called fetal growth restricted (FGR) babies. The National Health System (NHS) spends vast amounts of money on treating the complications of FGR pregnancies in newborns and infants.
Moreover, being small at birth increases your risk of becoming diabetic and having heart problems in old age. At least 10% of the NHS budget is spent on treating diabetes of older people (type 2 diabetes) alone. Given that the quality of life in later life, and how long we expect to live depends to a certain extent on the events that occurred during pregnancy, there is a strong argument for the use of animals in the advancement of knowledge in this area of research. The overriding benefits to using mice to answer these questions are their short generation time and the ease of manipulating environmental conditions, but above all the possibility of altering their genetic make up. Resource allocation is under tight control of the genes in our cells, so the study of genetically modified models is likely to provide important new insights into this fascinating field of developmental programming of adult disease.

This project addresses two main questions: how do babies use maternal resources optimally, and why are babies that don't use those resources properly more likely to develop illnesses such as diabetes and cardiovascular disease? By answering these questions we should be able to come up with a solution to delay, reverse or prevent diseases in the womb, and their long-term effects (in the first instance in mice, which can then be tested for application to humans).

Specifically, the expected benefits of this project are:

1- Generation of three new mouse models of human pregnancy complications and/or metabolic dysfunction (that is, diabetes and obesity)

2- Identification of two new mechanisms underlying major pregnancy complications (fetal growth restriction; pre-eclampsia, which is a disease in mothers that is characterized by increased blood

pressure and abnormal substances in urine; and miscarriage, which is when a baby dies in the first six months of pregnancy)

3- Elucidation of two new molecular mechanisms that can explain why and how baby growth impairment is linked with diabetes in later life

4- Assessment of two potential drugs in mice for the treatment of fetal growth restriction/pre-eclampsia and/or type-2 diabetes

Major outputs will be scientific publications (expected to be around 8) describing the findings of the research with the above mouse models.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We are investigating issues related to the recent “explosion” in the number of people affected by obesity and diabetes, which cannot only be explained by our genetic makeup. We know that it is the interaction between genes and the environment that ultimately causes diabetes and obesity. However, we know very little about how the environment provokes changes in the behaviour/activity in our genes. We think that the answer to this lies in natural “chemical” signals that are physically placed or removed from our genes (this is called epigenetics, literally meaning on “top of our genes”). We will induce changes in these chemical signals (epigenetic marks) in mice that are exposed to sub-optimal nutrition or other adverse environmental factors (e.g. drugs, hormone-disrupting chemicals, manipulation of their eggs [oocytes] in a test tube), measure metabolic and cardiovascular characteristics in these mice, and see how these epigenetic marks contribute to the phenotypes of their offspring and of subsequent generations of mice (grandoffspring and great-grandoffspring).

The major benefit of our research will be the provision of new knowledge and the better understanding of growth diseases (including pre-conceptional causes) and associated developmental, physiological and metabolic complications. Other potential benefits relates to the early diagnosis of growth and metabolic-related diseases and the design of new therapies to prevent and cure these diseases.

Specifically, in the short term this project will identify the extent to which resource allocation is under the control of our genes, and how the environment interacts with the DNA to modulate these processes. In the medium term, the knowledge gained will assist in the design of drug or dietary interventions for the improvement of common pregnancy complications and metabolic complications (diabetes and obesity). In the long term, we hope that drugs or nutritional interventions that have been tested in animal models will inform human intervention trials.

How will you maximise the outputs of your work?

The main output of this work is in the form of scientific publications (primary research papers, literature reviews, book chapters). We will seek to file patents relating to discoveries with potential clinical impact. All datasets will be made publicly available upon publication. Our tissue bank will be shared with colleagues and/or used for future/other work.

Our work is highly collaborative. This project license will allow us to consolidate previously established collaborations, as well as setting up new ones. We feel that collaborative work is the fastest way to achieve progress and to maximize resources that can be of great benefit to groups of people working closely together.

Dissemination of our work and knowledge, beyond our research field, will be carried out to the lay public in the form of press-releases and attendance at public engagement events, as we have done in the past, having seen our work widely covered in the national and international press, and having participated in various science festivals/public engagement sessions.

Species and numbers of animals expected to be used

- Mice: 9840

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically in the 'parental' experiments we will perform dietary manipulations (i.e. diets with varied constituents) to the mother and/or father, genetically altered or not, at any stage of their reproductive age, and analyse the effects of nutrition in the offspring during intra-uterine life. We will also be able to apply a physiological stress, for example placing pregnant dams in an environment with low oxygen concentration, and follow the outcome in offspring, or a specific therapy to correct a specific pregnancy complication arising from a genetic manipulation. These parental experiments were devised to allow for the effects of environmental exposures, physiological stresses or therapies, that were applied to parents, to be followed in the offspring for several generations (so called transgenerational study). Within these experiments the main surgical procedure that might be done in some animals is the narrowing down of the maternal vessel that provides blood to the fetuses, with the aim of reducing the blood flow by 40%. After recovery from surgery, other procedures are terminal in some animals, for example, we will follow the transfer of nutrients from the mother to the fetus by measuring the accumulation in the fetus and placenta of a radioisotope injected into the jugular vein of a terminally anesthetized pregnant dam. Parents may also be injected with substances, or drugs delivered by small devices called 'osmotic minipumps', which are implanted under the skin and can slowly release the drugs as they expand in volume as water is absorbed. We will study the effects of these substances or therapies in the development of the offspring but also in the parents themselves.

In the 'offspring' experiments, we will follow and study the offspring, after they are born and all the way until they become adults, obtained from parents that have either undergone experiments or not (the latter act as controls). Under these experiments we will study the effects of diet, physiological stressors

and will apply potential therapies (via minipumps or injections) to correct health problems, primarily related to growth and metabolism (e.g. how mice handle high sugar in the blood stream).

The vast majority of mice to be used in this project will experience procedures that will only cause mild and transient discomfort. Importantly we also expect that health problems caused by manipulation of genes will not cause any lasting harm and will be sub-threshold or mild. Examples of procedures that will only cause mild level of non-lasting suffering are blood sampling, live imaging (that require some level of animal restraint), housing in specially designed cages, called metabolic cages, that we use to measure water, food intake, and collect urine and faeces, and tests devised to understand how food is being converted into energy, where either sugar or olive oil will be administered through a tube leading down the throat to the stomach, or insulin by injection in the area that contains the abdominal organs (or peritoneal cavity).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The major surgical procedures refer to insertion of fertilised embryos into the uterus (or womb), vasectomy (surgery that blocks the sperm to reach the male reproductive fluid) in male mice, and the narrowing down of the maternal vessel that provides the blood flow to the fetus, all of which may cause transient pain (however medication that relieves pain will be provided). There is a very small chance of infection as all the surgical procedures are done under the most stringent surgery guidelines.

The major experimental procedures that are not done as a terminal step (i.e. the mice will die after being given lethal dose of anaesthesia) relate to: a) the implantation of small mini-pumps to deliver drugs or other substances to the blood stream at a constant rate; b) the administration by oral gavage (through a tube leading down the throat to the stomach) of specific amounts of nutrients (sugar, olive oil), with small amounts of blood being taken from mice at regular intervals to see how long it takes for those nutrients to clear from the blood; c) injection of hormones like insulin, drugs or other compounds. These procedures will not lead to lasting harm, but instead are associated with transient pain and discomfort, which are mitigated by the prompt use of medication that relieves pain. In rare occasions, infection or inflammation at the sites of injection or implantation may occur.

Certain procedures such as those related to measuring blood pressure, imaging, or the placement of mice in a low oxygen (known as hypoxia) chamber, may require a period of adaptation. The adverse effects are mainly stress-related that can be alleviated by a short period of training.

The major abnormalities we are expecting to see from genetic manipulations will only affect a small number of mice, and are likely to arise during fetal life. These include fetal loss, prematurity, and developmental defects. The most common effects we expect to see in the genetically altered mice are related to growth (of the whole animal and/or specific organs) metabolic (not responding well to high sugar levels, not responding well to the action of insulin). Nutritional or genetic manipulation of a number of mice may render them pre-diabetic, diabetic, or obese. When studying how these animals respond to tests aimed to evaluate how they respond to insulin (the so called insulin tolerance tests), some mice may develop exceedingly low levels of sugar in their blood (called an hypoglycaemic event) which need to be counteracted with an injection of sugar.

Ill health (normally associated with piloerection - which is erection or bristling of hairs due to the contraction of small muscles at the base of hair follicles that occurs as a response to cold, shock, or fright- subdued behaviour, loss of appetite and weight, inactivity, shortness of breath, diarrhoea) will be a very rare event in mice used under this licence. We apply very strict criteria to define the health status of the mice, and depending on their wellbeing only mice will either be treated or killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect over 90% of mice to experience only mild and transient discomfort, with less than 10% experiencing moderate suffering.

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We want to understand how a fetus communicates growth and developmental needs to its mother through the placenta. Mice are the most suitable model for this project because of similar placentation processes to humans and because it is the most amenable species to genetic manipulations *in vivo*. The physiology of the mouse placenta, mouse growth and metabolism shares important features with humans, and can thus be used to model human disease. Mice also offer unique advantages when performing nutritional studies during pregnancy and metabolic studies during their life-course.

What was your strategy for searching for non-animal alternatives?

Observational studies in the animal are an absolute requirement for the successful completion of our aims. Where possible we will follow up these observational studies in the animal with non-animal cellular systems to gain mechanistic insight into specific cell signalling pathways.

Why were they not suitable?

The scientific understanding of placental, maternal and fetal signals that control resource allocation requires the study of whole organisms. For our work we need to apply physiological assays in a living mouse (for example placental nutrient transfer assays; or uterine blood flow measurements) in order to understand the interplay between the mother, the placenta and the fetus in growth control. While *in vitro* systems (that is cells cultured in a dish) are potent tools for dissecting molecular pathways, they cannot

address the kind of questions we are asking at the level of whole body complexity. We need to study how different cell populations behave and interact as part of a complex environment in a living animal. Each tissue type, for example fat cell, placental cells, liver, brain, heart cells sends out and respond differently to the signals present in the peripheral blood system such as it occurs in the whole living animal. This level of complexity can't be addressed in cell culture based experiments.

However, we will run experiments in cells as much as we can, in order to optimise better experimental design and to achieve a reduction in the number of animals required. For example, once we identify a target gene that we suspect might be involved in growth control, we will conduct gene knockdown experiments in cell lines (using technology, called siRNAs and/or CRISPR, that is based on the use of RNAs to guide molecular scissors to specific genes to cut them out) and assess the effects on cell proliferation parameters. We have and will continue to derive mouse embryonic fibroblasts (MEFs) (primary and/or immortalised) from many of the mutant mice we generate or hold. MEFs are particularly valuable for dissecting molecular pathways downstream of the gene of interest. We will also use appropriate human term placental samples from the REDACTED study, an ongoing study in our Department (REDACTED, which comprise serial ultrasonic data and maternal blood at 12, 20, 28 and 38 weeks of gestational age and placental samples, at birth, from 4000 unselected first time mothers) for translating our mouse studies into human populations. We will also use human adipose tissue samples from collaborators to provide translation of metabolic findings in mouse models of nutritional manipulations into human obesity and diabetes.

In addition, to translate fundamental biomedical research into clinically useful products or protocols, it is essential to test key hypotheses in pre-clinical models, such as the ones we will be developing during the course of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used are usually set with the help of a mathematical model, which we call a 'power analysis' method. It allow us to calculate the minimal number of animals we need to use, for a particular experiment, in order to find differences between groups of animals, whilst making sure that those differences we may find are not due to chance.

When appropriate, we conduct pilot studies to ascertain the variability of the data before applying 'power analysis' statistics. In some instances, previous experience (ours, or from the literature) is used to select sample sizes.
For this project we will also verify our estimates against new experimental tools that came to our attention within the National Centre for the Replacement and Reduction of Animals in Research (NC3R) website (https://nc3rs.org.uk/experimental-design-assistant-eda).

In general terms (of the numbers of animals required), we expect that ~ 8-12 animals per treatment group is sufficient to obtain the desired results for most of the physiological assays (for example, glucose tolerance test, which is a test we use to know how well the body clears an unhealthy amount of sugar we may have in blood; or placental transfer assays, which allows us to follow how well nutrients go from the mother to the growing baby across the placenta). For growth kinetics we use statistical modelling based on historical growth data we have accumulated over the years, in collaboration with local statisticians, which allow us to obtain an unprecedented level of accuracy for detecting onset of growth restriction and patterns of growth rates, whilst using the lowest number of animals possible.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Reductions in animal usage will be achieved through the use of *ex-vivo* methods (that is, organs or cells taken out from mice) and/or *in vitro* methods *(*that is, cells growing in a dish*)* and careful experimental design that includes power analyses and optimized breeding strategies (to reduce the number of mice that don't carry the genetic alteration and therefore do not show what we are looking for).

We will keep the number of animals to a minimum by making as many observations and measurements as possible on individual mice and by removing as many tissues as appropriate for *ex-vivo* studies (i.e. we collect most tissues and organs at post-mortem even ones that are not required at the time for any particular study - from this tissue bank, we are able to facilitate later studies without the need for additional numbers of animals, thus significantly reducing the need to use more animals).

In the past we developed *ex-vivo* and *in-vitro* models, such as primary culture of placental endothelial and pancreatic cells, which are the cells found in blood vessels and pancreas, respectively, and used established cell lines by others to replace or complement the studies using live mice (i.e. *in vivo*) for particular aspects of the work, and will continue to do so in this project. Replacing the use of mice for the core fetal growth studies will not be possible as we interrogate, for example, the communication between the placenta and the fetus, and the transfer of nutrients from the mother to the fetus through the placenta. However, by conducting some experiments *ex-vivo* and *in-vitro*, which are aimed at finding underlying cellular/molecular mechanisms, we are able to replace, at least in part, the use of animals for that specific purpose.

What other measures apart from good experimental design will you use to minimise numbers?

We collaborate with others in the placenta, growth control and developmental programming fields, sharing tissues, mouse embryonic fibroblasts (MEFs) and experimental results from our various genetically engineered mouse knock-outs. We are part of local schemes (i.e. Strain Enquiry list) that share information about strains, surplus of mice and potential tissue sharing.
Wherever possible we adopt non-invasive procedures enabling repeated measurements in the same animals (e.g. Time Domain Nuclear Magnetic Resonance, or TD-NMR for short, which is a machine that allow us to know very precisely how fat or how lean a mouse is) thus minimizing number of animals required.
Moreover, the culture in a dish of small sacs of fluid found on the outside layer of the ovaries, called follicles, which contain immature eggs (oocytes), and oocytes surrounded by specialized granulosa cells, called cumulus cells, will allow us to expose oocytes to high levels of stress hormones (e.g.

glucocorticoids) that could only otherwise be achieved *in vivo* through exposure of mice to very stressful stimuli (e.g. restraint, exposure to predator odors such as coyote, bobcat urine or tape-recorded calls of owls). This technique will therefore reduce animal suffering, as follicles or cumulus-oocyte complexes will be collected from dead animals that themselves do not need to be exposed to stressful stimuli.

To reduce the number of animals we usually perform pilot work in cells growing in a dish, to help the design of the *in vivo* work, and also use cellular models to complete, and complement, the *in vivo* experimental work. The design of our experiments and data preparation/publications are guided by the NC3R's PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) and ARRIVE (Animal Research: Reporting of In Vivo Experiment) guidelines, respectively.
We write comprehensive Study Plans for each experiment including: a statement of the objective(s); a description of the experiments, covering topics such as proposed treatments, the size of the experiment (number of groups, number of animals in each group), and the experimental materials; and an outline of the method of analysis of the results are included (which may include a sketch of the analysis of variance and some account of the tests of significance to be made and the treatment differences that are to be estimated).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

- We will use mice at all stages of development, and these include genetically altered animals and wild-types. We will use standard and state-of-the-art methods to produce genetically altered animals, alongside with specific methods to study resource allocation during pregnancy and lactation, and growth and metabolism in postnatal life. The vast majority of the procedures only incur transient pain and discomfort to the animal, and overall most of the protocols fall under the 'mild' severity level. A number of procedures we intend to do are 'terminal' (for example, euglycemic clamps, which requires maintaining a high insulin level in mouse blood for a specific amount of time, is a way to quantify how sensitive specific organs are to insulin actions, and placental transfer assays, which is applied to follow how well nutrients are transported from mother to the fetus, through the placenta) and the ones that are not, do cause the least pain, suffering, distress or lasting harm to the animals.
  However, some of our proposed genetic manipulations are likely to be associated with lethality around birth, (a common observation in mice with severe growth problems in the womb) and other developmental phenotypes (e.g. anemia, which is low level of oxygen carried by red blood cells, and increased risk for malformations of the brain). It will be difficult to predict the nature of developmental phenotypes that will arise in newly generated REDACTED. However, we intend,

for some selected cases, to study the molecular mechanisms that lead to those potentially harmful phenotypes. Once the phenotype is fully characterized and tissues are collected from those diseased animals, any subsequent work will be done at early stages of disease, therefore prior to the beginning of any overt discomfort.

- We will minimise suffering by using analgesia (which is medication that is given to relieve pain) and/or anaesthetic (meaning loss of sensation, which may include inducing sleep) or any potentially painful procedures and by careful monitoring of the animals to ensure they are not in discomfort. Once we have established the level of discomfort that might be caused by specific genetic mutations, we will apply clearly defined endpoint criteria to minimize suffering. In addition, we will endeavour to identify markers at the cellular level that are indicative of early onset of disease, thus minimising the need to maintain mice with overt disease.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have not considered the use of less sentient animals (sentient means ability to perceive or feel things) because our work is obligatorily focused on mammalian species, and all mammals are sentient). To achieve our objectives we need to use a mammalian species that have a placenta and that can be manipulated genetically.

Mice are the species of choice because specific genes can be manipulated (e.g. knocked-out) in either specific organs or the whole body (and importantly, the knockout mutation is passed on from generation to generation). This allow us to understand what these genes do during development of the animal – in our case, we are interested in genes that control resource allocation (e.g. nutrients) and the roles they may play, for example, in the placenta (the organ that provides nutrients from the mother). We have ways of following up the nutrients going from the mother to the fetus, as a terminal procedure, and if a gene is very important in this process we should be able to identify it by studying a mouse that does not have that gene working properly in the placenta. We have a number of procedures in which an animal has been terminally anaesthetised, and we use analgesics and/or anaesthesia to minimize pain of some of our procedures. We use non-invasive techniques as much as we can (for example to measure blood flow from the mother to the fetus and from the fetus to the placenta, or to measure body fat composition). To investigate how stress before conception can influence offspring characteristics, we will take eggs (oocytes) from the ovaries of dead mice and expose them to high levels of stress hormones; we could not naturally achieve these high levels of stress hormones in live mice without causing significant stress (e.g. restraint, exposure to a predator).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To improve the quality of life of the animals we:

- reduce contingent harm by group housing where possible to keep singly housed mice to a minimum. This in turn reduces any stress and stereotypical behaviour.

- use environmental enrichment EE, within what is available to us at our animal facility. In general, EE is an animal housing technique composed of increased space, physical activity, and social interactions, which in turn increases sensory, cognitive, motor, and social stimulation. Igloos, running wheels, saucer wheels, fun tunnels, and other objects in the housing environment foster this sensory cognitive, social, and motor stimulation by promoting exploration and interaction. EE can be maintained through restraining (e.g.handling tunnels), thus minimizing stress when for example an injection is needed.

- keep animal transportation to a minimum (most of our mice are bred in house and kept in one facility).

- use analgesics to lessen pain.

- provide 'behavioral' training to mice undergoing specific procedures (e.g. blood pressure measurements by tail cuff; acclimatization to hypoxic chambers; acclimatization to metabolic cages)

- use scoring sheets to monitor the health of animals undergoing procedures.

- use mash, with improved nutritional composition/palatability, for animals likely to lose weight- e.g. before they start a treatment where weight loss is expected
, and kept for the duration of the procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Laboratory Animal Science Association (LASA) guiding principles documents of aseptic technique (https://www.ubs.admin.cam.ac.uk/files/lasa_aseptic_surg.pdf)

ARRIVE (Animal Research: Reporting of In Vivo Experiment) guidelines for preparing papers for publication (https://www.nc3rs.org.uk/arrive-guidelines)

PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines for planning our experiments (15 topics including formulation of the study, dialogue between scientists and the animal facility, and methods) (https://www.ncbi.nlm.nih.gov/pubmed/28771074).

British Journal of Cancer (2010) May 25;102(11):1555-77 (https://www.ncbi.nlm.nih.gov/pubmed/20502460)

How will you ensure you continue to use the most refined methods during the lifetime of this project?

To be informed about latest advances we will primarily use the National Centre for the Replacement and Reduction of Animals in Research (NC3R) website (https://www.nc3rs.org.uk). It provides an

extensive library of 3Rs guidelines, resources, practical information and themed hubs. It also provides links to publications, other online resources, and video and training materials.

The REDACTED Biomedical Services website provides a portal to numerous sources of information, with a few listed below:

(AALAS) American Association for Laboratory Animals Science

(FELASA) Federation of European Laboratory Animal Science Associations

(ICLAS) International Council for Laboratory Animal Sciences

(InterNICHE) International Network for Humane Education

https://www.nc3rs.org.uk/welfare-assessment

http://enrichmentrecord.com/

https://science.rspca.org.uk/sciencegroup/researchanimals/implementing3rs/rodentwelfaregroup

Implementation of the advances will be defined on a case-by-case basis, and will be informed by the latest NC3R recommendations.

Explain the choice ofspecies and the related life stages

In species like humans, wellbeing and health in later life is in part determined by past experiences whilst in the womb. Life in the womb in mammals is made possible through the action of a specialized organ, the placenta, that provides the maternal nutrients and gases necessary for the growth of the offspring. We know very little about the communication between the fetus, the placenta and the mother and the 'signals' that regulate this seamless cooperation. For our studies we need to use a placental mammal, with placental characteristics close to human ones, and whose genome can be edited with ease so that we can interrogate the role of genes in the signalling between the placenta, the fetus and the mother. The mouse is the only animal that can fulfil this criteria, and thus the obligatory model for our studies. We will use genetically altered mice and also wild-type mice for our studies.

We will use mice that are pregnant and breast feeding so that we can study how genes can influence the nutrient resource allocation, through the placenta and the maternal milk. We will also study adult mice to understand better how life in the womb determines wellbeing and health in later life. When choosing both the animal species and life stages for our work one other overriding factor was the possibility of modelling human disease (e.g pregnancy complications and disease in later life, such as diabetes and heart disease), so that the data obtained could be applied to clinical research. Moreover, we made the conscious decision of using models and life stages that were amenable to therapy (drugs or nutrient manipulations) with the view of preventing, delaying or curing pregnancy complication and metabolic disease.

NON-TECHNICAL SUMMARY

77. Identifying genetic and biological factors and treating Otitis Media in mouse models

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To identify means to treat otitis media by determining the genetic basis, pathobiology and role of infectious agents in otitis media using mouse models of conductive hearing loss.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Otitis media (OM) is an inflammatory disease of the middle ear that is extremely common in children. Chronic OM with effusion (COME), also known as glue ear, is the most common cause of hearing impairment potentially causing learning delays and behavioural problems. The preferred treatment for COME is the insertion of grommets (the most common surgical operation carried out in the UK) but the effectiveness of this procedure is relatively low. Acute OM (AOM) associated with bacterial infection is the commonest reason for antibiotic prescription in the UK. There are currently no other effective treatments for COME or AOM. This significant clinical need can be met through discovering biological factors that influence OM using mouse models, these can then be tested as potential targets and means to better treat or prevent the disease.

What outputs do you think you will see at the end of this project?

By exploring the biology of the infected middle ear in mouse models of otitis media we will gain a fuller understanding of the genes and associated pathways that predispose to the disease, this data is likely relevant to disease in human. These combined studies will provide knowledge on host pathways, molecules and cells that can then be tested as candidates for improved therapy to better treat (drugs) or prevent (vaccines) disease.

All data obtained during these studies will be made publicly available through peer-reviewed publication and presentation at local, national and international scientific meetings and conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The data realized in these studies will inform us on factors relevant to human OM disease that will then be tested to potentially offer better ways to treat the disease in the clinic.

We estimate that we will study genes and pathways in two to four novel REDACTED over the time course of this licence; preliminary studies of the OM phenotype and host microbial interaction would take up to 2 years investigation in each case. Further detailed investigation of host-microbial interaction using human otopathogens will be undertaken in at least two established or novel REDACTED; in each case these studies would last for up to the duration of this licence and include investigations for therapeutic intervention (estimated 2 routes of vaccine administration of up to four formulations and 2 routes for drug administration of different immune modulating and antimicrobial substances). We would seek an industrial partner to take forward any promising novel treatment regimen once found.

How will you maximise the outputs of your work?

Through coordinated studies with an existing set of local, national and international collaborators and clinical partners we can enhance the level and diversity of output from our studies in the mouse models of OM. To take forward any promising novel OM treatment identified, we would seek an appropriate industrial partner.

Mouse models will be made available to other research groups and all data obtained and protocols used in our studies will be made available by publishing it in free to access format in high quality journals following peer review.

Output from the studies will also be presented to the scientific community through presentation at local, national and international meetings and conferences (including the biennial International Society for Otitis Media conference).

Species and numbers of animals expected to be used

- Mice: 31,100 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The most common experiment is the infection of mice by bacteria, typically these bacteria are applied through the nose of the mouse and then the bacteria in the nose and ears of the mice are assessed after 1 to 7 days of infection when the mice are killed humanely. Blood and other fluids are collected to

assess the effect of the interaction between the bacteria and the mouse. In some experiments changes in the middle ear are monitored after administering substances that might improve the disease outcome.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There is very little evidence of pain, distress or suffering through the development of OM for the animals used in our studies. Our experiments are carefully planned and implemented and any new substances to be administered are first tested in only a few mice. All mice used in the study are carefully monitored by the person carrying out any procedure and welfare assessment is recorded throughout the lifetime of the animal, these practices are well established in our animal house.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Over 80% of mice should be subject to only sub-threshold severity and the remainder would experience a maximum of Moderate severity during their lifetime.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The auditory system is complex and it is not possible to perform meaningful studies on hearing without using the intact animal. The middle ear itself is a complex structure that communicates with the nasal passages and nasopharynx via the Eustachian tube. Otitis media is inflammation of the middle ear space and is characterised by the accumulation of a complex inflammatory fluid and hearing loss, again this cannot be properly reproduced outside the animal. The natural route of middle ear infection is by ascending infection of the Eustachian tube, a feature that we mirror in our studies. To study the mechanisms of otitis media and treatment it is therefore necessary to work with living mice.

The mouse shares similar anatomy and physiology of auditory system and also shares disease genes that predispose to otitis media in humans. The mouse genome is known and genetic manipulation is possible and reagents are readily available to enable meaningful cellular, biochemical and immunological studies to be carried out. The hearing organs in lower animals such as frogs and fish are anatomically different from mammals and otitis media cannot be modelled in these species or in flies.

What was your strategy for searching for non-animal alternatives?

Some *in vitro* experiments utilising specific types of host-derived cell (e.g. stem cell derived immune cells or middle ear derived epithelial cells) can be used to examine certain features of that cell type and its role in host-microbial interaction and signalling.

Why were they not suitable?

The complex inflamed middle ear environment, which is the key feature of otitis media, cannot be recapitulated *in vitro*.

There are no effective alternatives to using live animals when carrying out studies on hearing and otitis media.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on extensive experience gathered for these types of study over many years of breeding and experiment and appropriate statistical calculations for the number of animals required we design robust experiments that minimize the number of animals necessary for study.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

For otopathogen infection studies we derive spontaneous streptomycin resistant versions of the strain before experiment whenever possible. This enables us to plate mouse samples on antibiotic containing media and avoid the loss of approximately 19% of data from count plates that occurs due to overgrowth of mouse indigenous flora when using non-antibiotic culture plates.

Power calculations used to decide the desired number of animals for experiment are carried out in consultation with a local statistician.

What other measures apart from good experimental design will you use to minimise numbers?

By carrying out several different analyses from multiple tissues and fluid obtained from a single mouse we have maximized the information that we obtain from any single animal and reduced the overall number of animals required for experiment. We also take bone marrow cells and middle ear cells from

mice to grow in the laboratory, by studying these cells we gather relevant information on their function and potential role in OM disease. Some studies to explore cell function are also carried out in the laboratory using available cell lines.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse will be used in the studies associated with this licence. OM occurs spontaneously in these mice and there appears to be little pain, suffering, distress or long lasting harm associated with this phenotype. In order to investigate the disease, we use minimally invasive procedures and anaesthesia wherever possible. Mice are often inoculated with pathogens that are placed in the nasal cavity of the mouse and/or treated with medicines to assess their potential for improving hearing and disease. Adverse reactions to these tests are rarely seen but may include some unforeseen response to particular medicines or vaccination.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The auditory system is complex but the architecture and function of the mouse ear is very similar to that of human. The mouse is the lowest mammalian species in which the full range of studies necessary for the scientific investigation of otitis media can be effectively carried out, with findings that are relevant to human disease. Some experiments on hearing can be carried out on frogs and fish but these are not informative on human OM as the animals do not get the disease.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We continually assess the impact that the experiments carried out have on the animals used. Welfare assessment is a key aspect of this project and will be performed and recorded throughout the lifetime of the mice, these practices are well established by the highly trained and experienced staff at our animal facility, where all mice are bred and housed. In addition, where ever possible non-invasive tests only causing temporary discomfort will be performed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The NC3Rs and ARRIVE guidelines will provide the best practice guidance for the use of animals in our procedures.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our Institute sends out regular updates on the 3Rs and once a month I check the website for any new information that is relevant to our studies. Through continual monitoring of the scientific literature and by attending relevant national and international meetings we can keep abreast of any advances in the scientific field that could help reduce the number of animals used for study or lessen the severity within any given experiment.

Explain the choice ofspecies and the related life stages

We investigate otitis media, a very common disease of human, that results in hearing loss. The mouse has similar anatomy and physiology of the auditory system compared to human and OM in the mouse closely resembles the disease in human. Mutant REDACTED develop symptoms of OM spontaneously in adults at about 4 to 5 weeks of age. The mouse is the lowest mammalian species in which the effective scientific investigation of OM can be carried out.

Many *in vivo* animal otitis media infection and treatment studies are carried out in the chinchilla (Chinchilla lanigera) because its auditory system is similar to that of man and disease can be reliably induced through direct inoculation of the middle ear. However, natural translocation of bacteria to the ear from the nasopharynx is difficult to achieve in this species and limited reagents are available for biochemical and immunological analyses.

NON-TECHNICAL SUMMARY

78. Imaging of Cardiovascular Diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult
Rabbits	adult
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim is to develop novel molecular contrast agents and imaging technologies for application in patients, and obtain the requisite information to determine whether they can be applied in humans. This overall aim falls into two key elements:

1. To determine, in vivo and in explanted tissues, the biodistribution, pharmacokinetics, targeting efficacy and mechanisms of novel contrast agents/therapeutic agents which have been developed with a view to application in humans with cardiovascular disease, for radionuclide, magnetic resonance, optical and X-ray imaging. To inform a decision on whether biodistribution studies or trials in humans, are justified.

2. To test in vivo and in explanted tissues, and provide proof of principle for, novel imaging techniques and instrumentation developed with a view to application in humans or animals (e.g. MR dynamic contrast, dynamic time dependent imaging, combined imaging modalities, or methods of correction for motion).

A retrospective assessment of these aims will be due by 23 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heart and circulatory diseases remain the most common cause of death in the UK and are responsible for approximately 240,000 deaths per year. Coronary heart disease is the most common single cause of death affecting about 117,000 people per year. Heart attacks frequently occur without preceding clinical symptoms but suddenly can lead to life threatening complications and approximately half of patients affected by a heart attack die immediately often before reaching hospital. The purpose of this project is to develop experimental animal models of cardiovascular disease to be used in proof-of-concept and validation studies of novel imaging methods, contrast agents and devices for earlier and more accurate diagnosis of heart disease, to better guide interventional treatment and to monitor how patients respond to therapy. If heart disease can be detected earlier with more understanding of the underlying pathology,

this may lead to better medical and interventional treatment of patients and eventually to a reduction in the disabling effects of heart disease and improved survival.

What outputs do you think you will see at the end of this project?

The project outlined will allow us, with the help of disease models, to develop novel imaging techniques and devices for image guided intervention that will help to better diagnose and quantify the severity of atherosclerosis (plaque build up in arteries) and myocardial ischaemia (lack of oxygen to heart muscle due to blockage of blood vessels) and to improve current interventional procedures for the treatment of cardiac arrhythmias, congenital heart disease and heart failure. It thereby may allow us to more efficiently treat patients with coronary heart disease and help to assess how patients respond to treatment. This knowledge will help us in identifying patients that are at high risk of a heart attack and provide the appropriate treatment to patients based on more quantitative and objective measures. Ultimately this study aims to minimise the number of heart attacks by early detection and interventional therapies and improve the efficacy of interventional treatments to cure atrial fibrillation (irregular heart beat) and heart failure.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The expected immediate benefits of this research are the ability to make an informed decision whether to test the new contrast agent in humans, or to abandon the agent, or return to the in vitro or chemical laboratory for further modification.

Better contrast agents and chemistry will improve the quality of imaging (e.g. by improving structural homogeneity, improving affinity, reducing blood clearance and excretion times thus improving target-to-background ratios, giving better detectability of smaller disease). Making radiochemistry of labelling simpler and more robust will lead to shorter production times and hence better efficiency (less technician time, less radionuclide waste by decay), and in turn to wider availability to more hospitals without costly cyclotron and radiochemistry equipment and radiochemical expertise.

Thus with more widely available contrast agents, more patients will benefit from the technology available. We expect several new imaging agents to be translated to human trials as a result of this programme of research. In addition, the benefit of validating novel imaging techniques and devices for image guided intervention will help to better diagnose and quantify the severity of myocardial ischaemia and to improve current interventional procedures for the treatment of cardiac arrhythmias, congenital heart disease and heart failure.

Whether directly by the development of new imaging technologies, or indirectly by use of imaging as a tool in basic biomedical research, better quality and wider availability and applications of imaging technologies will lead to better clinical decision making and better quality of life for patients, reduced drug development costs, and reduced costs for health services. Once these diseases have been identified in a patient, imaging also has the potential to non-invasively evaluate therapeutic efficacy, providing rapid feedback on therapeutic or interventional effectiveness. The beneficiaries will be patients, health services and pharmaceutical companies.

How will you maximise the outputs of your work?

We will closely collaborate with industrial partners to ensure that the developed imaging probes can be tested in phase II and III studies for safety and efficacy and ultimately be commercialised to ensure widespread clinical use of the developed probes for patient benefit. Similarly, we will closely collaborate with industrial partners to develop prototype software and hardware that can be subsequently shared with other academic centres for wide spread clinical testing. We will also disseminate the results of this work at conferences and workshops and publish in peer reviewed national and internal scientific journals. In addition, we will organise workshops at REDACTED where we will share our results and provide hands on training for REDACTED and external academics interested in this work. Other means of dissemination will include talks at the Pint of Science initiative or active participation in the summer festival of the Royal Society.

Species and numbers of animals expected to be used

- Mice: 14000
- Rats: 1500
- Rabbits: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, an animal in this Project License will be:

1) Induced to express a certain cardiovascular disease including atherosclerosis, aortic aneurysms, myocardial infarction, heart failure, cardiotoxicity and vascular remodeling by using special diets, surgical or pharmacological interventions.

2) Imaged in vivo by MRI, PET, SPECT, OCT, IVUS under anaesthesia either inhalable or injectable to detect cardiovascular diseases with or without administration of contrast agents.

3) Treated with therapeutics for modulation of cardiovascular diseases.

4) Humanely culled.

The duration of the experiment will depend on the Aim of the study and the individual Protocol used. However, all protocols have been refined to that the minimum experimental duration to achieve the scientific objectives.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The expected impact on the animals includes the induction of cardiovascular diseases including atherosclerosis, aortic aneurysms, myocardial infarction, cardiotoxicity, heart failure and vascular remodeling in a reproducible and controlled manner.

Typical adverse effects for the animals include:

1. Weight: Weight loss will be assessed in comparison to age-matched control animals wherever possible. To reduce animal use, control animal weights will be recorded and pooled into growth curve data that are specific to the strain and the animal unit.

- Weight loss of 10% or more in the absence of other clinical signs (see below) will result in increased monitoring and supportive measures such as wet mash diet.

- Weight loss of 15% in the presence of other clinical signs (see below) will result in humane killing.

- Weight loss of 15 - 20 % in the absence of any other clinical signs will result in humane killing.

2. Posture: Continuous hunched posture or repeated phases of intermittent hunched posture over a period of 24h or prostration will result in humane killing.

3. Food/fluid intake: Food and water consumption of 50% as compared to normal average intake over a measurement period of 48h will result in humane killing.

4. Diarrhoea: Intermittent diarrhoea is defined as diarrhoea that lasts less than 12h. Intermittent diarrhoea for a period of 12h will result in intervention in the form of increased monitoring frequency and rehydration. If the diarrhoea does not improve within the following 72h despite intervention, the animal will be killed humanely.

5. Coat: Animals with a staring coat with marked piloerection will be humanely killed.

6. Behaviour: An animal showing subdued behaviour, even when provoked, and little peer interaction will be humanely killed.

7. Body temperature: persistent hypothermia for 48h.

8. Abdomen shape: Animals showing abnormal visible distension of the body TOGETHER with weight increase AND abnormal breathing will be humanely killed.

9. Cardio-respiratory distress (rapid breathing, tachycardia, wheezing) would result in humane culling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The expected severities and proportion of animals experiencing each severity includes:

1. Mild 60%

2. Moderate 38%

3. Severe 2%

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 23 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We require the use of animals because:

1. Data generated from this body of work may be used to inform whether to go forward to human clinical applications. Regulatory agencies require animal data to demonstrate safety and efficacy before molecular imaging agents or therapeutics (that can be validated through imaging) can enter human trials.

2. To validate the mode of action new/improved molecular imaging agents, experiments are required that cannot be conducted in humans for ethical and scientific reasons (e.g. contrast agent distribution requires intact physiological barriers and excretion mechanisms).

3. Bio-distribution in whole organisms (i.e. tracking the injected agents route/ accumulation and excretion through the body), with intact biological barriers and excretion mechanisms, is key to clinical use.

4. Most aspects of cardiovascular pathologies can only be studied in live animals (e.g. atherosclerotic plaque progression, aortic aneurysm expansion, myocardial infarction and cardiac function) because

there are complex interactions between different body systems, which cannot be replicated in anything other than an intact animal.

What was your strategy for searching for non-animal alternatives?

Most of the contrast agents to be studied have not been used in man before and require animal data before approval for human studies. In many cases, even if the contrast mechanisms are well-established, it is unethical to use the tools (e.g., inhibitors) required to validate the corresponding targeting mechanisms and to understand the biological mechanisms in humans. However, in some limited cases, absolute replacement using humans is a possibility, e.g. when contrast agents that are already used in humans are evaluated for clinical utility and uptake mechanisms. If this is feasible and allowed by the regulatory agencies we will do so.

Although, non-animal alternatives cannot replace the complexities of the interactions of these probes in whole body systems or with realistic models of cardiovascular disease, prior to all in vivo work, human and animal cell- and tissue-based methods will be used as relative replacements to answer as many research questions as possible and build solid hypothesis to be subsequently tested in vivo. For example, this includes ex vivo experiments designed to (objective 1) determine target-binding efficiency, agent toxicity to cells, agent stability in cells/tissues/serum; (objective 2) phantom experiments to demonstrate function and capability of the new instrument. Any new/improved molecular imaging agents or instruments, which are found by ex vivo experiments to be unlikely to succeed in animal or later human trials will be eliminated at this stage

Why were they not suitable?

Alternatives apart from those listed above, are not suitable because non-animal alternatives cannot replace the complexities of the interactions of these probes in whole body systems or with realistic models of cardiovascular disease.

A retrospective assessment of replacement will be due by 23 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals required based on published information about the proposed animal models regarding the reproducibility and prevalence based on our own pilot data whenever possible.

A typical study might be planned as follows:

For testing a new molecular imaging agent in mice (Objective 1), we estimate animal numbers using a power calculation (two-tailed t-test, $\alpha=0.05$, power=0.9, typical measurements of 7.8±3.5(signal) and of 2±1(noise) yielding $\delta=5.5$ with $\sigma=3.5$) yielding N=9 animals/group. To account for complications with anaesthesia, specific diets, interventions or treatments, we would plan to investigate 10 animals/group. If target-to-background (signal-to-noise), or difference between experimental and control groups, is expected to be large (>1 order of magnitude change, e.g.in the case of using effective contrast agent blocking substances), or found to be so by pilot experiments, statistical significance may be achieved with fewer animals/group. However, we will not use less than 3 animals per group to comply with generally accepted scientific reproducibility criteria in the field.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Pilot experiments will be performed where necessary on small cohorts, to provide statistical data allowing animal number estimations for definitive larger experiments. Where possible, multimodal imaging will be used to multiplex and study two or more agents/mechanisms simultaneously in the same animal. Multimodal cross-validation will yield superior data because each animal will be the control for itself – data will be intrinsically paired. Sometimes, it will be possible to study >1 vascular pathology per animal (e.g., vascular remodeling and plaque progression in 2 different vascular segments), with the same advantages.

What other measures apart from good experimental design will you use to minimise numbers?

Imaging to determine tracer distribution rather than conventional ex vivo organ counting is a major contributor to reduction. It allows repeated time-dependent measurements on the same animal as animals are only killed at the last time-point; for example, if a study involves six time-points, the animal numbers are reduced to one sixth. Since each animal serves as its own control, the data are statistically also more robust, which in turn leads to further reduction as smaller cohort sizes are required (because inter-animal variability no longer needs to be considered at the experimental design stage). Moreover, not only contrast agent distribution in vivo, but potential time-dependent and unexpected re-distribution can be detected through serial imaging. All these attributes contribute to a greatly improved benefit: cost ratio (benefit=data quality/quantity, cost=animal numbers/procedures).

A retrospective assessment of reduction will be due by 23 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Species: Mice, rats and rabbits are the species of least neurophysiological sensitivity that provide the capability to support the development of various cardiovascular diseases (e.g., atherosclerosis, aortic aneurysm, myocardial infarction) and the minimum size compatible with the scale of resolution/movement associated with the imaging technique. Resolution of whole-body imaging techniques is of the order of 0.1-1mm.

Animal models: We will use cardiovascular disease models established through (i) use of genetically altered or wild-type animals that develop atherosclerotic in combination with high-fat diet, (ii) genetically altered or wild-type animals that develop aortic aneurysm in combination with chemical or pharmacological compounds, (iii) genetically altered or wild-type animals that develop myocardial infarction through surgical occlusion of the coronary artery, permanent or transient, (iv) wild-type rabbits that form atherosclerosis by a combination of surgical injury of the aortic endothelium and high cholesterol feeding and plaque rupture and thrombosis by pharmacological triggering, (v) genetically altered or wild-type animals that develop vascular remodeling following mechanical injury of the vessel wall, (vi) genetically altered or wild-type animals that develop cardiac diseases using chemotherapeutics, (vii) genetically altered or wild-type animals that develop vascular calcification with special diets and compounds. Only the models and progression stage that are key to a required outcome of each project goal will be used.

Methods: The use of cardiovascular models is necessary to pre-clinically validate new or improved cardiovascular-specific contrast agents. New and improved contrast agents will be validated in this project and hence, must be used in conjunction with the appropriate models. To thoroughly validate new contrast agents for later translation into human trials, the use of a variety of cardiovascular models is required. Their use is also required to perform preclinical studies in vascular biology including disease progression, vascular heterogeneity and evolution, and treatment response. To study vascular biology and exploit the power of existing and emerging imaging methodology, new and improved contrast agents are required to obtain the necessary imaging data. Differing cardiovascular models such as those of disease progression in mice and plaque rupture in rabbits are necessary to study progression and clinical end-points; in this context repeated imaging with specific molecular imaging contrast agents is a very powerful method to quantify atherosclerosis evolution and molecular changes that lead up to a clinical event over time. Various animal preparation approaches to define and control the development of cardiovascular diseases are essential for these studies; this includes modification of the lipoprotein system (either by using genetically altered strains or by special diets) and/ or surgical

interventions that cause injury to the vessel wall or the heart that trigger disease. Specific insight into molecular processes can be obtained either via genetic approaches (genetically altered animals) or via pharmacologic approaches (e.g. inhibitor molecules). To discover what treatments might reduce cardiovascular diseases the use of animal models together with therapeutic approaches is required, whereby repeated imaging serves as a very powerful method to inform on time-dependent changes in the very same animal; administration of therapeutics is mandatory in this setting. Moreover, cardiovascular models must be employed to pre-clinically validate new imaging instrumentation that is specifically developed for use in relevant applications. Common to all imaging methodology is the requirement of the animals remaining motionless during imaging, which renders general anaesthesia essential. General anaesthesia is also necessary for surgical procedures (e.g. myocardial infarction, vessel wall injury).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Less sentient animals cannot be used as they do not have a fully developed cardiovascular system to replicate the complexity of the diseases of interest.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Minimising suffering: Animal cardiovascular disease models are set up to develop cardiovascular pathologies and complications. As vascular and cardiac pathologies and cardiac disease progression and regression as well as the development of new contrast agents specifically aimed at the detection of molecular processes are goals of this project, we require to progress disease to late stages of development stages; also, treatment responses requires first that cardiovascular diseases are in place, which need to be treated (as compared to untreated control cohorts) to mimic realistic situations as normally relevant to human treatment. Animals will be monitored daily at early stages post-surgical interventions and at least three times weekly once early clinical signs have developed.

It is a part of PPL conditions and our ethical understanding that we let animals only develop cardiovascular diseases to a level of burden required to answer the specific research questions of each individual experiment, for example: (i) if initial in vivo experiments are performed to investigate the uptake of a new contrast agents in early atheroma, the answers can be obtained by the presence of relatively small plaques without the need of advance disease or plaque rupture; (ii) the use of repeated imaging in disease progression and treatment experiments where we then can quantify vascular and cardiac burden by imaging and obtain statistically better data (repeated imaging reduces suffering by reducing the required animal cohort sizes). In fact, imaging will help us in many cases to better assess the overall disease burden in our animals. Once an individual experimental goal is reached the animals will be culled regardless of whether the endpoint has been reached.

Inhalation anaesthesia will be used wherever possible to minimise transient pain and distress, e.g. during imaging. In addition, full recovery between periods of anaesthesia, rehydration during long imaging sessions, respiration/cardiac function monitoring, body temperature monitoring/maintenance

will be conducive to animal wellbeing. If food withdrawal is required for metabolic studies, we will use further spaced out repeated imaging to allow the animals to take in food ad libitum for a minimum of 28h before the next session of food withdrawal.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow established published guidelines to ensure experiments are conducted in the most refined way. These includes:

1) The Responsibility in the use of animals in bioscience research produced by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs).

2) The Home Office Guidance on the Operation of the Animals (Scientific Procedures) Act 1986.

3) Accepted limits of volumes and frequencies when administrating compounds and anaesthesia (Appendix 1a in Action Plan section).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed by updates from the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) website and seminars on the 3Rs organised within and outside of our institution.

Additionally, we have direct support and contact with an NC3R's regional Programme Manager who supports the application of the 3Rs at REDACTED and is a member of the Policy and Outreach Group. This includes providing expert advice and coordinating the sharing of best practice.

Explain the choice of species and the related life stages

Adult murine, rat and rabbit models of cardiovascular diseases are used in this Project License because they reproduce many of the traditional cardiovascular risk factors associated with the development of atherosclerosis, aortic aneurysms, myocardial infarction and heart failure, vascular remodeling as seen in the corresponding human conditions.

A retrospective assessment of refinement will be due by 23 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

79. Immune phenotype and dynamics in ocular autoimmune disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To identify and measure mechanisms that regulate ocular autoimmunity. To assess the efficacy of therapeutic manipulation of some of these mechanisms.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is known that in some diseases the immune system attacks otherwise normal tissue with potentially devastating consequences. Many human illnesses are autoimmune in origin and one is idiopathic inflammatory eye disease (generally known as uveitis). The chronic nature and cost of treatment for these conditions places an enormous burden on modern health care. Uveitis is a leading cause of blindness in working age adults living in developed countries; new cases present at a rate of 75 people per 100,000 and up to 35% of patients become visually disabled. Poor vision secondary to uveitis impacts significantly on general quality of life. The minimum cost of treating one patient with uveitis for one year in Europe in 2008 was £3,600. The current state of knowledge is that autoimmune diseases arise in the context of a permissive genetic background, following a triggering event. Following this triggering, the disease process can be characterised as a chronic inflammation, that damages normal tissue function and that waxes and wanes with time. Many different cell types are recruited to the target organ, showing that autoimmunity arises through the co-ordinated effects of many different signalling events. The complexity of the response is the reason that studies of the whole organism are essential for research into treatments for autoimmune disease. This research into animal models of uveitis will have the benefit of revealing how specific mechanisms can be manipulated to produce an improved clinical outcome.

What outputs do you think you will see at the end of this project?

New information: We expect to develop new information characterising the dynamics of ocular disease. We will also produce new information on the regulation of tissue health in ocular inflammation by specific molecules in signalling and effector pathways. Finally, we expect to have shown the impact of novel interventions.

Publication by poster and oral presentation at national and international meetings such as the annual meeting of the association for research in vision and ophthalmology (ARVO).

Publications in peer reviewed journals such as the Journal of Immunology or Nature Immunology. We are also active in outreach to patient groups and lay members of the public, where we present and discuss research.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Short-term benefits (throughout project): Increase in knowledge of uveitis, and the development of models and strategies for analysis that can be applied to human disease. Training of individuals who specialise in ocular research.

Medium-term (over 2-5 years): Communication to a professional audience through publication and a wider audience through outreach to patient and public groups.

Long-term (greater than 5 years): Validation of therapies for the treatment of uveitis in humans and animals using novel approaches based in part on the understanding of the disease developed during this project.

How will you maximise the outputs of your work?

We maximise the outputs by seeking out collaborations with scientists working in other disciplines (engineering, mathematics) who can use data produced in out investigations to develop novel approaches to mathematical modelling and image processing.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The project studies ocular inflammation at the back of the eye. This is an autoimmune process with minimal systemic side effects. It arises following treatment that leads to an immune response that is directed at the retina and causes inflammation, and tissue damage. This treatment requires the injection of substances that initiate the immune response, or of cells that cause the disease. Following the induction of disease, images from the back of the eye can be recorded with specialised equipment, to be analysed to determine, for example, if an experimental treatment can reduce disease. This sometimes requires that animals receive a general anaesthetic. Rarely (1% of experiments) following

whole body irradiation, animals will receive a bone-marrow transplant. This is a stressful procedure of moderate severity.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We carry out these studies in mice, for whom sight is a secondary sense. In general, uveitis is not painful and animals show little abnormal behaviour during the course of disease. As in humans, the initial disease sets up a long-standing grumbling inflammation that comes and goes through time. By monitoring this in the long-term we can investigate how patients with chronic persistent disease might be treated. Generally experiments are carried out over a period of months, but some studies last as long as a year. Animals that receive a bone-marrow transplant recover to normal behaviour over about a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild and subthreshold in 99% of cases. In 1%, where animals receive bone-marrow transplants, the severity is moderate because of this.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The study of fundamental and novel mechanisms of disease continues to rely on whole animal models because the complexity of the pathology cannot be mimicked in simpler systems. All modern drugs developed for the treatment of human disease have relied on the use of animal models. Experimental autoimmune uveitis (EAU) in mice is a mild disease that does not produce systemic distress related to the disease process and uveitis cannot be studied in simpler models, as the effects on the anatomy of the eye are critical in assessing the disease. The rodent model is therefore the least severe approach to addressing our objectives. Suffering is minimised by using the least severe experimental model relevant to the underlying mechanism and using clinical monitoring that detects the effects of interventions at early timepoints.

What was your strategy for searching for non-animal alternatives?

Where appropriate we use in vitro models of immortalised cells and primary cell lines to assess the biochemistry of individual pathways, identify appropriate drug targets and validate them prior to use in more complex disease models.

Why were they not suitable?

In vitro models do not recapitulate the complex anatomy of the eye or the physiology of the disease process of EAU, nor are they suitable for studying how the disease develops through time, which is a crucial aspect of these chronic conditions in both animals and humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Breeding is estimated at 500 animals per year, based on current usage in our group. Experimental usage is estimated at 300 per year which is 10 experiments per year divided between two post-graduate/post-doctoral researchers.

Sample size calculations are calculated by computer modelling to estimate how many animals are necessary for an experiment to have approximately an 80% probability of detecting a real difference between groups.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Online tools were consulted but by and large they assume the use of parametric statistics, which are inappropriate for clinical assessment of EAU and assessment of EAU by cell counting, even after standard normalisation procedures. We therefore used statistical packages in R that allowed us to estimate sample sizes.

By comparing cell numbers in treated versus untreated animals, we can use a stepped design, where the total numbers for the experiment are split over two or more time points, coupled to a Bayesian analysis, so that if see larger effects than we have modelled for, we can stop the experiment when a robust data has been obtained.

What other measures apart from good experimental design will you use to minimise numbers?

We use efficient breeding, pilot studies, computer modelling. Tissue sharing occurs on an ad hoc basis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

EAU is a model of autoimmune disease that has little impact on mouse behaviour, but offers a powerful model to study the basic mechanisms of the disease and the effects of interventions on immune system function. In comparison to other disease models, the levels of distress are lower and this allows for longer term experiments which can address important aspects of the disease process.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Autoimmunity is an emergent property of vertebrate immune systems. It is influenced by age, sex and environment. While individual pathways can be isolated in some circumstances, the disease cannot be modelled in a less sentient species.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We continue to refine our methods for monitoring clinical disease and are actively studying unsupervised algorithm and machine-learning based approaches to allow us to analyse disease through time, develop more sensitive measures of treatment efficacy and correlative approaches to better quantify immune changes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We participate actively in 3Rs seminars, presenting our approaches and learning from others.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through continuing education including attending and contributing to 3Rs focused seminars and lectures.

Explain the choice ofspecies and the related life stages

We use animals that are known to be susceptible to the disease experimental autoimmune uveitis (EAU), and which develop this disease from the juvenile (4 weeks of age) stage onwards. Typically mice are 6-8 weeks of age at the time of experiments.

Home Office

NON-TECHNICAL SUMMARY

80. Immune responses to persistent infection and vaccines

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims to understand how the immune system responds to viruses, cancers and vaccines, and to use this information to design better therapies and new vaccines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Infections and cancers are major human health threats. For infections we know that immune responses are important and we also know that vaccines are one of the most effective medical interventions ever created. We still lack vaccines for many important infections such as hepatitis C, HIV, Cytomegalovirus and Epstein Barr Virus. In recent years the power of the immune system to protect against cancers has been revealed. The same processes that generate effective immune responses against viruses can also impact on cancers. The aim of the project is to unpick in detail how the immune system recognises viruses and vaccines and to harness this information to produce better interventions in a range of settings.

What outputs do you think you will see at the end of this project?

New information that will help to understand the nature of the immune responses to viruses and vaccines, the role of specific new types of immune cell and also how we may harness these responses to tackle cancer. The information on how best to use the vaccines can be directly used to design better strategies (types of vaccine or combinations of vaccine) in different infections and cancers. We aim to publish the results in peer-reviewed journals and conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Within the timescale of the project we hope to have answered a few key questions about how the immune system responds to vaccines and viruses. For example the role of a new type of immune cell (the REDACTED cell) and related cells that have not been well explored in this context. We also hope to have answered questions relevant to the use of such vaccines in cancer therapy to help design trials in patients for cancers such as melanoma. These trials and vaccines are being designed over the next 2-3 years and our results can help contribute to making the best vaccines from the different choices available. The research community will also benefit from knowledge obtained.

How will you maximise the outputs of your work?

We have collaborated widely to improve the outputs of the work and have colleagues in labs across the world whom we will share our data with. This includes academic colleagues in universities as well as collaborators in biotech companies aiming to develop vaccine strategies. We also will present the data at scientific conferences in the fields of immunology and infection as well as cancer immunotherapy and publish the data in respected journals (recent publications are in Cell Reports and Nature Communications for example). The data published will include the relevant negative data as well as positive results which can be followed up by the field.

Species and numbers of animals expected to be used

- Mice: 15000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically a mouse will receive an injection (eg. immunisation with adenovirus) followed by four blood tests taken over a period of eight weeks to test the effect of the immunisation. A proportion of these animals may also be challenged with an infectious organism (e.g. influenza) or administered with an anti-cancer compound after a challenge with a tumour.

All animals will then be killed humanely before one year of age.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There will be minimal impact from the immunisation and at most short term general effects related to any vaccination (<48 hrs). There may be some transient pain associated with a subsequent blood test to assess immunogenicity.

For experiments where antibodies will be injected (eg: depletion of specific cell-subsets using monoclonal antibodies), there is a risk of reaction against the 2nd dose of the antibody (e.g. a severe allergy). Should this reaction occur (recognised by rapid onset of immobility and a change in breathing pattern) mice will be killed immediately.

For experiments involving tumour challenges we will monitor the size of the tumour over subsequent days to weeks to assess growth and stop the experiment appropriately according to well-defined humane endpoints (in particular tumour size).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Expected severity for protocols 1 and 2 are expected to be 50% moderate based on previous work. Mice in protocol 3 will mostly experience sub-threshold severity and it is estimated that less than 5% will experience mild severity from ear notching or blood sampling.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Despite efforts to carry out replacement strategies using organ cultures, not all of the cell types involved in vivo can be successfully grown in vitro and therefore the immune responses cannot yet be fully replicated in vitro. Consequently, animal models are still required to study the mechanisms of immune responses during vaccination and infection.

What was your strategy for searching for non-animal alternatives?

We are developing models to study some of the simplest elements of virus persistence in cell culture. For example we have set up infectious model systems for HBV and HCV where intracellular responses can be assessed. We are also working on models of human tonsil where some aspects of immune homing can be measured in vitro. If we have indications from these cell culture models which could lead to replacement of the planned in vivo work we would take advantage of this.

The lab works with human studies including analysis of Phase 1 clinical trials. The experiments planned are only those where we cannot achieve the same objectives by analysis of human subjects. These trials have focused on the development of adenoviral vectors for prevention and therapy of Hepatitis C Virus and for protection against Respiratory Syncytial Virus (RSV). We have ongoing studies of HCV, HBV, HIV and CMV in the lab, as well as analysis of human innate T cell responses such as REDACTED cells which can control bacterial and viral infections in tissues. These data have been used to plan better experiments in the mouse model, which can then be used to address questions most relevant to the clinical setting.

Why were they not suitable?

Such ex vivo experiments cannot address the immunogenicity of a range of vaccines - we can only test very few vaccines in humans. To define which of the potential approaches might be best (and safest) we still require an intact and flexible in vivo system. It also needs such a system to assess the efficacy of induced responses against challenge. Finally, we cannot fully address the mechanism of action of specific components of the system (eg: specific cell types) unless we use an in vivo model where they are lacking or modified.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have largely estimated them based on previous usage over a period of time. For each individual experiment the numbers used are based on power calculations for the appropriate endpoint (e.g. immunogenicity or protection) - these numbers are typically in the order of 5-10 per group for most experiments. The total numbers included also take into account mice needed to establish breeding colonies for specific experiments, although clearly we aim to keep those numbers to a minimum.

During the analyses of immune responses in the key experimental protocols, we typically find small standard deviations (measures of how variable the readings are). In these experiments we are also looking for large effects (eg: 5 fold), but also those which distribute over time, which increases the power of detection. In a typical experiment, if the vaccine induced T cell response is 2%, with a standard deviation of 0.3, we can detect a 50% reduction in response in the experimental group (with similar standard deviation), with $p=0.001$ (a p value less than 0.05 is generally regarded as significant in such studies). If the standard deviation were increased to 0.66 (range 1.2-2.8 for the control group and 0.2-1.8 in the experimental group), we can still detect a response at $p<0.05$. Thus for experiments of this kind 5 per group provides appropriate sensitivity to detect moderate effects even at a single time point.

For gene expression experiments n=3 is the minimum required to generate statistically robust datasets and we have already achieved this. We have a bioinformatician working in the group who can provide further ongoing advice about statistics. Using group sizes of 3 we can use standard statistical tools (based in the package R) to define gene expression profiles taking into account multiple comparisons using RNAseq techniques. For the emerging technology of single cell RNAseq, which gives greater resolution of transcriptional activity, we have developed parallel techniques which also work on groups sizes with a minimum of 3.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In many cases, the numbers of animals required will be reduced by repeated, longitudinal measurement of responses through serial blood analysis. The immune response to an immunisation may be measured weekly in a set of five mice over a period of several weeks rather than culling five mice every week. This approach also provides valuable information on the development, or not, of protective immune responses prior to challenge with a pathogen or tumour. We will be using the NC3Rs' Experimental design assistant which we have used during our previous licence.

What other measures apart from good experimental design will you use to minimise numbers?

Animal numbers will be optimised by purchasing wild type mice for specific experiments rather than breeding them. Genetically modified strains bred in-house will be closely managed and where possible both males and females used.

We routinely use many tissues from a single animal at the end of the experiment instead of using individual animals for each tissue. This overall reduces the number of animals required.

Occasionally we will share tissue with other members of the group to perform genetic analysis of responses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The complex interaction of immune cells and tissues dictates the need for using model organisms . Mice have a relatively short lifespan and are also considered the least sentient species available for this type of analysis of immune correlates of protection for many human pathogens.

The immune system of mice has been well-studied over many decades and there are well-optimised reagents and protocols available. The immune cell biology of mice currently provides the best and most highly characterised model for understanding human immunity.

We are able to use the wealth of published data to design and refine our experiments leading to contribution to this knowledge through our own publications. This contribution will in turn reduce and refine animal experiments in this field.

In the previous licence we used rats to test models of hepatitis C and the vaccines against this disease. This was successful but we can refine the experiments now using mice as a new model has been developed using the same virus. This will provide an important refinement for this study.

When experiments involving Listeria challenges are undertaken we will use Listeria monocytogenes DPL 1942 expressing ovalbumin when possible. It is genetically attenuated and therefore less pathogenic than wild type L.monocytogenes.

Animal welfare and well being will be closely monitored in close collaboration with the highly trained BMS staff.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The mouse immune system has been shown over time to be a good model to use for human immunity, especially in the context of vaccines. Only mammalian immune systems contain all the relevant components we need to analyse and the well-defined structural composition (lymph nodes and organs) makes this a very accurate system to define the totality of the immune response of the animal. The experiments require days or weeks for the immune responses to develop and require an intact adult animal for completion.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The mouse is a very well defined model for immunologic experiments and the model proposed using MCMV, adenovirus vectors and other viruses is highly reproducible and therefore can be used more efficiently and with the maximum refinement. For example we have developed the use of the non-replicating adenovirus model, which has less impact on the animal and used protocols we have refined over time. Thus we have minimised the amount of blood drawn per time-point by optimising lab immunology protocols and minimised the numbers of bleeds required per protocol. The use of a range of highly defined genetic (genetically altered) models with specific immune defects to probe the mechanisms of antigen presentation and T cell activation/homing make the mouse model especially appropriate. In particular we can now use mice with tissue-specific expression of Cre recombinase, a molecule which recognises specific (Flox) sites in DNA and allows activation of such genes in vivo. Such animals can be infected with adenoviral vectors where the antigen can be modified through insertion of Flox sites, or crossbred with specific genetically modified strains expressing genes under Flox sites: this very specific approach reduces the chance of encountering a harmful phenotype which could be encountered using genetic knockouts in all cells. We will also in some experiments use a doxycycline or Tamoxifen-inducible Cre system to allow for temporal control of Cre expression, allowing us to refine the model further.

Following an amendment to our previous licence we developed a challenge model for Hepatitis C in rats. A mouse-adapted strain of Rat Hepacivirus (NrHV) is now available meaning we are now able to develop this model in mice.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The NC3Rs website provides guidance to best practice through e-learning, blogs and videos. Information to aid design and planning of experiments is also available, in particular, the experimental design assistant.

Guidelines for the welfare and use of animals in cancer research by Workman, P. British Journal of Cancer (2010) 102(11), 1555-77) provides guidelines for the tumour work under protocol 2.

Relevant LASA publications https://www.lasa.co.uk/current_publications/

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The REDACTED has an NC3Rs regional program manager and can provide expert advice and co-ordinating the sharing of best practice. There are also termly meetings for all PPL and PIL holders where information on the 3Rs is often disseminated.

We also use the handbook, Festing MFW and Altman DG, 2002 ILAR J; Festing MFW, Overend P, Gaines Das R, Cortina Borja M and Berdoy M, The Design of Animal Experiments (2002) Laboratory Animals Ltd., London, to inform experimental design.

Explain the choice of species and the related life stages

Adult mice will be used in this project. There are well defined models and reagents are readily available.

NON-TECHNICAL SUMMARY

81. Immunity and haematopoiesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim is to identify novel pathways that regulate immunity and haematopoiesis during homeostasis and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system has evolved to protect the host and fight disease. It works throughout the body, interacting with the multitude of organs and tissues, and the nervous system, to maintain immune homeostasis and tissue repair, and defend from infection. However, there are occasions when the host immune system fails to combat the attack.

For example the World Health Organisation (WHO) estimates that virally and bacterially-induced Pneumonia and diarrhoea combined lead to 29% of all child deaths globally; that over 880 million children require treatment for helminth parasites; and that in 2017 there were 219 million cases of malaria (a protozoal parasite) worldwide with 435,000 deaths. By understanding the immunobiology of infection we aim to discover new opportunities for better prevention and treatment of disease, to reduce human suffering. For instance, one of the greatest achievements of the 20th Century was the almost total eradication of poliomyelitis following the development of the polio vaccine (99% reduction from 1988 to 2010). However, for many diseases we still have no working vaccine.

In other instances the immune system over-reacts leading to auto-immunity such as inflammatory bowel disease, or may be inappropriately elicited e.g. when pollen or house dust mites cause allergy and asthma. In many of these inflammatory diseases the immune system becomes dysregulated and anti-inflammatory responses that should protect from excessive collateral damage become misdirected. Asthma is a common chronic inflammatory disorder that is characterised by inflammation and hyperreactivity of the airways, and afflicts approximately 235 million people worldwide including 1 in 5 children in the UK. Significantly, 5 – 20% of sufferers develop severe asthma that is not controlled even by newly developed treatments (arising from immunology research). Furthermore, there is growing awareness that acute asthma exacerbations are often associated with viral infection. WHO also predicts that by 2030 chronic obstructive pulmonary disease (COPD), for which there is no effective treatment, will become the third leading cause of death globally. It is critical that we understand the fundamental regulation of the immune system so that we can continue to develop new therapies to relieve human suffering.

Notably, in some circumstances the cellular and molecular peacekeepers of the immune system can be silenced and fail to destroy abnormalities like cancer. It has been estimated that in 2018 ~9.6 million people died from cancer (WHO). However, recent studies of the immune system, relying heavily on fundamental experiments using mice, have led to the development of new therapeutics that prevent immune suppression and enhance immune-mediated killing of cancer cells. Whilst, this is a significant

breakthrough in cancer treatment, and yet another validation of the importance of studying the immune system, not all cancers can be treated successfully with these new drugs, highlighting the importance of continued work to discover new targets.

Interestingly, the maintenance of immune balance impacts on tissue homeostasis. For example, a lean healthy body is associated with the presence of a type-2 immune microenvironment, whilst obesity is associated with type-1 immune reactions. The incidence of obesity is increasing (1 in 4 adults, and 1 in 5 children in UK are now considered obese - NHS), with significant effects on susceptibility to other diseases including cancer and asthma. Once again, it is critical that we investigate the contribution of the immune system to the deleterious effects of the over-consumption of food.

The aim of this project is to investigate the fundamental regulation of immune responses to identify new targets for therapeutic intervention.

What outputs do you think you will see at the end of this project?

The immune system is critical for the defence of the body from infection, but it can also misfire and start to attack the body (autoimmunity). Infectious disease is the biggest killer of mankind world-wide. Viruses alone kill more than twice as many people each year as cancer. Asthma is a common chronic inflammatory disorder that is characterised by inflammation and hyperreactivity of the airways, and afflicts approximately 235 million people worldwide. Although many asthma patients respond to corticosteroid medication, such treatment can be associated with negative side-affects. Significantly, 5 – 20% of asthmatics develop severe asthma that is not controlled by standard treatments, and they account for a significant proportion of the morbidity, mortality and cost of the disease.

There is therefore a desperate need to understand how we can selectively arm the immune response to combat pathogens, or pacify inappropriate immune reactions that harm the host. With this knowledge we can work towards better prevention of disease (through vaccination, prophylaxis and good practice), improvement in diagnosis at an early stage to increase the benefit of treatment and/or reduce transmission, and development of new therapeutics. These are long-term goals, but the objectives of this project are to provide some of the necessary information to make this possible.

Consequently, the immediate core benefit of the work will be that we will increase our fundamental understanding of the molecular and cellular pathways that regulate haematopoiesis (the process of making immune cells) and immunity, especially asthma and allergy. A better understanding of these mechanisms and specific candidate genes will allow us, and the scientific community, to develop novel approaches to modulate immunity and blood formation to prevent disease.

We have disseminated our research in over 90 manuscripts published over the past ~9 years. Furthermore, within a similar time-scale we have produced two novel antibodies (anti-IL-25 and IL-25 receptor) that have been humanised and licenced to pharmaceutical companies, for the treatment of asthma and allergy.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

The important long-term benefit of our research is to contribute to the development of treatments to both prevent and treat immune and haematopoietic diseases. We have already identified new therapeutic targets and developed drugs that are in preclinical development for the treatment of asthma and allergy and continuing with these studies will enable us to support work to take these drugs forward for clinical trials. In addition, we will continue to pursue the identification of new treatment strategies, for example by using disease models to identify novel gene candidates that can be targeted therapeutically.

In the longer-term we expect our findings to inform and guide new therapies in a variety of human diseases including asthma, allergy, autoimmunity and obesity.

The generation of transgenic animals within this programme will also be valuable to other scientists aiming to develop therapeutics to these and related diseases by facilitating more rapid progress in their investigations.

How will you maximise the outputs of your work?

It is important that our work is made available to the wider community once we are satisfied that it is robust and reproducible. All our published research manuscripts are available through Open Access.

I am also invited to present our work at national and international conferences where we can present work in-progress before publication. This can generate new ideas and lead to collaborations. Indeed, we have a number of collaborations world-wide, with research scientists and clinicians, in which we provide know-how or reagents.

Species and numbers of animals expected to be used

- Mice: 70,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Our experiments in mice will mimic, in an experimentally controlled fashion, the various scenarios the immune system has to deal with (e.g. vaccination, infection, autoimmune disease, asthma, inflammation, cancer). The majority of mice are expected to experience only very mild, if any signs of discomfort.

We will administer substances by a variety of routes, choosing the most suitable and least invasive route possible e.g. most commmonly by injection into the peritoneal cavity, in the water or food, via inhalation through the nose, or by injection into the blood.

Some mice may undergo surgery (e.g. to enable injection of cells into the kidney capsule). Surgery may also be performed to investigate how the nervous system interacts with the immune system.

Most experiments are completed within 2 to 4 weeks. For instance to model asthma, ragweed pollen extract is administered through the nose for five to ten continuous days, or cytokine may be given by three doses into the peritoneum. Two blood samples may be taken to monitor potential improvements in asthma symptoms. The lung function of mice may then be assessed by plethysmography (a procedure ease of measuring breathing, performed under terminal anaesthetic).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The majority of mice are expected to experience only very mild, if any signs of discomfort, and are regularly monitored during studies.

However, some animals will lose weight in response to infection or inflammation. If animals lose up to 20% of their body weight they will be killed humanely as soon as they are identified.

Cancer studies involve the development of tumours. For example, the onset of colorectal cancer can lead to anaemia and weight loss. Such animals are observed at least twice daily and will killed humanely to avoid suffering should they show signs of ill-health (e.g. weight loss, deterioration in body condition).

A few animals might experience weight loss with bloody diarrhoea as a symptom of inflammatory bowel disease (IBD). We will ensure that the experimental design will keep the number of mice that experience any form of discomfort as small as possible. Such mice will be killed humanely as soon as they are identified.

Temporary impaired mobility of one limb may be observed whilst studying how the immune system repairs damaged nerves, but this is expected to resolve within 2 - 4 weeks. Failure to resolve will result in the mouse being killed humanely.

Mice will be given pain relief prior to recovery from anaesthesia and whenever necessary to alleviate pain as advised by the veterinarian.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Approximately 80% of mice will be below the severity threshold.

Approximately 15% of mice will reach MILD severity.

Approximately 5% of mice will reach MODERATE severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although we undertake many experiments using ex vivo cells, the existing in vitro assays do not accurately mirror the more complex molecular and cellular interactions that regulate immune and haematopoietic cells in vivo, leaving no practical alternatives to studies in whole animals. Despite the initiation of studies (by others) to perform computer modelling of the immune cytokine network these systems do not currently represent a viable alternative to experimental research. In particular, translational aspects of our research, such as the modulation of the immune system, are only possible in an in vivo context.

What was your strategy for searching for non-animal alternatives?

We do perform numerous in vitro assays to both define the function of the factor or cells under study, and to refine how we should continue the research so as to optimise the information gained. However, even these assays are better performed with primary cells or tissues ex vivo rather than with cell lines that may have an altered state due to their long-term culture. In this way we can better predict how the molecule will act in vivo.

We are currently investigating the potential for using tissue organoids in which innate immune reactions can be investigated, and specific haematopoiesis programmes monitored and manipulated.

We undertake human studies. With collaborators we have refined an allergen challenge model in which skin blisters can be raised at the site of immunisation to give access to serum and cellular infiltrate.

We also have a collaboration to study primary cells from asthma patients in vitro.

Why were they not suitable?

It is not possible to recreate, in vitro, the multi-cellular organisational structure that comprises the immune system. There is incredible complexity to the immune system e.g. immune cells may be produced in the bone marrow, but need to migrate to the thymus to develop and mature, before migrating again to the site of infection to combat disease, before migrating again to provide a memory of the battle so that they can be recalled rapidly if the same infection is detected (even years later). This diversity of microenvironments and time-scale cannot be reproduced in a culture dish or isolated organoid.

There are critical ethical issues that surround investigations involving human volunteers. The use of human cell culture and blister analysis offers tremendous insight, but before we attempt to manipulate the human immune system we need significant amounts of preclinical information that help to inform on the likely efficacy and potential side-effects.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The group have attended courses on experimental design and statistical approaches and have sought further statistical advice from colleagues whenever necessary. Experimental animal numbers will be determined using available information, factorial design and power analysis to ensure that minimal numbers are used. Where new protocols with unfamiliar end-points are undertaken statistical advice will be sought to ensure group size and experimental design are sufficient to account for the expected variance. Pilot studies, will be used to test the practicality of experimental design and provide estimates of variability for power analysis to determine future sample sizes. Where appropriate, experiments will exploit a within-sample repeated-measures design to maximise the statistical analysis from fewer animals.

We have considerable experience in the generation of gene-modified mouse strains and constantly assess production success rates to ensure that we optimise and maintain standards of productivity. We are also implementing new CRISPR-based protocols aimed at reducing the numbers of mice used to produce gene-modified strains and the complexity of breeding programmes used to produce compound strains with gene-modifications at multiple alleles.

We also have extensive experience in managing complex breeding programmes. This may be to generate conditional knockout mice, requiring the intercrossing with specific Cre-expressing mouse strains (both constitutive and inducible), or to assess combined gene disruption to assess gene redundancy. These programmes require large numbers of animals since the probability of generating the correct genotypes decreases with the numbers of alleles involved. Several of our projects involve developing mouse models with multiple genetic modifications.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

My group and I have attended courses on experimental design and statistical approaches and will seek further statistical advice from colleagues whenever necessary. My lab members and I are also aware of online tools such as Experimental Design Assistant (EDA) and G*Power (http://www.gpower.hhu.de/).

What other measures apart from good experimental design will you use to minimise numbers?

There is an on-going cryopreservation programme in which valuable lines are frozen. This both secures the lines and allows us to send embryos rather than live mice to other researchers who have the technical capability to receive them.

Breeding programmes are optimised to ensure as little over-breeding as possible. We aim to keep “surplus” animals to a minimum and in the current programme we have averaged fewer than 9% surplus animals.

Where possible we are combining gene reporter alleles to produce compound reporter mice to reduce the maintenance of individual reporter strains.

In order to reduce the numbers of breeding pairs the mice will be kept as homozygous lines (when appropriate and with occasional back-crossing to maintain line integrity), provided that they do not have a harmful phenotype.

To maximise the information from a single animal, we will aim to provide additional tissues to appropriate scientists so that they do not have to breed mice specifically for their experiments.

We have introduced the generation of gene-targeted mice from in-bred ES cells. This removes the necessity to back cross lines for several generations.

Once characterised, we have made our animals available to the scientific community thereby removing the need to generate multiple animal lines with the same genotype.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse has been selected for this project based on it currently being the "lowest" mammalian species in which these experiments can be performed robustly and reproducibly. Their immune and haematopoietic systems are the best analogue for those of humans and many models of human disease have been developed in them. The mouse also benefits from well-established and robust technologies for transgenic and gene-targeted genetic alteration.

We are using a number of interventions, which potentially can lead to clinical signs that mimic human diseases including rheumatoid arthritis, multiple sclerosis, inflammatory bowel disease, viral infection, bacterial infection, cancer, asthma and aging. The vast majority of the procedures that we undertake will be mild with a minority being moderate. In fact we aim to keep suffering to mild in most cases, or failing that moderate since these are more likely to provide us with meaningful information. However, in a very small number of cases e.g. viral and bacterial infections, and experimental autoimmune

encephalomyelitis (EAE), it may be unavoidable that the animals develop moderate clinical signs. In particular, this will be the case when we aim to modulate immune responses testing approaches that are intended to reverse rather than prevent the disease. Batches of virus or bacteria, or toxins/drugs may vary in pathogenicity or toxicity, whilst different strains of mice may vary in their resistance or susceptibility. To reduce the risk of unanticipated suffering we will first low dose groups of two mice, a further two mice may be tested at a higher dose and so on until an appropriate dose level is reached. We use a comprehensive monitoring and scoring system to assess the animals throughout experiments.

Where possible we will use the shortest models of disease that will yield satisfactory data.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are currently the "lowest" mammalian species in which these experiments can be performed robustly and reproducibly. Their immune and haematopoietic systems closely resemble those of humans and many models of human disease have been developed in them. The mouse also benefits from well-established and robust technologies for transgenic and gene-targeted genetic alteration.

We do perform numerous in vitro assays to both define the function of the factor or cells under study, and to refine how we should continue the research so as to optimise the information gained. However, even these assays are better performed with primary cells or tissues ex vivo rather than with cell lines that may have an altered state due to their long-term culture.

The vast majority of the procedures that we undertake will be mild with a minority being moderate. We aim to keep suffering to mild in most cases, or failing that moderate since these are more likely to provide us with meaningful information. Furthermore, we perform airway plethysmography and optogenetics on terminally anaesthetised mice to reduce suffering.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We use a comprehensive monitoring and scoring system to assess the animals throughout experiments. This will be refined if/when additional methods of health monitoring are identified as useful and robust.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Surgery will be carried out according to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

Tumour studies will be undertaken according to the principles outlined by Workman et al., Br J Cancer (2010) 102:1555-1577. Guidelines for the welfare and use of animals in cancer research.

Intrathymic injections will be undertaken with a minimally invasive procedure rather than one requiring osteopathy (de la Cueva et al. 2007. Lab Animal. 36:27).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our named information officer, veterinary surgeon and facility managers keep us informed of advances in 3Rs that can be implemented.

Explain the choice ofspecies and the related life stages

All our in vivo experiments are performed in mice and many of our other experiments in vitro/ex vivo require cells and tissue from donor mice. Mice are currently the "lowest" mammalian species in which these experiments can be performed robustly and reproducibly. Their immune and haematopoietic systems closely resemble those of humans and many models of human disease have been developed in them. The mouse also benefits from well-established and robust technologies for transgenic and gene-targeted genetic alteration.

Home Office

NON-TECHNICAL SUMMARY

82. Immunological mechanisms in pregnancy and cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Immune cells, Pregnancy, Cancer, Infections

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To understand how immune cells, in particular those of the female reproductive tract, regulate placental development and how they may be exploited to improve treatment of cancer, with a focus on ovarian cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our work suggests that interactions between the placenta and maternal immune system are key for normal placental development and fetal growth. The placenta develops from the trophoblast that forms in the blastocyst, an early stage of the embryo. Once formed, it nourishes the fetus through the umbilical cord. **Pregnancy complications** like miscarriage and the hypertensive placental disorder pre-eclampsia are due in part to placental dysfunction. The mechanisms of the interactions between the placenta and maternal immune system are unclear, and we seek to determine them. In doing so, we may help understand the nature of pregnancy complications, including those caused by viral infection in the womb. Moreover, we will be able to study immune responses to SARS-Cov-2 during pregnancy in a mouse model of COVID-19 and the potential problems to pregnancy during the infection. Also, we will have the opportunity to test vaccines thay may be effective at preventing pregnancy complications linked to the infection.

The immune cells found in tumours and in the placental bed are remarkably similar and similar mechanisms may underlie the growth of cancer and the placenta.

Less than 50% of patients survive 5 years after diagnosis of **cancer of the ovary**. Due to the asymptomatic nature of the early stages of the disease, most cases are diagnosed in advanced stages. After surgical removal and chemotherapy, the cancer comes back in 70% of cases, so we need to find new treatments.

New immunotherapies are changing treatments of patients with certain types of cancer, like skin cancer. Ovarian cancer spreads primarily to other tissues in the pelvis and the peritoneal lining. A fluid, called ascitic fluid, accumulates in the abdomen when malignant cells spread to the peritoneum. The accumulation of this fluid is called ascites. Ascites contains immune cells, suggesting immunotherapy may be a possible treatment option. Natural Killer (NK) cells are among the white blood cells present in the ascites. NK cells have a natural propensity to destroy tumour cells and our preliminary studies show the presence of NK cells in ascites, suggesting that if we understand the basic mechanisms of how these NK cells work, we may enhance immunity against cancer cells.

What outputs do you think you will see at the end of this project?

Better understanding of how immune cells help fetal growth, may protect the fetus from congenital infections and also aid in anti-tumour immunity. Moreover, we will be able to study immune responses to SARS-Cov-2 during pregnancy in a mouse model of COVID-19 and the potential problems to pregnancy during the infection. Also, we will have the opportunity to test vaccines thay may be effective at preventing pregnancy complications linked to the infection.

Publications of papers in scientific journals.

Production of new GA mice for research.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The scientific community will benefit from new understanding of the immune processes leading to pregnancy complications and cancer.

In the long term, data generated may benefit patients and clinicians by contributing to the development of effective immunotherapies, which will ultimately reduce the health and economic burden caused by pregnancy complications and ovarian cancer.

How will you maximise the outputs of your work?

Data will be presented at conferences and published in open access journals. We may also publish according to the ARRIVE guidelines to make sure others either don't have to repeat our experiments or, if they do, they will have all the information necessary to do so.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The vast majority of the mice will experience only mild and transient discomfort that does not cause any lasting harm, for example blood sampling, mating, and live imaging.

Surgical procedures will be used in a small minority of cases to generate genetically altered animals. For example, some male mice will undergo vasectomy, whereas some female mice will undergo surgical transfer of embryos into the uterus. However, non-surgical procedures may also be used to transfer embryos into the uterus as these procedures are reaching a success rate that matches the surgical procedure.

Some mice may undergo total body irradiation, which is used to prepare host mice for engrafting donor blood cells from another mouse.

Some mice, including pregnant mice, will undergo experimental infection, while others (non-pregnant), will undergo administration of tumour cells.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Surgical insertion of fertilised embryos into the uterus (less than 2.5%) or vasectomy (less than 1%) may cause transient pain, however peri and post-operative analgesia will be provided.

Infection or other signs of ill health (bristling of hairs, subdued behaviour, diarrhoea) may occur in irradiated mice (less than 0.3%) and may only last for a period of 24 hours, after which, if the signs persist, mice will be humanely killed.

Experimental infections and tumour burden may cause signs of ill health. These signs are expected in less than 1% of the mice and may include bristling of hairs and hunched posture, inactivity or lack of appetite, diarrhoea or shortness of breath, and up to 15% of body weight loss - as measured against control, untreated littermates matched for sex and age). These signs may only last for a period of 24 hours, after which, if the signs persist, mice will be humanely killed.

Initial studies in other laboratories suggest that SARS-Cov-2 infections in non-pregnant mice causes only mild symptoms. Because nobody knows how pregnant mice will respond to SARS-Cov-2 infections, we need something to compare to. For this reason we will also infect mice with agents known to cause pregnancy complications, such as miscarriage or retarded growth of the fetus. These agents include the influenza virus, for example, or a parasite known as toxoplasma. Pregnant mice infected with these agents may experience temporary weight loss and temperature. Mice will be culled before they give birth, so any effect to the unborn progeny will not be carried.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect over 95% of mice to experience only mild and transient discomfort, with less than 5% experiencing moderate suffering.

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use mice because they are essential to evaluate pre-clinically strategies that use immune cells to improve pregnancy outcome and to fight cancer.

The mouse immune system is similar to the human immune system that data we obtain are applicable to clinical research. For example, in both human and mice, a special type of immune cells, called natural killer cells, abound at the maternal-fetal interface, and in both species the type of placentation is invasive. Moreover, new methods to reawaken the immune system in cancer patients have been established in mice and are demonstrating clinical benefits in humans.

What was your strategy for searching for non-animal alternatives?

There are non-animal models of cancers, but we cannot measure how immune cells prevent the spread of cancer in these models.

Some aspects of the tumour microenvironment may be analysed in three-dimensional models of ovarian cancer. Three-dimensional organ cultures that allow the study of some components of the maternal-fetal interface, including endometrium and the tissue that make the placenta, i.e. trophoblast, have also been developed. We collaborate with groups who have developed these systems and, in the future (possibly within the duration of this project), it will be possible to use these models to potentially address the role of immune cells in pregnancy.

We have access to both patient samples, and state-of-the-art monoclonal antibodies. These cells and reagents can be used in test tubes to study some, but not all, fundamental aspects of the interactions between immune cells and cancer cells.

Why were they not suitable?

(1) Uterine immune cells in the body are dependent on their specific environment, which is why animal models are required to understand the fundamental biological processes.

(2) Although there are non-animal models of ovarian and other cancers, we cannot measure how immune cells which kill cancer cells prevent the spread of cancer (metastatic cancer) without using animals.

(3) To translate fundamental biomedical research into clinically useful products or protocols, it is essential to test key hypotheses in pre-clinical animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Where relevant, factorial experimental designs are used, rather than the one-thing-at-a-time approach, to maximise the information obtained from the minimum resource. For most of the experiments in which we measure variables, sample sizes are usually set using power analysis, generally using a significance level of 5%, a power of 80%, and a least practicable difference between groups of 25%. Otherwise, previous experience (ours, or from the literature) is used to select sample sizes.

In terms of the numbers of animals required, we expect 6-8 animals per treatment group to be sufficient to obtain the required results. However, because the number of some of the immune cells in the uterus is small, we expect to have to use rather greater numbers of animals per group to obtain satisfactory results. We will use tools such as the Experimental Design Assistant (EDA) which can be found on the NCR3 website (https://www.nc3rs.org.uk/experimental-design-assistant-eda).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will use tools such as the Experimental Design Assistant (EDA) which can be found on the NCR3 website (https://www.nc3rs.org.uk/experimental-design-assistant-eda).
Also, advice on the proposed experimental designs and methods of analysis of the results will be taken from the Statistical Services Unit.

What other measures apart from good experimental design will you use to minimise numbers?

We consider our previous work and experience as well as published work. If we use the procedure for the first time, we run a pilot study. We typically use control animals and blind the experimenter to the genotypes and treatments of the animals.

We will design our experiments guided by the PREPARE guidelines.

We will write a comprehensive Study Plan for each experiment. The Plan will include a statement of the objective(s) and a description of the experiment. This description will cover experimental treatments, size of the experiment (number of groups, number of animals/group), and experimental material. An outline of the method of analysis of the results will also be included in the Plan. This may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated.

We will make appropriate arrangements to randomly assign animals to experimental groups and blind studies and will plan and conduct studies to enable them to be published according to the ARRIVE guidelines.

We will share tissue with other researchers.

We optimise breeding colonies with the help of the Mouse Colony Management System (MCMS) database.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mice, including embryos, adult and pregnant adult mice.

We will use standard and state-of-the-art methods to produce genetically altered animals, along with specific methods to study immune responses during pregnancy, infection, and cancer. The models and methods we use are those which cause the least pain, suffering, distress or lasting harm to the animals.

For example, herpesviruses (e.g. cytomegalovirus) are the pathogens of choice for the infection models in pregnant mice. While relevant to human pregnancy because cytomegalovirus causes congenital disorders, the mouse cytomegalovirus does not cross the placenta, and only causes mild and transient discomfort to the strain of mice we use. Moreover, to avoid any collateral damage to the offspring, infected pregnant mice are humanely killed before giving birth.

The cancer model we have chosen to use is based on injecting mouse cancer cells into the abdominal cavity of mice. These cancer cells mimic the tumour spread experienced by patients with ovarian cancer, however do not spread further through blood, thus causing only a mild form of cancer. Nonetheless, with this method we can accurately measure the immune response to the cancer itself, thus furthering our understanding of immunity to cancer.

For some experiments we will administer substances that switch on modified genes (transgenes). Although these substances are generally injected in the abdominal cavity, we can also administer them with the food, which we can flavour to make it more palatable. By administering the substances with the food, we reduce the risk of complications in pregnant mice. This route of administration with the food can also be used when repeated administrations of the substance are required.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have considered the use of less sentient species, however their reproductive biology is too different from that of mammals to be informative and their immune system is too different from the human immune system to model anti-tumour immunity.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To improve the quality of life of the animals we keep mice in groups where possible and keep mice singly-housed to a minimum. This reduces contingent harm, stress and stereotypical behaviour. A good use of environmental enrichment is maintained along with minimal stress through restraining. i.e. for intravenous injections. We also do not transport many animals as most of our mice are bred in house and kept in one facility.

We use analgesics to lessen pain.

Scoring sheets are used to monitor the health of animals undergoing procedures.

Mash will be provided for animals likely to lose weight before they start a treatment where weight loss is expected.

We will use infrared thermometers to monitor temperatures to precisely assess potentially raised body temperature as a result of experimental infection. Currently there are no correlative data available but we will collect data with the view of using body temperature as refined criterium to use in this work.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

British Journal of Cancer (2010) May 25;102(11):1555-77
(https://www.ncbi.nlm.nih.gov/pubmed/20502460)

LASA guiding principles documents of aseptic technique
(https://www.ubs.admin.cam.ac.uk/files/lasa_aseptic_surg.pdf)

ARRIVE Guidelines for preparing papers for publication (https://www.nc3rs.org.uk/arrive-guidelines)

In planning our experiments, we consider the 15 topics of PREPARE guidelines, including formulation of the study, dialogue between scientists and the animal facility and methods (https://www.ncbi.nlm.nih.gov/pubmed/28771074).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will follow advances through the NC3Rs website which provides an extensive library of 3Rs resources, guidelines, practical information and themed hubs. Provided are also links to publications, other online resources, and video and training materials.

The internal website also provides a portal to numerous sources of information. Some of these are listed below:

(AALAS) American Association for Laboratory Animals Science

(FELASA) Federation of European Laboratory Animal Science Associations

(ICLAS) International Council for Laboratory Animal Sciences

(InterNICHE) International Network for Humane Education

https://science.rspca.org.uk/sciencegroup/researchanimals/implementing3rs/rodentwelfaregroup

Explain the choice ofspecies and the related life stages

We have chosen the mouse to study immunological mechanisms in pregnancy and cancer, because the mouse immune system is similar to the human immune system. Therefore, data obtained are applicable to clinical research.

We have chosen to use pregnant mice so that we can study the function of immune cells during pregnancy.

Mice are essential to evaluate pre-clinical strategies that use immune cells aiming to improve pregnancy outcome and to fight cancer. The species we have chosen is the one that we believe best mimics human disease.

Prior to embarking on animal experiments, we will collect as much evidence as possible from publications and by using in vitro models of immune cell activation.

Home Office

NON-TECHNICAL SUMMARY

83. Immunotherapeutic interventions for cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, immunotherapy, vaccines, cancer-associated fibroblasts

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to develop novel vaccines such as DNA vaccines and plant viral vaccines for cancer patients with low tumour-infiltrating lymphocytes with the further focus on combinations of these vaccines and inhibitors of tumour micro-environment such as cancer associated fibroblasts (CAFs).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is a significant public health issue, with one in 3 people diagnosed, and a quarter of all deaths in the UK attributable to it. In recent years we have witnessed the emergence of immunotherapeutics such as monoclonal antibodies checkpoints inhibitors pembrolizumab and nivolumab which made a significant improvement in the treatment of many cancers. These treatments largely rely on tumour infiltration by T lymphocytes (TILs) and hence, those patients who have low TILs do not benefit from these expensive treatments. In this project we are looking to address novel concepts leading to the development of novel treatments such as vaccines and therapeutic interventions such as CAF inhibitors which will lead to improved survival of patients with low TILs.

What outputs do you think you will see at the end of this project?

1) data on efficacy and immunogenicity of novel vaccines including next generations of DNA vaccines and plant viral vaccines, and combinational approaches with immunomodulatory antibodies and chemotherapy

2) identify novel epitopes in target antigens feeding the information to the publicly available databases for epitope identification

3) generate knowledge on how novel vaccines operate in the setting of immunosuppressive tumour microenvironment

4) generate novel vaccine candidates for testing in a clinical setting

5) shed light on immunosuppressive properties of cancer-associated fibroblasts and macrophages in relation to the function of anti-cancer T cells

6) manuscripts and patents defining the above

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The findings will engage the interest of the following groups: clinical oncologists, scientists interested in immunotherapy, cancer vaccines, vaccines for other diseases including infectious diseases, and biotechnology focused on vaccine development and gene therapy.

On the long term the project will benefit the patients with head and neck cancer and potentially other cancers where the target antigens are expressed such as lung cancer because our novel vaccines target antigens which are expressed in both cancer types. From work on inhibition of tumour microenvironment or combinational approaches we expect that patients with highly fibrotic tumours (CAF high tumours) will benefit. These approaches may be particularly beneficial to patients in oral cancer and triple negative and Her2 positive breast cancers for which there are currently no effective treatments. The project will also benefit patients with myeloma who require long term maintenance therapy. In myeloma, vaccination in remission post-therapy in the setting of minimal residual disease is widely considered the optimal setting for immunotherapy in particular, when disease is de-bulked and immunosuppression markedly reduced. This represents a window of opportunity to develop effective antigen-specific T-cell response aimed at preventing future relapse of the disease. We also expect NHS and health services in other countries to benefit in terms of cost reduction using vaccines and anti-fibrotics and better therapeutic options.

How will you maximise the outputs of your work?

The findings of this study will be disseminated through publications in peer-reviewed journals and presented at national and international meetings.

Results will also be disseminated through the European Cancer Immunotherapy group and the US Cancer Vaccine Consortium.

We participate in well-established public outreach and engagement activities that ensures our research is communicated to the local community including local charities, local branches of national charities and patient groups, as well as the general public. Last year, for example, our local outreach initiatives were attended by more than 50,000 individuals during National Science Week, NHS patient day and cancer research activities.
Our group is actively involved in these activities and all PhD students take part in these engagements.

If pre-clinical vaccine testing is successful then an early phase clinical trial will be developed through the NCRI for example. REDACTED. This group forms a central part of the UK's oral cancer research infrastructure, bringing together clinicians, scientists, statisticians and lay members to co-ordinate a strategic portfolio of suitable for publication.

Species and numbers of animals expected to be used

- Mice: 3100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

It is anticipated that a large proportion of mice will receive at least one injection with a therapeutic intervention including novel vaccines or combinations of vaccines and inhibitors of tumour microenvironment, and will be challenged with a tumour. In most of cases mice will receive several treatments following tumour challenge to observe a better therapeutic effect. In some cases the tumour challenge will occur prior treatment. Typically mice will be kept until a statistical significance in the experimental outcome (differences in rate of tumour growth between experimental and control groups) has been achieved. In some cases, where intermediate results such T-cell responses in circulation need to be measured, mice will also be bled weekly.

In experiments to test efficacy of novel vaccines (Objective 1) mice will be vaccinated with a candidate vaccine and will be challenged with the tumour (before or after vaccination), this may be combined with depleting antibody to deplete individual immune cell subsets (such as anti-CD4 or CD8) or cytochrome C (to deplete antigen presenting cells) given on different occasions to reveal the immune mechanisms involved in immune induction or effector functions.

In experiments to test combinational strategies (Objective 2) mice will be vaccinated and will be challenged with tumour (before or after vaccination), CAFs or immune cells maybe be transferred together with the tumour, in some experiments combined with immunomodulatory and/or immune subsets depleting antibodies or cytochrome C given on different occasions to reveal the immune mechanisms involved in immune induction or effector functions or impact of CAFs on individual immune cell subsets. Experiments with CAFs may also include CAFs inhibitors.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We expect skin necrosis and ulceration
in s.c. models which will be closely monitored. This is limited to the B16 model and is required so the meaningful experimental outcome can be achieved e.g. significant difference in rate of tumour growth between the experimental and control group or tumour free survival. In rare cases in the myeloma model we expect effects on normal behaviour including
locomotion and hind-leg paralysis. Mice will be monitored at least daily to monitor sings of adverse effects.

Any signs of slower movement than usual will require more frequent monitoring with a specific attention given to hind legs. Mice slow down and might eventually wobble or drag one leg. The effects on

normal behaviour including locomotion and hind-leg paralysis (these are not reversible) will be a humane end point and hence the animal is expected to be terminated within 1h. Inability to close the mouth or chew from the presence of tumour or swelling
as a result of the procedure and is not expected to last once discovered. In mammary gland models the tumour is induced on the underside of the mouse hence there is the potential for abrasion injuries. There is a potential for ulcerations in these models. Both abrasion injuries and ulceration will be the end points in mice with mammary tumours. Some mammary tumour models disseminate but metastasis are unlikely with the size of primary tumours we will use. If mice develop metastasis they should be killed. Weight loss
may occur for any period providing if it is under 20% of body weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of mice will experience mild severity, in some cases (10%) moderate severity will occur.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immune activation influences multiple cell types across the body concurrently and this cannot be adequately modelled *in vitro* at the current time. Similarly, to study the interactions between an ongoing immune response and a growing tumour, or to evaluate immune-mediated pathology there is unfortunately no viable alternative to *in vivo* modelling except using animals.

What was your strategy for searching for non-animal alternatives?

We are committed to replacing mice where possible and we evaluate immunotherapeutic agents on cell lines *in vitro* when we can. For example, TLR agonists such as plant viral particles will be evaluated in extensive *in vitro* experiments using cell lines transfected with TLRs and antigen presenting cells expressing the respective TLRs isolated from patients PBMCs. For DNA vaccine screening of vaccine prototypes will involve evaluation in HEK293 cells with the subsequent Western blot analysis and only candidates with the highest expression in cell supernatants will be selected for further evaluation of

immunogenicity in mice. On the other hand as we understand more how cancer vaccines operate in patients we will consider taking vaccines directly into patients without testing in mice. A good example of this is neoepitope targeting vaccines which have been proven safe and immunogenic in several clinical trials making a good case not to undergo testing in mice but moving directly into patients' setting.

We will also use extensive tissue culture assays to evaluate CAFs inhibitors. We have been developing tumour 3D-organoid and tumour slice models to allow modelling some of the key aspects of CAF-T cell interaction such as T-cell exclusion and mobility for both head and neck and breast cancer. The suitability of these novel model systems is still under evaluation.

Why were they not suitable?

However, the above approaches are not suitable to evaluate whether TLR agonists are capable of inducing T cells responses when delivered with antigen as well as evaluate. Similarly it is not possible to recreate the complexity of the interaction of CAFs with various components of tumour micro environment *in vitro*.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical considerations

We have performed Power Analysis to determine group sizes for the types of experiment to be conducted under this PPL using the PS:Power and Sample Size calculation program.

T cell responses - for the study of T-cell responses we estimate that we need to detect a two-fold difference in mean with a standard deviation in each group of 1. A two-sided t-test at the 5% significance level and with 80% power predicts that this requires 5 mice per group. Through experience we find that between 3 and 5 mice per group are sufficient to obtain statistically significant differences; again replicate experiments are performed and data may be pooled if appropriate to strengthen the statistics.

Immunotherapy - we are planning to study changes in tumour burden as the primary endpoint for these experiments. Tumour burden will be monitored periodically using growth measurements and the area under the curve (AUC), post treatment, will be compared statistically using an independent samples T-test between the vehicle control and vaccine/treatment alone groups; and between vaccine alone and vaccine + treatment. Each experiment will be carried out with equal numbers of control and

experimental subjects. In our previous study where a vaccine was found to significantly reduce tumour growth each subject group was normally distributed with a maximal standard deviation of 1233 (mm^3/day). This study was used to calculate the sample size required in these experiments. If the true difference in experimental and control means is a 50% decrease, we will need to study 10 tumours per group to reject the null hypothesis (where means of the experimental and control groups are equal) with 90% power and 95% confidence. This calculation was performed using the PS: Power and Sample Size Calculation version 3.1.2. This number will be adjusted to maintain statistical power as these experiments are carried out and more accurate estimates of means and standard deviations are obtained.

Replicate experiments are then performed to confirm reproducibility and when appropriate data may be pooled to increase sample size.

Pilot experiments will be carried out to inform the experimental design of larger studies, including dosing regimen, expected humane endpoint (e.g. for mice in control, untreated groups).
These power analyses will be informed by the pilot studies, or our historic studies.
Technologies such as whole body imaging also result in lower numbers of mice since they allow longitudinal follow-up of the same mice over time. These alternatives avoid the need for increases in mouse numbers due to limitations of the number of blood samples that can be taken from the same mouse, or allow tumours to be followed longitudinally to assess tumour the kinetics of tumour inhibition. We will also make every effort to decrease experimental bias and minimise experimental variability.
An example of this will be if the humane end points are based on an assessment of the condition of the animal, an experienced and blinded animal technician will be asked for their assessment. Objective measurements such as tumour measurement, whole body counts etc. generally do not need blinded observers.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have performed Power Analysis to determine group sizes for the types of experiment to be conducted under this PPL using the PS:Power and Sample Size calculation program .

What other measures apart from good experimental design will you use to minimise numbers?

The majority of mice used under this PPL are inbred thereby minimising intra-group variability and allowing reduced mouse numbers for experiments. Small pilot experiments are initially carried out where simple factors such as appropriate dose or route of administration are not clear. Where multiple inter-relating parameters need to be evaluated larger factorial experiments are performed to minimise the number of control mice needed.

The development of new technologies (e.g. multi-parameter flow cytometry and RNAseq) has significantly increased the amount of data that can be obtained from a small number of cells from one individual animal. These technologies are exploited as fully as possible enabling group sizes to be smaller and for more data to be obtained from longitudinal studies (e.g. from sequential blood sampling or tumour imaging) without the need to cull mice to take, for example, the spleen, at each time point.

For subjective measurements (tumour infiltration with immune cells such as T cells), and where possible, scoring is performed by an experiences pathology technician to minimise bias. For most other measurements (e.g. analysis of cell frequency in tissues by flow cytometry ex vivo and measurement of tumour volume) measurements are objective and blinding is not required. Groups of mice used in experiments are routinely sex and age matched and where possible taken from the same litters. Allocation of mice for experiments is performed blind as researchers request animals which are then supplied randomly from a breeding stock by a technician with no knowledge of the experiment. In addition and where feasible, mice for tumour challenge experiments will be randomised by assigning animals to groups prior to therapy to ensure an equal distribution of tumour mass within each group. This ensures that all animals have detectable tumour prior to treatment and prevents bias. Many of our previous publications conform to NC3Rs ARRIVE Guidelines (https://www.nc3rs.org.uk/arrive-guidelines) and we will continue to publish to this standard.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Choice of species/agents

This PPL will use mice as these are the least sentient of the species appropriate for this research. Mice represent a relevant animal model for these studies and the clinical successes now being reported using immunomodulatory drugs or vaccines against cancer were dependent on data arising from such murine studies. In addition, the wide availability of inbred and GA strains and murine specific reagents will facilitate the successful attainment of our research goals and maximise the data obtainable per mouse. Where possible agents to be injected into mice are obtained from published/commercial sources and their dosages and adverse effects (if any) are therefore known. Should substances be used for the first time in mice by us, individual mice will be treated and monitored closely for adverse effects .

Regular monitoring

At least daily monitoring by the PIL holder is expected for all the models. Any animals which are anticipated to be nearing a defined end-point are monitored more closely by the PIL holder. Cages housing tumour-bearing animals near the critical end-stage of disease are marked for special attention. If an animal has reached the humane end-point of disease or is displaying signs of distress/suffering the technicians will either cull the animal or inform the personal licensee that the animal should be culled immediately. Should mice show signs of unexplained distress the NVS will be consulted. Through careful monitoring of established end-points the proportion of deaths is low ensuring that mild (Protocol 1) or moderate severity (Protocol 2-5) is not exceeded.

Humane end-points

Animal death is not considered an acceptable endpoint measure. Our humane endpoints are based on recognised guidelines and chosen to allow evaluate the effect of tested interventions on tumour growth (growth inhibition). Subcutaneous or mammary tumours are easy to monitor by measuring tumour size. Animals with subcutaneous tumours will be killed if tumour exceeds 1.5 cm in diameter (recommended for experiments that investigate therapies) or if the tumour ulcerates with score 4 and above (Table 2, Protocol 2). Animals with mammary tumours will be killed if tumour exceeds 1.2 cm in diameter as larger tumours might impact mobility or tumours might ulcerate. Animals with oral tumours will be killed if tumour exceeds 0.5 cm in diameter, we do not expect ulcerations with our oral models. For oral tumours weight loss of 20% will be a measurable endpoint. For myeloma if palpable spleens are 1.5 cm or an early onset of leg paralysis (problem with mobility) occurs, animals will be killed. Use of *in vivo* imaging should allow refine further our humane endpoints. If tumour interferes with normal behaviour (feeding, drinking, movement), posture or locomotion the animal will be killed in all models.

Anaesthesia

Usually agents and procedures are delivered/performed without anaesthesia to reduce trauma. If required anaesthesia will be administered according to published sources and by persons appropriately trained to do so. If necessary warming mats will be used to aid recovery from general anaesthesia. For longitudinal blood sampling local anaesthetic is applied to the tail prior to bleeding and lubricant used to prevent soreness. Mice will not be subjected to general anaesthesia/sedation on more than 6 occasions.
Procedures are combined under the same anaesthesia when possible (electroporation and IVIS imaging for example).

Cell injections

Cells for injection are usually grown under aseptic conditions *in vitro* or obtained directly from mice. Cells will be visualised for signs of infection and washed in PBS prior to injection. Mice receiving new cell lines will be maintained in isolation prior to health screening to prevent transmission of pathogens. The transfer of identifiable cells (e.g CFSE labelled, or congenically marked) is not associated with any adverse effects. Cells for i.v. injection will be visually inspected immediately prior to injection to prevent embolism; efforts will be made to perform injections prior to 3 pm to allow time to monitor mice for signs of embolism and other clinical signs.

Blood sampling

Blood sampling will generally follow Home Office guidelines.
Animals may be test bled on up to 5 occasions. Tail bleeding by vein incision with a suitable anaesthetic is the quickest and least stressful method.

Administration of vaccines, antibodies and CAF inhibitors

In general vaccines used in this PPL are well tolerated with no adverse effects. All cytokines to be tested will be injected locally hence no problems are anticipated. Anti-fibrotics CAF inhibitors we intend to use have an excellent safety profile. We established that CAF inhibitors are best delivered by oral gavage. Antibodies (CPI, anti-CD38 and depleting antibodies) we plan to inject are not expected to generate any serious side effects such as a cytokine storm ets. Reagents are prepared under endotoxin low conditions to minimise immune activation which could compromise experiments and induce adverse effects in mice at high dose. Some agents may require dilution in a solvent other than saline (e.g. DMSO or ethanol). In this case concentrated stocks will be diluted in saline prior to injection to ensure that solvent is low (<10% of volume and <20% volume for detergents as recommended by recognised guidelines. Generally, injection volumes will be kept as low as possible but will never exceed those in recognised guidelines.
Our group has expertise and extensive experience in electroporation to deliver DNA vaccines and in oral gavage for CAF inhibitors.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The scope of this project is to evaluate the novel candidate vaccines/ nanoparticles or tumour micro-environment both required functional immune system of an adult animal. These require interaction of many components of the immune system within the immune system and with the tumour and often require time to mature e.g. the immune response to vaccines goes through several stages including initial activation followed by an effector stage and finally by memory formation. Similarly the tumour microenvironment will take as long as the tumour to develop.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

1) low endotoxin preparations of agents for injections, in most of cases the agents for injections will be prepared aseptically

2) minimise a number of injections if they cause any irritation e.g. oral submucosal/ sublingual injection

3) use of soft food pellets for 48h after oral injections and when oral tumours become noticeable. The use of one needle/one injection is now a common practice in our establishment

4) cages housing tumour-bearing animals or other disease models near the critical end-stage of disease are marked for special attention

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Guidelines for the welfare and use of animals in cancer research, 2010.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

All PILs working under this license will subscribe for monthly updates on the NC3Rs website. A dedicated research technician will attend NC3R conferences and will update the PILs under this licence at a lab meeting.

Other on line resources will be accessed including: the European Commission 3Rs databases https://ec.europa.eu/environment/chemicals/lab_animals/3r/key_resources/databases_en.htm

the European Centre for the Validation of Alternative Methods (ECVAM) search guide: https://ec.europa.eu/jrc/en/scientific-tool/eurl-ecvam-search-guide

Explain the choice ofspecies and the related life stages

In this PPL we are interested in developing novel immunotherapeutic strategies to combat cancer we therefore require an adult mouse with a mature immune system to investigate how various component of the immune system interact with cancer.

Home Office

NON-TECHNICAL SUMMARY

84. Impact of psychosocial stress on nervous system function and ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aims of the project are to determine the biological mechanisms by which psychosocial stress manifests physically within the body, resulting in changes to genes, proteins and cells of the nervous system, and the overall behaviour of the organism. This work is undertaken with the long-term objective of understanding the biological basis for stress-induced medical conditions, thereby informing on the developing of disease-modifying therapies for such conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We know that the stress response is a conserved series of complex biological processes throughout many species that represents a fundamental mechanism for detecting changes within our internal and external environments. As such, it is essential for the survival of many species. In most cases, the stress response results in biological changes that allow for adaptive responses to such changes; this is called homeostasis.

However, depending on the degree of stress (acute or chronic), and at what period in your life you experience it (young; old), stress can induce maladaptive responses which confer a risk for developing a range of debilitating medical conditions. Mental illnesses such as anxiety and depression, cardiovascular diseases such as high blood pressure, metabolic disorders such as type two diabetes and immune disorders such as inflammation are all examples of medical conditions that can arise as a result of an impaired stress response.

Therefore, to develop therapies that deal effectively with the causes of such conditions, rather than merely treat their symptoms, it is essential to understand the full biological role of the stress response in altering the underlying processes which lead to the pathology.

We know that the nervous system, the brain in particular, is the key orchestrator of the stress response because it coordinates the activity of different organ systems, thereby allowing for adaptation throughout our body. However, we have yet to fully understand the pathways which result in processes altering the genes and proteins that determine the activity of cells composing the various stress networks throughout the brain and various organ systems. We also do not know why certain forms of stress are beneficial and lead to adaption, whilst other forms confer a vulnerability to disease. Knowing this could help to develop strategies that provide protective measures in vulnerable individuals, thereby preventing the onset of such conditions in the first place.

What outputs do you think you will see at the end of this project?

The primary outputs will be:

1) New scientific information that contributes to our greater understanding of stress biology and how this contributes to various diseases, will be disseminated by publishing in peer-reviewed scientific journals and by presentations at scientific conferences and Lay public events.

2) Scientific justification for future drug development studies focused on treating stress-induced medical conditions.

3) Patents for new drug targets.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

SHORT TERM:

1) Basic biomedical scientists and clinicians in various medical disciplines (neurology; gastroenterology; metabolic diseases): advancement of basic neurobiology knowledge and how this underpins the pathology and symptoms of medical conditions.

2) Drug development scientists: identification of novel drug targets for potential translational exploitation.

LONG TERM:

1) Healthcare policy makers (e.g. NICE): translation of the basic scientific knowledge into and the new pharmacological therapies it give rise to, will be used in the rational decision-making for optimal healthcare policies.

2) Patients suffering from various stress-induced disorders will benefit from personalised drug therapies which are capable of addressing the fundamental causes of their condition, thereby modifying the core disease, rather than simply treating the symptoms.

How will you maximise the outputs of your work?

All this work is conducted with external collaborators as well as Lay research monitors associated with my Funders. Therefore, I will use these extensive networks to disseminate the knowledge. I will strive to publish the data, both positive and negative, in the most widely read scientific journals.

Species and numbers of animals expected to be used

- Mice: 8000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Broadly, animals will be exposed to stress, primarily by altering their interactions with other mice.

The project can broadly be divided into two phases, namely the induction of stress in mice and then the investigation of the biological consequences of the stress responses in these mice

INDUCTION OF STRESS:

For early life stress, the behaviour of the mother will be altered which results in a fragmented mother-pup relationship. This impairs the quality of the care she imparts to her offspring, resulting in an enhanced stress response in adulthood.

For adult stress, test mice will be exposed to a more aggressive strain of mouse which results in social subordination and a stress response.

ASSESSMENT OF STRESS RESPONSE

To determine what consequences stress has on a range of organ systems, a range of techniques will be used, for example:

1) Changes in physiology: under anaesthesia, brain activity and how it changes in animals exposed to stress will be determined using standard recording techniques.

2) Changes in genes, proteins and cells: animals will be killed humanely and the stress-induced changes in a variety of biological processes, within different organs, will be determined.

3) Behavioural assays: stress induced changes in native mouse behaviour will be determined using a range of behavioural tests to assess any anxiogenic/depressive-like behaviours.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

All the adverse effects will be as a result of their exposure to stress. This can result in changes in:

1) Behaviour: animals may exhibit an increased fear response, for example agitation to normal handling.

2) Metabolism: animals may have altered body weights due the effects of stress on various hormones or their motivation to feed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of the animals will be used in Protocols 1 and 2, and subjected to some form of stress. Therefore, for the majority of animals, the most extreme level of severity will be categorised as Moderate

However, a significant proportion of the experiments fall into the non-recovery category because they will be conducted under terminal anaesthesia with the animal being unconscious throughout and therefore insentient during the actual experiments.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objectives of the project are to elucidate which life experience, in the form of stress, alter the coordinated functioning of various body systems, such as the brain and peripheral organs, resulting in changes in the behaviour of the animal.

The research questions necessitate the use of native animal tissue since the anatomy, physiology and neurochemistry of different neuronal circuits in specific parts of the brain and native animal behaviour can only be elucidated by studying the intact animal itself. Furthermore, to investigate the changes that occur in brain function due to conditions such as stress or depression, it is necessary to expose animals to such conditions and then determine the consequent effects on the brain itself.

What was your strategy for searching for non-animal alternatives?

1) Cell-culture: It is possible to assess the impact of certain brain proteins on cellular activity by expressing the proteins in cultured cells.

2) Computation neuroscience: as scientific knowledge advances, there is a growing availability of computational models of brain function.

Why were they not suitable?

1) Brain function, and the associated diseases, arises from a multitude of individual cell types (millions). It is simply not feasible to faithfully replicate the molecular, morphological and functional complexity of

these different brain cells, in basic in vitro cell system.

2) Modelling: in order to get robust models, it is essential to feed robust primary data into the various algorithms. The lack of available primary data regarding the effect of stress on the parameters under investigation in this project precludes the use of such technology at this stage.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are largely based on the numbers used during similar experiments for my last two Project licences. However, the following refinements have been added:

1) Power calculations: when pilot data provided an effect size, I used this to calculate the optimal sample size for individual experiments.

In all case, sample sizes for individual experiments have been calculated using the following parameters:

Power: 90%

Alpha: 0.05

Population Variance: according to the parameter being assessed

2) However, some of these experiments are novel and at this stage, it is unclear what the outcomes will be, therefore precluding the identification of an effect size, and thus power calculations. In such incidences, we have been guided by the minimal number animals normally required for such techniques, e.g., histological, n = 5; gene arrays, n = 8.

Finally, we have taken into account the additional animals required when experiments fail as a normal consequence of scientific research.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

I have made use of all local support including our statistician and other resources such as the ARRIVE or PREPARE guidelines.

What other measures apart from good experimental design will you use to minimise numbers?

Together with my collaborators, we will use our experience, demonstrated in numerous publications, to use the minimum number of animals which are required to provide scientifically valid data. Since my collaborators also work on body systems other than the brain, we will utilise multiple organ systems from individual animals thus resulting in a reduction of the total number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

I will be using mice and models of psychosocial stress in:

1) Adulthood: social defeat model of chronic stress

There are a range of models of chronic stress, which invariably require the animal to be exposed to extended periods (~ 6 hours per day for 20 days) of aversive experiences. The model I will employ exposes the animal to a conflict situation with another mouse which can last anything from 30 seconds to 2 minutes, after which the animal is removed from the resident compartments. This is repeated for up to 10 days. As such, the model is highly refined to allow for the induction of psychological stress with the minimum amount exposure to stress.

2) Early life stress (ELS): limited nesting and bedding mode.

Again, a range of ELS models require the exposure of the mouse pups to extended periods of separation from their mother, during the very vulnerable first two weeks of life. The model I will employ does not alter the amount of time the mother spends with the pups. Instead, the model replicates the importance of the quality of maternal care, rather than the amount of maternal care. As such, the model directly addresses the most important factor in terms of ELS, without induces any additional harm to the animals.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The aim is to understand how the perception of stress, at the mental level, alters the functioning of various body organs. As such, for most of the project, it is important that a certain levels of sentience is required to mentally perceive the adverse experience, so that the emotional limb of the stress response, rather than a basic reflex reaction is elicited. This therefore precludes the use of other animals such as fish or amphibians.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

At all stages of the project, experiences will be monitored to determine whether aversive procedures can be minimised without adversely affecting scientific outcomes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

I will seek out the guidance of my NACWO and fellow scientists in the field in order to ensure measures of refinement are always optimal.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will maintain an up to date knowledge of advances in the field, using the conventional routes of scientific articles and conferences, alongside local expertise in the form our NACWO and Named Veterinary Surgeon.

Explain the choice ofspecies and the related life stages

The overall aims of the project are to study how emotional stress alters the functioning of various mammalian organ systems.

Mice will be used as the broad anatomy and physiology of this species is well understood and provides the best compromise in terms of correlating with human biology whilst exhibiting the lowest level of sentience.

Since the aim is to understand the effects of stress at different periods of life, it is imperative to use animals at different ages. Therefore, we will use both neonatal and adult mice.

Home Office

NON-TECHNICAL SUMMARY

85. IMPROVING THE CLINICAL OUTCOME OF CUTANEOUS WOUNDS

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Pigs	adult
Rats	adult
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to address the clinical problem caused by wounds that are difficult to heal (due to chronic disease such as diabetes, cancer, or physical trauma) by developing a range of materials and therapies that will target specific elements of the wound healing cascade and will speed up the wound closure and healing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Non-healing wounds are a significant and growing clinical problem. The cost of non-healing/chronic wound care is estimated to consume at least 6% of NHS expenditure in the UK, and many are still left with chronic wounds that simply won’t heal using current treatment options causing distress and very poor quality of life.

Another major issue is burns. In the UK alone there are 13,000 hospital admissions every year due to burns, of which 1,000 are due to severe burns. The initial insult is often followed by on-going traumatic experiences with continued treatment, including reconstructive operations, disfiguring scars and compromised functioning of affected parts of the body.

The costs to the patient are much harder to quantify but should be considered in terms of physical and emotional pain and associated psychological damage.

Therefore we will investigate a range of novel technologies/ products for wound healing that can: 1. Increase the rate of wound closure; 2. Reduce scarring; 3. Reduce infection; 4. Improve the quality of the wound healing as a whole.

What outputs do you think you will see at the end of this project?

Our dermal replacements have been designed in different formulations to attend different patients' needs. We are developing products that is very easy to apply into the wound void to assure contact with the entire topography, maximising the chances of successful healing. We prioritise the use of high quality products, yet using inexpensive materials, which may reflect in an affordable and off-the-shelf products with different clinical applications.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

The products we are developing intend to be high quality products, yet affordable and off-the-shelf, with potential to treat many debilitating conditions, particularly those wounds which simply won't heal, aiming to help elderly people and those with chronic conditions such as diabetes, cancer and burns. We aim to reach the market in the next 3-5 years.

How will you maximise the outputs of your work?

A supportive network of clinicians is accessible to our research hubs, and they are actively involved in many current research programmes. This network as well as patients' support groups have been invaluable in focussing previous projects to enable clear patient benefit.

We have collaborations with various Hospitals in Londo,n which provides invaluable advantages for this translational research. We are also academically linked with the Universities, which places our research at the interface between strong academic basic and clinical sciences.

The Institute has a strong track record in scientific publications and training young scientists and doctors in the field of Tissue Engineering/ Regenerative Medicine through the research we develop here.

This work will be disseminated among the academic public by conferences, abstracts and full research articles publication, as well as amongst the public and patients.

This work will be discussed with our collaborators and local support groups for patients and families suffering with non-healing/ chronic and burn wounds in order to be as assertive as possible and have a real patient-focus approach.

Species and numbers of animals expected to be used

- Pigs: 150
- Sheep: 0
- Rats: 150
- Mice: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

We intend to create small wounds on each animal, allowing a large amount of data to be produced while using a minimum number of animals. The wounds will be treated with our skin replacement materials and followed up rigorously for 8-12 weeks. The wounds will be monitored weekly with assessment for infection, inflammation and dressing changes.

Suffering to the animal will be minimised through the use of anaesthetics and well-established analgesia and protective dressings which reduce any pain associated with the creation of the wounds.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

From our experience with these models we expect an uneventful recovery from surgical procedures under general anaesthesia and that post-operative pain will be controlled by use of analgesics. Aseptic technique will be used for all surgical procedures to minimize unintentional infection.

Use of electrocautery at surgery will minimise risks of postoperative haemorrhage. Insertion of wound chambers is usually painless and we have not seen any problems in animals with chambers during the previous studies. Animals will be administered with regular postoperative analgesia (e.g. temgesic) for 48h, and additional analgesia if they appear to be in pain (e.g. diminished appetite, immobility, changes in defaecation or urination, abnormal vocalisation, general loss of condition).

In all animals any abnormal signs (e.g. diminished appetite, immobility, changes in defaecation or urination, abnormal vocalisation, excessive wound infection, general loss of condition) will be investigated by the personal licence holder who shall remain responsible for the animal whilst increasing the frequency of monitoring. The vet will be consulted and their advice taken as to minor remedies or major interventions. This may restore the animal's wellbeing in a short timeframe. Minor remedies may include cleaning and re-dressing an exposed wound or the administration of antibiotics if this is experimentally appropriate.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Procedures will be mild (protocol 1) and moderate (protocol 2) in severity and analogous to minor routine surgical procedures performed clinically on human patients. Such procedures include removal of cancers and treatment of moderately sized burns with skin replacement biomaterials and are now routinely undertaken as day cases with no overnight hospital admission.

In the unlikely event of any abnormal signs that are likely to exceed moderate severity – prolonged vocalisation, sustained excessive temperature increase, failure to eat or drink, vomiting, excessively suppurating wounds or if a systemic infection occurs –or if the animal fails to respond to treatments in the expected time the animal will be killed by a Schedule 1 procedure.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vitro systems utilising the cell populations responsible for wound repair have been considered and are used extensively as alternatives to the use of animals. Additionally, discarded tissue has been used by our group as an ex vivo model which replicates the architecture of intact skin.

In order, however, to further develop therapies for clinical use an in vivo model must be used to replicate the complexity of wound healing in a clinical setting. This is particularly important where vascularity, immune function, tissue durability and host interaction are required to be examined experimentally.

What was your strategy for searching for non-animal alternatives?

All initial toxicity and screening work was undertaken using well established in vitro or ex vivo models prior to the final validation.

Why were they not suitable?

Whilst both in vitro and ex vivo methodologies provide substantial information regarding the response of specific cells to materials or therapies, the response of a whole organism to wound healing therapies cannot be accurate replicated using existing techniques.

We can assure that only a small number of potential treatments for each study element will be taken forward for in vivo testing thereby ensuring that the number of animals used is as small as possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use the online tool "Experimental Design Assistant" / NC3Rs

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Prior to any tests, during the experimental design phase, we use online tools available (Experimental Design Assistant). An extensive library of online resources is available on the NC3Rs website to provide researchers and technical staff with the practical tools needed to put refinement into practice (http://www.nc3rs. org.uk/3Rs-resources).

What other measures apart from good experimental design will you use to minimise numbers?

All the preliminary tests for toxicity and biocompatibility will be performed using in vitro methods.

We intend to create multiple small wounds on each animal, allowing a large amount of data to be produced while using a minimum number of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Collection of small biopsies and/or abdominal fat for cell extraction for future implantation

Creation and treatment of cutaneous wounds/burns.

Suffering to the animal will be minimised through the use of anaesthetics and well-established analgesia and protective dressings which reduce any pain associated with the creation of the wounds.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Less sentient animal species do not provide the necessary data for treatments to be progressed to human clinical use. The healing process that will be tested require full organism physiology.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Our local NACWO will be consulted prior to any procedure. At any sign of pain, suffering from animals we increase monitoring and our vet will be consulted and their advice taken as to minor remedies or major interventions. This may restore the animal’s wellbeing in a short timeframe. Minor remedies may

include cleaning and re-dressing an exposed wound or the administration of antibiotics if this is experimentally appropriate.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

An extensive library of online resources is available on the NC3Rs website to provide researchers and technical staff with the practical tools needed to put refinement into practice (http://www.nc3rs.org.uk/3Rs-resources).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through constant literature review and update. We also take part on webinars and technical updates from NC3R regularly.

Explain the choice ofspecies and the related life stages

It has been shown that pig skin demonstrates many of the physiological, anatomical and biochemical properties of human skin so that any information obtained in these studies is of direct relevance to the way patients are treated.

Lower/smaller animal species do not provide the necessary data for treatments to be progressed to human clinical use though rats may be useful for some studies such as the testing of infection-signalling dressings, for example.

Previous work using similar approaches have been done for many years in our Institute and we never experienced failure or animal suffering.

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to provide and use the rat brief-access taste aversion (BATA) test as a scientific service to assess the taste of pharmaceuticals (e.g. for young children) at the early phase of development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By nature, a medicine cannot be expected to taste good. The active ingredients, which include acids and bases that allow medications to do their job, are often bitter or even unbearably salty bringing an offensive taste, which can be exaggerated by the dose.

Bitter taste is one of the basic taste modalities. Humans' distaste for bitter flavour may have evolved to protect against accidental poisoning. In fact, many potentially toxic substances taste bitter. Bitter is innately aversive for various species and each animal lives in its own "taste world".

Human subjects are the gold standard of taste analysis especially with nontoxic compounds. However, it is not always possible to use human subjects for taste analysis - for example, when assessing new chemicals without complete safety information, which is often the situation during the early stages of drug development. Although research is continuing in the area, it is complicated to use computer models or laboratory-grown cells, rather than live animals, to reliably look for "bitter" responses, as numerous different compounds, with different solubilities and at different doses, can all elicit "bitter" responses.

Using the rat brief-access taste aversion (BATA) test, taste of active pharmaceutical ingredients (APIs) which are intended for oral, intranasal and inhalational administration, can be evaluated during the early stages of development, ideally at the pre-candidate stage. Therefore, it is possible to screen and select the best compound molecule which can be more effectively taste-masked in future development stages. The rat BATA test can provide data which can assist companies to justify the appropriateness of formulations of drugs, for example medicines for children.

What outputs do you think you will see at the end of this project?

Data will support product development, product registration, patents, and ultimately lead to new products.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

- For research Sponsor companies, data can assist elimination of taste-aversive candidates prior to further costly development, and further animal research.
- The model can accelerate development: the BATA is a decision-making support tool.
- In the long-term the BATA will benefit patients with various diseases or conditions: the impact of this work is applicable in multiple treatment fields.

How will you maximise the outputs of your work?

Whilst publication of results would not be discouraged, it is expected that in most cases publication or dissemination will not be possible as the research will be conducted as a commercial service to companies.

Species and numbers of animals expected to be used

- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The rats will be placed in a box on a "Davis rig" ("lickometer"). The lickometer presents different bottles containing different solutions to the rat, and the rat is able to drink from each bottle for 2-8s, then another bottle, with another solution, is presented. This present-drink-present-drink cycle repeats until the rat has drunk from each bottle at least 3-4 times. The process takes up to 2 hours. The rats are placed in the machine once a day for up to 7 days (usually 5 days), which counts as an experimental period. The first 1-2 days are to get the rat used to the lickometer, and then the next 1-5 days are used for experiments with test substances. The first bottle to be presented is always water, and there is a water "rinse" bottle presented between each test substance. The machine detects how many licks per second the animal takes from each bottle. The aim is to detect "taste aversive" substances: substances that the rat really dislikes. To get a reliable "lick per second" rate, and to truly detect aversiveness, we need to ensure that the rat is thirsty, so the rat will not be allowed to drink for 22 hours before each lickometer session. After an experimental period (up to 7 days) has been completed, the rat is allowed to recover with free access to water for at least 7 days, then it can be used again for another experimental period. We plan to use groups of 10 rats for multiple experimental periods on an approximate week-on/week-off basis for up to 6 months.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The rats will be deprived of water during the experiments, so we expect to see signs of dehydration, like some weight loss or skin "tenting". We expect these signs to be short-lived, and only visible during the experimental days. We would expect the rats to recover from these (for example gain weight, or normal 6 month growth) during the recovery period between experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect all the animals to show mild signs of dehydration during the experiments. Rats have been shown to be very tolerant to these extents of water deprivation, and this particular research group has never had to kill a rat due to dehydration whilst developing the model.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the BATA is as a screening tool for assessment of taste-aversiveness at the very early phases of drug development. At this stage of formulation development, a lack of sufficient toxicology data prevents the use of humans to assess the taste of new molecules or formulations.

What was your strategy for searching for non-animal alternatives?

- "e-tongue"

Why were they not suitable?

The e-tongue *in vitro* tool uses biological sensors and has not been fully correlated to human taste yet.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

There will be 10 rats per group, and 2 groups of 10 rats will be used for 6 months at a time. The licence period is for 5 years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

- By repeatedly presenting test substances alongside water over multiple days; each rat is an individual control, eliminating the need for a control group.
- The group size was optimised during the development of the model. Re-using animals for multiple experiments reduces total animal use.

What other measures apart from good experimental design will you use to minimise numbers?

Re-using animals for multiple experiments reduces total animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rodents are most often used as subjects in taste research. In particular, rats and mice have been widely used for taste perception studies for many reasons: their high drinking capability, their taste similarity to humans and the large corresponding literature available on the comparison of humans and rodents, and their short lifespan. Therefore, all our protocols and equipments will be optimised for these species.

Several animal models exist for the taste assessment: the more commonly used are the two-bottle taste preference and the brief-access taste assay (BATA). With the two-bottle taste preference test there is a higher risk of the animal receiving a larger dose of the test substance, as the animal has access to the

solution for longer. This could then cause side effects and may affect the drinking rate. The two-bottle method also takes a long time to acquire enough data for a dose-response assessment. The BATA test is a better model for our aims, as it lowers the risk of side effects and gives a clearer indication of taste-aversiveness, as well as having robust scientific background and supporting evidence.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

A smaller, less sentient rodent species, such as the mouse, would be less tolerant to water restriction. A younger less mature rat would be less tolerant to water restriction and less capable of accessing the water provided during the tests; the growth rate of immature life stages would also introduce an extra variable to experiments reducing the validity of results and most likely result in using more animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The rats will be trained so they can get used to the lickometer. The training takes place in stages: first the rats are placed in the box with one bottle of water, and no moving bottles. The next day, the bottles will move and be presented separately, and all will contain water. The first "experimental period" for new groups of rats may include the use of a substance which has already been assessed by this study, such as quinine or caffeine. As well as being useful for training the rats, including known substances in this initial experimental period can also provide baseline information: this experiment can be repeated during the 6 months that the rats will be recruited to the study, and the results can be compared to their first try. This helps us check that the rats are behaving in a similar way at different times (for example from month to month).

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our facility is GLP-certified and experiments can be performed to GLP-certified standards where required; non-GLP studies are performed to the same standard operating procedures.

The PREPARE guidelines cover many topics that have been discussed whilst developing this collaboration between the research team which developed the model and our facility, and an adaptive approach to these will be useful for planning specific studies and continuing the project.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Staff actively seek opportunities for training and continuing professional development. We circulate the NC3Rs newsletters and take part in IAT and LASA activities. We communicate openly about animal welfare and suggestions and ideas for improvements are welcomed from all staff members.

An associated research team is in projects investigating taste aversiveness, including development and validation of alternative models, under a separate project licence. These developments can be incorporated into this service as they are validated.

Explain the choice ofspecies and the related life stages

Rodents are most often used as subjects in taste research. In particular, rats and mice have been widely used for taste perception studies for many reasons: their high drinking capability, their taste similarity to humans and the large corresponding literature available on the comparison of humans and rodents, and their short lifespan. This test has been developed and validated using adult male rats.

Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The main objective of this project is to develop new treatments to minimise scarring in glaucoma. This will include new wound healing modulating drugs, new devices in glaucoma surgery and improved drug delivery techniques in the eye.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is a large unmet clinical need being addressed in this project, with glaucoma being the leading cause of irreversible blindness and affecting over 70 million people worldwide. Glaucoma filtration surgery is the mainstay of surgical treatment in glaucoma, but it fails primarily due to scarring in 50% of patients after 5 years of follow-up. The toxic anti-cancer drug, mitomycin-C, is the current gold standard to prevent scarring in glaucoma filtration surgery, but it leads to severe adverse side effects such as tissue damage and severe infection.

This project aims to develop new treatments to prevent scarring in glaucoma patients. In addition, new improved animal models will increase our understanding of the disease mechanisms of complex wound healing in glaucoma surgery. This project will also help us to identify new therapeutic targets and to develop new drug delivery techniques and devices that could benefit millions of glaucoma patients in both developed and developing countries.

What outputs do you think you will see at the end of this project?

1. Improved drugs to prevent scarring after glaucoma filtration surgery in adults and children. This will lead to more successful surgical outcomes in glaucoma.

2. New glaucoma drainage devices that allow for better flow control and therefore prevent potentially blinding post-operative complications.

3. Refined slow release drug delivery methods to improve wound healing post-operatively and the surgical outcomes in glaucoma.

4. Increased understanding of the disease mechanisms of complex wound healing in the eye and identification of new therapeutic targets and biomarkers.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

1. Patients (next 5-10 years)

Our main impact goal is to increase the success rate of glaucoma surgery and to decrease preventable blindness from glaucoma. New anti-scarring drugs, drainage devices and improved drug delivery methods will lead to reduced complication rates and hospital visits, thereby significantly improving the quality of life of glaucoma patients and their families.

2. Health Professionals (next 5-10 years)

A new anti-scarring treatment will help ophthalmologists to better treat their patients, by increasing the surgical success of glaucoma surgery and without exposing them to the risk of toxic anti-cancer drugs like mitomycin-C.

3. Socioeconomic and Decision-makers (next 5-10 years)

A reduction in the side effects of the current toxic anti-cancer drugs will lead to less post-surgical complications, including reduced hospital visits and rate of re-operations, thereby saving costs for healthcare providers (NHS cost savings through post-surgical complications of over £40,000 per patient). On average, a patient with complications is hospitalised 1.2 - 3.8 days longer than those with no complications, costing an average of £1,711 - 4,225 including drugs, clinical costs and rooms.

4. Academic and Scientists (short-term, next few years)

The results and databases will be published in open-access journals so that the research will also benefit the scientific community.

How will you maximise the outputs of your work?

I will publish our methods and results in open-access journals so that the research will benefit the scientific community. Fibrosis is a multisystemic disease and I am part of the REDACTED (Inflammation, Tissue Repair, Scarring & Fibrotic Diseases) consortium. I will present our results at the annual REDACTED meetings and at national and international conferences. I will also set up collaborations with other researchers working on fibrosis in the eye and other parts of the body.

Species and numbers of animals expected to be used

- Rabbits: 1000
- Mice: 1000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

REDACTED

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Moderate severity for all animals (100%) undergoing experimental glaucoma surgery.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although we make extensive use of in vitro (laboratory-based, cell culture) models in this project, there is currently no effective way to model pathological scarring in glaucoma surgery outside the living animal. The new treatments must be able to prevent scarring in vivo (in living animals) to be successful in the clinic and the use of animals in this project is therefore essential to achieve this aim.

What was your strategy for searching for non-animal alternatives?

In vitro (laboratory-based, cell culture) models, e.g. collagen contraction assays, cell adhesion studies, cell viability assays.

Why were they not suitable?

Due to the complex nature of the wound healing process, in vitro studies alone only provide small clues to what may happen in the entire organism. To this end, only in vivo (in living animals) models can provide the accurate and complete results we require before taking our work forward towards human clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

During this project, we will use the minimum number of animals to achieve our scientific aims. This will be done by conducting statistical power analysis prior to initiating experiments to ensure that we only use the minimum number of animals required to produce valid statistical comparisons between the experimental groups. Based on previous studies, we will use 6 animals per experimental group as this is the minimum number of animals required to reach statistical significance.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will use the NC3Rs' Experimental Design Assistant to ensure that we use the minimum number of animals to meet the scientific objectives of the project. We also collaborate with statisticians and they will help with the sample size calculation and experimental design.

What other measures apart from good experimental design will you use to minimise numbers?

Our decision to use wound modulating agents or devices will be guided by extensive in vitro (laboratory-based, cell culture) studies. We will also conduct small pilot animal studies to give us an indication as to the efficacy of the treatment, therefore aiding in the design of the experiments to use the minimum number of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The animal model used is of the least severity that is able to deliver the science and in this case is moderate severity in nature due to the surgery involved. We will minimise animal suffering with the use of anaesthesia during each surgical intervention. We will always give analgesia after surgery. We will also limit the number of times an animal undergoes a drug dosing and animals will be kept for the minimum duration required.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The animal models have been designed to closely reflect human disease. The rabbit model is an established model of eye scarring and agents that have reduced scarring in the rabbit have been shown to be effective in humans in clinical trials. The mouse and rat models are also validated models of eye scarring.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To minimise suffering, we will administer appropriate anaesthesia for every surgical intervention. Analgesia will always be given to all animals before surgery, during surgery and for as long as required after surgery. We will also monitor the animals carefully in the post-operative period and any animal deemed to be suffering will be removed from the study by a Schedule 1 method.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the NC3Rs guidelines on the 3Rs (Replacement, Refinement, Reduction) and the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines, and the Association of Research in Vision and Ophthalmology (ARVO) Statement for the Use of Animals in Ophthalmic and Vision Research.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I am subscribed to the NC3Rs newsletter and get monthly updates about new advances in the 3Rs. I will contact the local NC3Rs Regional Programme Manager for advice during the project.

Explain the choice ofspecies and the related life stages

Where possible, mice or rats (adults) will be used in this project but due to their small size, certain techniques of glaucoma surgery and examination are extremely difficult, and in such cases, rabbits (adults) will be used instead. The rabbit model is a validated model of eye scarring that has previously helped in the translation of the anti-cancer drug, mitomycin-C, in glaucoma surgery.

Home Office

NON-TECHNICAL SUMMARY

88. Individual variation in the life histories of fish

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
Salmon	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project will assess the survival, growth, migration and metabolic patterns of wild, free-living fish; thus, they need to be caught in the wild. As transporting them to a Licenced Establishment is judged to be potentially harmful to their welfare, all procedures will be performed on the fish close to their site of capture (under POLE regulations) so that they can be returned to their capture site quickly after they have recovered from the procedures.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The biology and behaviour of many fish species are increasingly disrupted by environmental changes of both natural and anthropogenic origin. Fish have high ecological significance in rivers (often being apex predators), high economic value (in terms of income from commercial fisheries or angling) and a high societal and cultural value (public appreciating that fish, especially Atlantic salmon, are present in local rivers). Understanding how fish biology and behaviours are affected by environmental changes, how these might cause fish population changes, and how we might mitigate for any negative impacts, is paramount in the face of ongoing environmental change. Developing this understanding is particularly urgent for Atlantic salmon, brown/sea trout and grayling whose numbers are at their lowest for decades. For example, 94% of Atlantic salmon populations in England and Wales are now classified as at risk or probably at risk. In 2018, the numbers of adult salmon returning to Scottish rivers were the lowest ever recorded.

National and International organisations have expressed major concerns and stated that “Factors other than marine fisheries, acting in freshwater and in the ocean are contributing to continued low abundance of wild Atlantic salmon.” These freshwater factors can include in-river habitat change (e.g. removal of water or in-river plant cover), barriers (e.g. weirs and hydro-electric dams), etc., and will likely affect juvenile and adult growth and survival rates in the freshwater, and even at sea. In 2015, a national regulatory body developed a five-point approach to recover salmon populations in which they prioritise investigating the freshwater factors affecting juvenile and adult salmon life-stages.

Populations of UK wild salmon, sea trout are at their lowest ever levels and under pressure from a range of natural and anthropogenic issues. Our work aims to gain better knowledge and understanding of these pressures, which can be used to recommend and formulate policies to strengthen the abundance and resilience of these threatened populations. To this end, we have involved policy makers in the planning and development of our projects.

What outputs do you think you will see at the end of this project?

The expected outputs from this work will include :-

1. Novel information on life history strategies of individual fish, and consequences for their populations. The individual based knowledge that we will obtain from the PIT tag work proposed under this project licence application is exactly the kind of information that we require to enable us to understand and

predict the consequences of current and future changes in the environment at the population level. To obtain enough data to analyse the marine phase of the salmon lifecycle as proposed in this project licence application we need to PIT tag enough juveniles to account for the fact that only 7-12% of the juveniles tagged in the autumn are observed emigrating from the river and only 3-6% of those return from the marine migration.

2. An improved understanding of the habitat and existing and emerging effects of human activities on populations of these fish. The data obtained from this project licence application will provide novel information on the effect of habitat and anthropogenic pressures on growth and survival. From this we will produce recommendations for management and policy changes for freshwater where appropriate to protect and strengthen declining salmonid populations

3. Novel information on the movements and survival of migratory fish through estuaries and the near shore. There is a real void of information about the behaviour of migratory salmonids in transitional and coastal waters and the regulating authorities are looking for more information to enable them to implement knowledge-based management of salmonids in this environment. The regulating authorities are actively engaging in the work proposed under this project licence application and the outputs will influence future policies providing better protection of these species currently in decline.

4. Novel information and improved understanding will be presented in scientific publications and data will be provided for international evaluation of salmon stocks, where appropriate. Scientific publications will ensure that benefits from improved understanding of salmonid stocks is extrapolated beyond the local setting of this project. Data obtained under this project licence application will also feed into the evaluation/recommendation on high sea catches of Atlantic salmon.

5. Communication with stakeholder and the general public in the form of presentations and publications, where appropriate. Impacts on policy will help these populations in decline but only by communicating the results obtained under this project licence application and the resultant recommendations for management to stakeholders and the general public can we maximise the positive effects for salmonids and the environment they inhabit.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Short term benefits – years 1-3

- National and international governments will benefit from the population abundance data we collect on salmon and sea trout. This information will forge national and international policy for the improved management of these fish.

- National bodies will benefit from data we collect on fish tagged during our current project licence. This information will direct policies on river management and coastal planning and netting.

- As a research and education institution, we will benefit from continued use of current infrastructure, staff skills and experience, and use them to educate public and stakeholders nationally and

internationally.

- International collaboration through the working groups on salmon and trout

Long term benefits – years 3-5+

- Contribution to historical baseline data used for national and international salmonid stock assessments and through which to measure the effectiveness of policy changes.

- New and improved policies for the better protection of salmon and sea trout from coastal netting and coastal planning.

- New and improved models to better manage salmon and sea trout stocks for their protection and conservation

- Novel information for policy makers on the emerging effects of human activities on salmon, sea trout and grayling.

- Improved abundance of salmon and sea trout through the implementation of the above

How will you maximise the outputs of your work?

We have a track record of ensuring our work has a practical application.

We collaborate very closely with influential government organisations and conservation NGOs and they have helped design the hypothesis of our work here to ensure it is relevant and accessible to them to better protect these fish.

We hold regular meetings and sit on groups for local, national and international regulatory organisations and NGO's. We hold two fisheries steering group meetings a year where we disseminate our latest findings to a wide range of organisations. We organise conferences, workshops and events.

We will write several articles a year in our own and other stakeholder publications.

We will publish our work in peer reviewed scientific journals (The fisheries department published 29 papers in the last 5 years)

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, a fish will be captured from the wild (e.g. river) by electric fishing and immediately placed in a holding container with river water where they resume normal swimming behaviour within 2-5 seconds. The fish will be placed in anaesthetic for 2-3 mins until anaesthetised. Approximately 90% of the fish used under licence will be placed on a processing table to be weighed, measured, scale samples taken for ageing and genetics and then implanted with an internal PIT tag. This takes some 20 seconds per fish. PIT tag's are about the size of a grain of rice is implanted using an injector or minor incision of 2mm.

Approximately 10% of the animals used under licence will experience the procedures above and In addition, they will undertake surgery to implant a larger (circa 10-20 mm x 5-10 mm tag) into their body cavity. This involves making a incision of 10-30 mm and applying between 1 to 3 sutures

A fish is then placed in a recovery container of river water for up to 30 minutes before being released back into the wild where it was captured.

Some of these fish maybe recaptured. - upon recapture:-

In objective 1, some 10-15% of the 10,000 juvenile salmon and 3,000 juvenile trout that were anaesthetised, PIT tagged, weighed and measured, adipose clipped and scales were taken in September of each year will be re-captured the following spring as they migrate to sea as smolts. These will be recaptured in a rotary, screw fish trap, where they will be removed by hand net, anaesthetised, weighed, measured and the tag will be read with a PIT tag scanner. Once recovered, they are released back into the wild. On return to the REDACTED as adults their implanted PIT tags are read by automatic counters. Therefore, it is unlikely that these fish will be handled more than twice in their life.

In objective 2, the sea trout kelts, are captured by electric fishing in the winter, anaesthetised, weighed and measured, adipose clipped and scales taken. They will then have acoustic and DST tags surgically implanted into the peritoneal cavity. Once fully recovered the fish are released. The following summer some 30% of these fish will return to the river where we aim to capture them in traps and by electric fishing. Upon capture they are killed using a schedule 1 technique. These fish will have undertaken the initial procedures when tagged and then killed when recaptured. These fish will be caught and handled at most twice in their lifetime.

In objective 2 we are undertaking long term studies on grayling populations. Here fish maybe captured and handled annually for the lifetime of the animal, at most 5 years. Similarly, in Objective 1 a proportion of the trout will not migrate to see as sea trout but remain in the river as brown trout. Here these fish maybe caught annually for again up to 5 years or the lifetime of the fish. However, the numbers involved will be very low.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Impacts are described in the Action plan, despite repeated captures we recorded no effect on growth. Fish may experience stress at being held in the holding containers and short term pain during fin clipping and PIT tag insertion.

The most significant potential adverse effects come from the surgery to insert acoustic and DST tags. The incision is much larger and the length of surgery is longer at 2-3mins. Upon release back to the wild we want these fish to behave normally, therefore each fish is given the greatest of care to ensure the implantation process is smooth and as stress limiting as possible. We have refined our methods to use the minimum number of fish acceptable for an experimental purposes, use the smallest tags available, staff training and competency is paramount here to ensuring the procedure goes smoothly and limiting the negative impacts on each fish.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Approximately 90% of the fish we will use will experience a mild severity and 10% will experience a moderate severity.

What will happen to the animals at the end of the study?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the project is to examine natural behavioural patterns of free-living wild fish. This cannot be carried out by any other means than using fish either from the wild or released into the wild from hatchery stock.

What was your strategy for searching for non-animal alternatives?

We have considered using existing or writing custom computer programs to create a realistic but a virtual population that is subjected to the experiment and then measured, which is repeated many times. The result is an estimate of the effect of the experiment on the virtual population and some measure of its uncertainty (and therefore statistical significance).

Why were they not suitable?

The aim of the project is to examine natural behavioural patterns of free-living wild fish, this cannot be achieved without using wild fish

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals that will be used are based on combinations of power analyses, statistical principles, ecological understanding derived from our REDACTED and other studies, and previous experience of logistical considerations. Our team has a wealth of experience and our proposed work is tailored to their abilities and limitations. All numbers and capabilities in the REDACTED have been reviewed and updated for this PPL.

REDACTED salmon population dynamics Originally, the numbers of animals needed to derive robust estimates for important population parameters, such as marine mortality rate, was based on power analysis. Today, our data suggest that the numbers of animals proposed by that original power analysis is required to ensure data are sufficient to draw robust inferences. Specifically, our original power analysis suggested that we needed to mark 10,000 salmon parr in autumn to recapture 500 as smolts in the following spring and to redetect 50 as adults returning in the 2 years subsequent to that spring. We marked 8,422 salmon parr in the autumn of 2015 that resulted in 245 salmon smolts recaptured in spring of 2016 and a total of 52 adults redetected over 2017 and 2018. Similarly, we marked 5,253 salmon parr in the autumn of 2016 that resulted in 158 salmon smolts recaptured in spring of 2017 and a total of 28 adults redetected over 2018 and 2019. The number of salmon parr tagged in 2016 and 2017 were lowest since 2005 due to low stock levels and the resultant smolt and adult data highlight the need for 10,000 fish to achieve the target number of recorded smolts and adults suggested by the power analysis. In 2018 and 2019 tagged the target 10,000 salmon parr and the data from the adults from these cohorts will be collected in the next couple of years. Ultimately, it is the numbers of redetected returning adults that limits the precision of our population parameter estimates, and the numbers recorded during the last PPL were sufficient, but not excessive, to derive meaningful precision, i.e., an uncertainty within 1 % of the estimated returning adult population abundance; many fewer individuals would have resulted in greater uncertainty and meaningless precision, i.e., an uncertainty between 0 – 100 %.

REDACTED trout population dynamics. To derive robust estimates for important population parameters, such smolt contribution from different parts of the catchment and marine mortality of this partially migratory species fish have to be marked through out the catchment in sufficient numbers to take account of high levels of natural mortality as well as part of the population remaining in freshwater all their life. We marked 2,848 trout parr in the autumn of 2015 that resulted in a total of 96 trout smolts detected in spring of 2016 and 2017 and a total of 24 adults redetected over 2017 and 2018. Similarly, we marked

2,736 trout parr in the autumn of 2016 which resulted in a total of 143 trout smolts detected in spring of 2017 and 2018 and a total of 38 adults redetected over 2018 and 2019. Tagging 3,000 trout parr annually provide us with the data that we need for the current analysis but we may be looking to expand this in the future to provide answers to further questions.

Salmon and sea trout smolt acoustic tracking In our REDACTED, we aimed to acoustically tag 60 salmon and 60 sea trout smolts each year in each river under study. This number was a balance between the number required to derive an accurate estuary survival rate estimate with meaningful precision, which has to account for factors such as the perceived average acoustic receiver efficiency at the planned locations, and the logistical constraints of the fieldwork, including factors such as staff time and budget. Of those 60 targeted salmon and sea trout smolts, we actually tagged 120 salmon and 120 sea trout smolts in 2017 and 120 salmon and 119 sea trout smolts in 2018. Preliminary analyses suggest that these numbers are sufficient, but not excessive, to derive meaningful precision.

Sea trout kelt DST tagging In our REDACTED, we aimed to acoustically tag 50 sea trout kelts each year in each river under study. As for the smolt acoustic tracking study, this number was a balance between statistical requirements and logistical constraints. Again, preliminary analyses suggest that these numbers are sufficient, but not excessive to derive meaningful precision.

REDACTED and trout population dynamics For this study, the number of animals used is determined by the survey method – known as depletion; to derive species-specific annual abundance estimates using depletion requires data representing the number of captured fish of each species from a minimum of three consecutive electrofishing surveys. Therefore the final number of grayling and trout used will be proportional (according to the electrofishing inefficiency) to the number of grayling and trout present at the site. For this study, we have and will continue to replicate the depletion electrofishing surveys at six sites because that is the minimum number of sites required to represent the river using statistical hierarchical structures.

Salmon metabolic rates In our REDACTED, ran a pilot study consisting of 24 fish at each of five sites, however to undertake a more robust analysis of the potential effect of individual metabolic rate on future migratory strategy a larger sample size is needed.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

All experimental and behavioural studies undergo a pre-assessment statistical power analysis to determine the numbers of experimental animals required to meet the objectives of the study.

What other measures apart from good experimental design will you use to minimise numbers?

When collecting samples for e.g. genetic analysis the samples can often be preserved for further analysis ensuring that the maximum scientific benefit from samples and in the medium to long term reducing the number of fish that need to be sampled in the wild.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The tags and marks that we use on fish, enables us to not only identify the fish we have used, but saves us from having to re-use the fish with multiple procedures tags and marks in the future. Therefore, these techniques refine the impact on fish over both the short and long term.

Methods used in this project will include:-

Fin clips removes the posterior third of a rayed fin, the fin normally clipped is the pelvic fin. However, in the case of the adipose fin which we use to identify all our tagged fish and to save the risk of them having repeat procedures, we remove the whole fin. The adipose is the smallest and least used by salmonid fish, given all other fins are actively used for swimming. Therefore we believe, removing the adipose, will having the least functional impact on the fish and cause least harm.

Scales and tissue samples. - This is necessary to estimate age, growth, genetic sexing, DNA and stable isotope analysis. To limit suffering we make sure we only take the minimum number necessary from each fish (scales grow back after removal) and use the clipped adipose fin for tissue samples, removing the need for further flesh removal.

PIT tags are small transponder tags. The tags have an indefinite life and therefore continue to give individual identity information over the whole life-time of the fish. The PIT tags we use are 12mm in length and thus very small. the small tag is used to limit disruption to the fish and also to reduce the need for invasive surgical procedure. The tags can be inserted using an injector needle or small 2-3mm incision into the body cavity.

Floy' or streamer type tags - These are external identifying tag and rely on a plastic 'thread' being inserted into the fish muscle (normally the dorsal muscle adjacent to the dorsal fin) and being held in position by a 'T' bar in the muscle. They are required so that our DST tags can be recovered if the fish are caught by anglers or in a fish trap. To limit stress on fish these tags are only used on larger fish, mainly adults greater than 33cm in length.

Dye marks - In case the Floy tag falls out of the adult fish, we will use a Panjet dye mark to mark the belly again so that anglers and trap operators can identify our tagged fish so that we can recover our DST tags. Panjet mark is not suitable for small fish which can cause internal damage. Therefore, again,we only use this mark on larger adult fish greater than 33cm.

Stomach flushing - We may also take stomach content samples to determine if the in-river habitat is providing the optimum conditions for growth and survival. This involves passing water down a tube into

the fishes stomach so flushing the contents out through its mouth. To limit potential damage to fish and suffering, we use a soft tube, suitable for the size of fish and water pressure suitable for the size of fish.

Elastomer marks - These are thin treads of coloured liquid elastomer injected into the fish fins or as subcutaneous dots on pale coloured areas of the fish. Combinations of mark site and colours on individual fish can give a high number of batch marks. Adverse effects are minimal

Visual Implant (VI) tags are small (2 mm x 4 mm) pieces of plastic film that have a code printed on it. They are injected subcutaneously into areas of clear adipose tissue on the fish (often just posterior to the eye). Some inflammation can occur at the injection site but a skilled operator and good injector hygiene will minimise this.

Acoustic, radio and DST tags - These are necessary to be able to collect data from free swimming fish. Tags are inserted via surgery into the perennial cavity. To limit suffering we have refined our surgery procedure to include:- Ongoing training of suturing on dead fish, invested in suitable surgery equipment, ensure that equipment and surgery area is kept sanitised, accurate use of anaesthetic.

We constantly strive to refine our methodology to cause least harm, to ensure this only fully trained staff and those deemed competent will under take this work. Our work is reviewed by our Vet twice a year with on site supervision and each person is approved for competency.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The fish named in this licence are the subject of interest and must be kept alive to be released for future studying. Therefore we cannot use any other animals or species or animals that have been terminally anaesthetised.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Myself and members of the fisheries team will keep up to date with current advances in scientific analysis and sampling techniques.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Electric fishing is one of the main techniques we use to capture fish. We have written manuals and guidance on best practice to maximise fishing efficiency but by immobilising fish in the most sensitive way to ensure they are in good condition for research and monitoring purposes. We review literature and work with manufacturers of fish tags to feed back information on the quality of data obtained and also the observed experience of tag insertion and impacts on fish.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Undertake module 5 training every 5 years. I will read and and distribute, information obtained on the 3RS from relevant websites, including the ASPA gov. We sometimes work in collaboration with other universities and research groups and during collaborations we discuss best practice for ASPA work. We constantly strive to improve our processes and experimental protocol.

Explain the choice ofspecies and the related life stages

We are using salmon, trout and grayling because these are the fish of interest and it would not be possible to investigate our hypothesis using substitute fish or not using fish at all. We need to observe the natural behaviour of these animals in the wild. We will use adult trout, salmon and grayling and also juveniles called fry, parr and smolts. We will not use eggs. We will only use methods that are suitable for each life stage of fish, e.g. we will not insert acoustic or DST tags into 0+ fry.

Home Office

NON-TECHNICAL SUMMARY

89. Induction, assessment and prevention of adhesions

Project duration

1 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Post-surgical adhesions (PSAs) consist of fibrous tissue which sometimes grows excessively and can lead to constriction of the bowel and other internal structures, cause significant pain and even result in female sterility.

This licence will predominantly cover work done as part of our device development strategy and as such will focus on novel minimally invasive devices and new/modified techniques related to them. However, the intention is also to use this as a service licence to investigate other devices/ compounds with the ability to aid in the reduction of the problems associated with adhesions.

In a systematic review of 87 studies including 110,076 patients the incidence of small-bowel obstruction due to PSAs was 9% which is equal to 9,906 patients over a period of five years. If these figures are extrapolated to include adhesions at other sites (which have not yet been exposed to systematic review) it is likely that an excess of 10,000 patients per year could benefit from an effective PSA prevention strategy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The long-term benefit is the reduction or prevention of post surgical adhesions in both humans and animals will reduce post-operative complications, enable efficient recovery to normal movement, reduce or remove the need to carry out subsequent surgery to remove adhesions and thus improve patient welfare, reduce hospital in-patient time and reduce the financial implications.

The short-term benefits will be the development of new devices through initial in-vivo testing and the generation of data for submission to regulatory authorities.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Over the 6 months of this licence we would aim to use approximately 20 sheep and 60 pigs.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The models we use create adhesions, but we do not let these adhesions become painful to the animals as we treat just after creation to assess reduction or prevention and we know from previous studies that the treatments we use have good potential to reduce or prevent PSAs so we would regard this licence as only moderate in its severity. Some animals will be recovered from surgery and will be monitored for up to 6 months after the initial surgery. This may include repeated anaesthetics for the purposes of biopsy and/or non-invasive imaging. Any animals who show excessive signs of distress will be put down and examined in an attempt to determine the cause and also to assess the effect of the treatment applied to them. At the end of each study the animals will be put down and the tissue taken and examined to assess the efficacy of the treatment, also, where possible, tissue will be taken for other studies and/or educational purposes in an effort to maximise the usage and reduce overall number of animals used.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The formation of adhesions is a complex process involving many different components within the body (blood, lymph, enzymes, etc) all interacting and as such a complete live animal is needed to form adhesions for evaluation and subsequent treatment. Prior to live animal studies, procedures, materials or devices to be assessed will, where possible, be tested on cells or tissues in order to keep animal use to a minimum.

Reduction

Explain how you will assure the use of minimum numbers of animals.

All potential treatments, procedures or devices transitioning from the laboratory into live animal testing will go via pilot studies involving small numbers (typically 3) of animals - this is to be sure that the laboratory prediction is borne out in live tissues.

For many of the studies carried out under these protocols, several sites of injury can be induced in the same animal which allows us to reduce the number of animals required to produce scientifically relevant data. Also, the ability to use adjacent or remote tissues from the same animal as internal or autologous controls again allows a reduction in the number of animals required overall.

For those studies carried out under Good Laboratory Practice (GLP) compliance, a regulatory process required by the Medicines and Healthcare products Regulatory Agency (MHRA) and the Food and Drug Administration (FDA) for all pre-clinical studies leading to requests for use in man, statistically robust appropriate information must be derived and this typically requires between 6 and 10 animals per experimental group to satisfy these parameters.

The ability to remove organs and tissues under terminal anaesthesia from animals in one study to be used for in vitro or ex vivo studies or transplantation/implantation or to be used for training reduces the need to retrieve these organs or tissues from dedicated donors thus reducing the number of animals required overall.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The models we use have been evolved over the last 20 years and are as refined as we can currently achieve. We use smaller species (mice and rats) for initial studies to confirm that the laboratory prediction is borne out in live tissues but often need to use more appropriately sized animals (i.e. a similar size to humans) for many studies. Using a range of assessments including non-invasive imaging (e.g. X-ray or Ultrasound) has further refined our techniques allowing us to obtain more information whilst minimising the impact on the animals' welfare.

For some direct application treatments, to establish representative sized defects and relevant treatment doses, large animals are required. Also, for the new procedures, instrumentation is designed for humans and a representatively sized animal will therefore have to be used. There are some areas of anatomy which are specifically recognised within different species as best models – e.g. for meniscal cartilage the sheep is deemed more anatomically similar to humans than is the pig, while for bowel and vasculature the pig is deemed more representative of the human than the sheep. Choices of species will be dependent on the anatomic site under investigation.

Appropriate monitoring of animals post-surgery and intervention if necessary with pain relief medication will ensure animal comfort. Our experience is that the animals are not in any pain during these studies probably because most are treated and those that are not are not allowed to progress to the level of adhesion formation where humans would present with symptoms.

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to test and develop anti-infective drugs and vaccines as a service for customers. We aim to assess their therapeutic potential in animal models. These tests are carried out to satisfy regulatory guidelines to ensure any drugs and vaccines are safe for use in humans and animals.

The aim is to identify, develop and characterise new treatments with potentially better efficacy, and fewer side effects, than existing medicines and vaccines currently available to doctors and vets.

A retrospective assessment of these aims will be due by 30 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines and anti-infective agents play an important role in the routine health and wellbeing of both the human and animal populations. Routine vaccinations in humans and animals have largely prevented the spread of significant diseases and their associated illness and death (e.g. mumps, measles, polio, diphtheria).

There is a shortage of (in particular) effective antibiotics currently available to doctors, due to overprescribing of drugs for viral and trivial infections (for example) leading to bacterial resistance. This

means that bacteria have found ways of dealing with current drugs which means that drugs don't work as efficiently to kill (bacteria) like they used to. In a short space of time, at the current rate, there will be a shortage of effective antibiotics for a wide range of routine infections, which because of this, will mean that previously minor infections could become life threatening. This project would aim to aid in the development of new agents, possibly of new chemical classes, that maybe less prone to these resistance mechanisms in bugs.

Similarly, due to the increasing use of drugs that suppress the immune system in patients with cancer/HIV and other indications, fungal infections in the bloodstream and lungs for example are increasing. Standard therapies at the moment are often toxic in patients (e.g. one standard antifungal treatment causes renal damage) who are already ill. There is an unmet need for newer, safer, Anti-fungal drugs with better side effect profiles in such vulnerable, sick patients.

Vaccination protects the public from serious illness and complications of vaccine-preventable diseases which can include paralysis of limbs, hearing loss, convulsions, brain damage, and death. This project will aim to develop vaccines for a wide range of conditions that are safer and more effective than existing vaccines currently in human and animal use. Progress has already been made with therapeutic cancer vaccines (e.g. vaccinating young girls against a virus that can cause cervical cancer) and future potential targets include addiction, diabetes, high blood pressure and Alzheimer's disease, as well as for other targets such as allergies.

Where vaccine immunogenicity is tested, as they are biologics there could be a request to assess the biological activity of batches-this would only usually be for vaccines that were being used in humans, and for safety and quality purposes.

What outputs do you think you will see at the end of this project?

The short term outputs of this project will be the provision of high quality data , which will be used to make decisions as to whether to progress anti-infective agents and vaccines further, possibly into clinical trials. It will also provide data which may prevent further testing in animals, and hence an overall reduction in the numbers of animals used.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term, sponsors would benefit from the data produced, as it will enable them to make critical stop go decisions regarding their drugs or vaccines, and/or use the data produced to add to regulatory submissions to enable their drugs or vaccines to progress into clinical trials and possibly gain market authorisation.

The public or animals may benefit from this work, as it may lead to new products reaching both the animal and human market, with better and longer lasting activity, better treatment outcomes, and with

less side effects.

Some of this work will be carried out under the Good Manufacturing Practice regulations, which will ensure that any vaccines or peptides tested are high quality, safe and fit for use in humans or animals.

How will you maximise the outputs of your work?

The work will be shared with customers who will use it to determine their future drug and vaccine development strategy, or for submission in documents required by regulatory authorities. This organisation has no control over what happens to the data after we have shared it. Previously however, we have collaborated with customers and shared data we have produced in the form of Scientific publications.

Some customers do use the data we provide for stand alone publications, although this is not always communicated to us.

Species and numbers of animals expected to be used

- Mice: 17000
- Rats: 8500
- Guinea pigs: 2250
- Ferrets: 3000
- Other rodents: No answer provided
- Rabbits: 1200
- : 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In studies involving the immune system, an animal will typically be vaccinated with a material (maybe in a muscle, intravenously, or under the skin), which may be boosted with one or more further injections (typically two or three but maybe more) at a later stage. Either before or after the first dose, blood samples will often be taken (so we can measure and track the immune response e.g. production of antibodies). After a period of time (Typically 1-3 months) the animal will be killed, and organs like the spleen will be taken to measure a further immune response in a tissue.

In infection studies (typically lasting 48-96h, but up to 14 days or beyond), animals will be infected either systemically (e.g. in the lungs, intravenously) or maybe in the thigh, with a bacteria or virus or fungi (we will know the correct dose to give after we read scientific papers or small pilot experiments

we've already carried out). They will then be treated with a drug that we know from test tube work will kill the organism we are inoculating. The animals will then be carefully observed after we've infected them. We will measure temperature and record clinical signs, and continue dosing with the test drug. Occasionally we may take some blood or other samples too. If the animals get too sick (in most experiments this won't happen because we've already tested the infection at this dose), we will kill them to stop any further suffering. We will continue to monitor them depending on how sick they are right up until dosing ends and the experimental time is up. At that point we will humanely kill the animals and prepare organs e.g. the lung or the kidney to count the number of organisms present, and see if the treatments were effective.

Injections and blood samples that are carried out in animals are a very similar experience to what a patient would have when having the same done by a doctor or a nurse in a GP's surgery or hospital. To do this we often have to restrain animals for a short period of time, in a purpose built device, or by hand, so that we can collect samples or inject animals without overly harming the animals (like if they start to struggle).

Whilst this describes what typically happens, on some (very rare) occasions we may use mice that have been genetically modified to better model human disease. We may also remove food and water from animals for short and controlled periods of time to aid with dosing new drugs. For both occurrences, this may happen once or twice in a 5 year period.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals in most infection models may have symptoms like being cold, their hair standing on end and closed eyes. They will also lose weight. In animals that are treated with drugs, most of these effects will either be less pronounced or mainly absent, and they will be moving around their cage looking largely normal and eating and drinking and grooming normally. Depending on the way we infect the animals, they can start to show signs of illness from about 12h after we infect up to the end of the study.

Very occasionally we infect animals with a high dose of an organism that may cause it to have severe clinical signs. This is to test how good the drug we are testing is in a model of infection that you may see in a very sick patient in a hospital. We would expect most animals, even ones treated with drugs to show some clinical signs after this, like being cold, lose weight and look ill. In all cases we will humanely kill animals when its clear they will not survive. We observe these animals on these studies very careful, at short intervals, to make sure we can kill them humanely if we need to, or monitor the progression of their illness.

Animals treated with vaccines very rarely show any signs at all. The vaccines are not designed to make them feel unwell. Occasionally we will see some mild signs, sometimes where we inject the vaccine into. But in approximately 99% of animals we see no clinical signs of illness at all. The animals will move around, play and eat, drink and groom as normal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Overall figures in the last license showed that approximately 95% of animals suffered mild severity, 4% of animals suffered 'moderate' severity and less that 1% of animals suffered 'severe' clinical signs.

During the last license less than 2% of animals infected with a microorganism experienced severe signs, due to the careful chosen doses of infection used, the regular clinical observations, temperature measurements and weighings which will go up if animals are becoming ill due to the infection. Around 10% displayed moderate severity, and 88% mild severity.

On studies that examined the immune system greater than 99% of animals experienced no more than mild severity, caused by the injection of the potential vaccine to cause the immune response. Less than 1% of animals suffered severe clinical signs that resulted in death or humane killing.

We expect numbers to be similar under this project, although this will depend on the specific study types we perform.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 30 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed to demonstrate that the drugs or vaccines being tested can work in a mammalian system which is similar to humans. This may mean that we show, for example, that they can kill bacteria and stop animals developing infections, or show that they can produce an immune response (antibodies) to being treated with a vaccine. If they can't kill bacteria or produce an immune response in animals, then it's highly unlikely they will do so in man.

In some cases, for regulators checking the safety of drugs, or the quality of vaccines, these tests are required to be completed before the drug is dosed in humans, to ensure its safe, or can produce a consistent response when dosed to thousands of people.

What was your strategy for searching for non-animal alternatives?

There are no other non-animal alternatives for the work being undertaken on this project.

Prior to testing in animals, the drugs will have been tested in cells and against microorganisms to check on how toxic they are and how potent they are in killing organisms in test tubes. Drugs that are either toxic at low concentrations or do not kill organisms in test tubes would not be chosen to be tested in animals.

Why were they not suitable?

The intact Immune system is a complex system which is not fully understood and therefore for the work detailed in this project, there is no adequate test tube model to replace the whole animal, that can model all the processes under investigation.

Similarly, infection is a complex disease process involving the immune and inflammatory systems as well as the toxicity of the infective agent on its own. It cannot be adequately modelled in test tubes due to the complex interactions between the infection, the animal, the immune system and the drugs being tested.

A retrospective assessment of replacement will be due by 30 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers we have used are based on figures of previous usage from previous projects, or a projection thereof (based on estimated incidence). It is, however, impossible to accurately predict the number of studies that may be performed, in the circumstances.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

All experiments will be designed in order to achieve the scientific objectives using the minimum numbers of animals required. For study types that are less well established and for which historical data may not be available, the literature will normally be consulted to help establish the group size.

Alternatively, there may be other data to aid this process. The REDACTED are often consulted to assist in this process particularly where the study type is not routine.

Whenever possible, common control groups will be used in order to minimise the numbers of groups used.

For less established study types, preliminary pilot studies may be conducted whereby smaller numbers of animals may be used to generate data in order to ensure that the experiment operates to expectations and to generate some data which may be used to optimise the study design.

Experience has shown that occasionally, Sponsors have a preference with regard to their design and numbers of animals to be used. Rationale for the design will be requested from the Sponsor and such designs (particularly where they are at variance with EU requirement or studies usually conducted here) will be discussed internally (and the Home Office as appropriate) and forwarded to the Department of Statistics for advice. Such advice will be taken into account when determining the design/numbers to be used in the study with the goal of using the least number of animals to achieve the scientific objective.

What other measures apart from good experimental design will you use to minimise numbers?

For studies where a new drug, or a new infection is being tested in animals for the first time, we would often test that in a small group of animals (usually 3-5) to give us confidence that the dose or inoculum levels we chose are safe, and the organism/ drug affects the system its designed to, without making an animal too ill. These are called pilot studies.

We will also try and get as many outputs as we can from a single animal where possible. So if we need to get a level of infection in the blood and tissue, or if we need to find blood borne markers of infection we will often do that in the same animal, rather than use seperate ones.

A retrospective assessment of reduction will be due by 30 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

For our infection models, our animals are infected either by injection or installation of infective agents into the body (e.g. the lungs). We often start by doing small trials (or pilot studies) in small groups of animals to see the level of infection we see, and make sure its right for what we are trying to find out. Sometimes to mimic what happens in real patients, or to remove the effect of the immune response to infection, we administer drugs to suppress the immune system.

When we infect our animals, they do get sick, as humans do when they have say a chest or other infection, but we watch them very closely, provide them with extra bedding to keep them warm, and sometimes provide special foods and gels to keep them fed and hydrated. When our animals get too sick and we know they won't recover, we kill them humanely to end any suffering. For the vast majority of our infection models, most of our animals suffer only moderate symptoms (weight loss, go cold, look ill and stop grooming a little, but are still active) because we do these pilot studies, and because we watch the progression of their disease after we infect them.

On occasion where we infect with a higher dose of infection, the same observations apply, but we would check the animals more regularly as they get sicker. Some of these animals would die without our intervention, and when it becomes apparent that an animals will not recover based on clinical signs, we would humanely kill them and not allow them to suffer further and die.

Our studies involving checking the immune response to vaccines cause very little distress to animals. They are usually a series of single injections or boosters several days apart. Sometimes there will be blood sampling during the course of the study, but mostly all the samples will be collected under anaesthesia at the end of the study, or after the animal is dead. During this whole procedure more the 95% of the animals would show no clinical signs at all and will be eating and drinking and acting normally.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The vast majority of studies are carried out in mice, which are the least sentient species that have an immune systems similar to man, or give the clinical signs and symptoms of infection seen in patients.

Both immunology and infection models last for at least 24h or very often much longer, and it is impractical to keep animals anaesthetised for such long periods of time, without affecting the answers to the experimental questions we are asking.

We use adult animals to model infection and immune responses as their immune system is mature and responds more predictably in comparison to juvenile animals. Effects in adult animals relate better to what is seen in the clinic as well, where the vast majority of patients are adults.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Rodents and guinea-pigs will be mainly used for the tests conducted under this licence. These species are considered to be of the lowest neurophysiological sensitivity commensurate with achieving the study aims. The ferret may be used for discrete modelling of some infectious disease (e.g. influenza and other viral infections) due to its similarity in clinical signs, and immune and inflammatory responses to man.

Infection models

Generally, for infection models, the use of organ / tissue burden data collection endpoints will be used whenever practicable as due to the nature of the infective titre administered, animals should develop a meaningful infection (relevant to the infectious agent) without displaying severe symptoms of infection. The assessment of organ / tissue burden of a microbiological agent would be made post mortem after a period of infection, though for some infection models the progression of the infection may also be assessed by methods such as; serial blood sampling (e.g. bacterial sepsis model) or swabs (skin infection model).

In rare cases, however, it may be necessary to administer an infective inoculum where a lethal inoculum of a microbiological agent is used to evaluate the effectiveness of a test material. This model would only be performed when the anti infective properties of a test material have already been established e.g. generation of tissue burden data or evidence of immune response in a vaccine.

Measurement of microbiological burden (tissue burden) in an animal will be undertaken as a data end point wherever possible to assess the anti-infective properties of a test material, meaning reduced infective inocula and clinical signs of moderate severity (a pilot study would be performed to optimise the infective inocula) . However in rare circumstances, this may not be appropriate due to the nature of test material (e.g. a vaccine) or specifics of the organism under test (may not be amenable to such studies due to growth characteristics to allow this data endpoint, or its specific interaction with host), the stage of development of the test material, hence the requirement for a model resulting in more severe clinical signs.

For all infection models signs of clinical disease will be carefully assessed by observation and recording of body temperature , with the frequency of observation thereafter being dependent on the clinical condition of the individual animals. Bodyweight will be assessed at least once daily. For models where severe clinical signs are expected, this observation minimum would be reduced, with the frequency of observations again dependent on the individual clinical condition of the animal. In both cases, supportive measures (e.g. extra bedding, more palatable food, food supplements, additional heat) will be employed for animals exhibiting clinical signs.

All animals on infection studies will have signs of clinical disease assessed. If animals are rendered neutropenic prior to infection, they will be checked at least twice daily for the onset of clinical signs.

From the induction of neutropenia the frequency of assessment will depend upon whether animals are exhibiting clinical signs, along with information from published literature. When animals are displaying

clinical signs then the frequency of checks will be increased from the normal twice daily to approximately every 6 hours or as required.

Body weights and body temperatures will be measured at least daily after induction of neutropenia.

Supportive husbandry (e.g. extra bedding, food gels, additional heat sources) will also be offered as appropriate.

In some cases, the provision of samples (e.g. blood or nasal lavage in ferrets) which will allow a 'global' assessment of the individual animal condition which would assist in tracking disease progression.

Surgical procedures will be carried out in accordance with the principles set out in the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) and appropriate

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

For any surgical interventions, then the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) will be followed.

For blood sampling and dosing then the following guidelines/literature will be followed:

First report of the BVA/FRAME/RSPCA/UFAW joint working group on refinement, Laboratory Animals, 27, 1-22 (1993).

A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Journal of Applied Toxicology, 21, 15-23 (2001).

Regulatory guidelines

WHO guidelines on nonclinical
evaluation of vaccines. Annex 1.

ICH Topic M 3 (R2)
. Non-Clinical Safety Studies for the Conduct of
Human Clinical Trials and Marketing Authorization for Pharmaceuticals.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

This will be achieved by regular discussions with our Named Information Officer, colleagues in Animals Technology, and by attending appropriate training courses and conferences, or getting feedback from such events.

Explain the choice ofspecies and the related life stages

Most of our experiments will be carried out on mice and rats as these are the smallest relevant species that we can use that have an immune system and that respond to infection that is comparable to humans. In some specialist cases we may use other animals (e.g. the guinea pig, hamster, ferret, cotton rat and rabbit) because what we are trying to find out is better done in that particular species rather than to the rat or mouse. For instance you can model human influenza in a ferret, but not in a mouse or a rat, and a ferret produces both the symptoms and immune response to the flu virus as humans do. Human flu viruses are not viable in rodents.

The only other time we would use a species other than a mouse or rat is to continue work that has been previously done in that species. For instance if previous work, and results gained, had been carried out in a guinea pig, it would make no scientific sense to start the next stage of a programme of work in a rat or a mouse.

We will be using adult animals in our studies, as we do not expect to be investigating either immune responses to vaccines or treatments for infections for use in young animals or children.

A retrospective assessment of refinement will be due by 30 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

91. Intrinsic & extrinsic effects on B cell differentiation

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims to define the extrinsic and intrinsic factors involved in B cell differentiation
.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will produce data that increase our knowledge of how B cells respond to immunisation. B cells are lymphocytes that are best known for producing antibody in response to infection. The production of antibody and memory B cells is crucial to successful protective immunity and without B cells, humans and mice are severely immuno-suppressed. The function of vaccines is dependant upon the effective production of an antibody response and, as such, it is of crucial importance to understand how B cells respond to antigen and, furthermore, to improve upon our current therapies through increased knowledge of the basic mechanisms. B cells also can initiate immune responses through ferrying and presenting antigen and they have been shown to regulate immune responses in models of disease in mice such as EAE and collagen induced arthritis. The therapeutic benefit of depleting B cells in arthritis have indicated the regulatory roles of B cells in autoimmunity beyond autoantibody production, and understanding how B cells hyperactivated when cross-reacting with self antigens may lead to ideas how to treat autoimmunity and how to induce self-reactive responses therapeutically, e.g. in cancer therapy. Our clinical work has shown that diurnal changes are important for the efficiency of vaccine responses, especially in older individuals. This study will identify diurnal changes in B lymphocytes causing this effect, which may lead to ideas on how to improve the antibody response to vaccination.

What outputs do you think you will see at the end of this project?

This project licence and the experiments described within it will produce data that increase our knowledge of how B cells respond to immunisation, specifically, to study how B cells undergo affinity maturation and generate memory to immunisation, and to study the signals regulating B cell differentiation in locally inflamed tissues. This will encompass both how B cells behave in isolation and how they interact with their environment (e.g. other immune cells in the local microenvironment).

The project represents basic research, and within the lifetime of the project it is unlikely that there will be direct benefit to patients. It is anticipated that this body of work will be published in high ranking international journals and discussed at scientific meetings. This work will give valuable information on the improvement of vaccine strategy on aged people, and our understanding of B cell autoimmunity.

Short term benefits will be advancements in basic science of B cell differentiation in response to infection and vaccination, the development and maintenance of humoral memory, and on the mechanisms of activation of self-reactive B lymphocytes.

Medium term benefits may be new ideas how vaccine responses can be enhanced, or how new vaccines to difficult to target antigens may be formulated, or how vaccines generating cross-reactive immunity may be generated, or how antibody responses in the aged immune system may be enhanced. There may be new ideas on how autoimmune B cells can be targeted therapeutically, or how ongoing

autoimmunity may be targeted to slow the disease process. Further, this may lead to new ways of inducing autoreactive antibody responses, e.g. in cancer therapy. Lastly, the project could generate new mouse strains that are useful in the generation of new monoclonal antibody drugs for industry.

Long term benefits may be the translation of these ideas into clinically effective drugs.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The outputs of this project will have very broad reach, encompassing basic research that will informing the fields of immunology, vaccinology, and cancer immunotherapeutics, and at the same time improving vaccination on aged people, and developing a potential target on B cell in autoimmune disease, a broadly applicable new cancer vaccination method towards the clinic.

The project
will have broad academic benefit, provide new knowledge on signals regulating GC B cells selection and antibody response (e.g. antibody feedback, circadian), and information on the role of polyclonal antibody responses to autoantigens by active vaccine and new ways of inducing autoantigen specific antibody responses. New reporter mice provide how to select high affinity GC derived plasma cells to supporting the development of high affinity hybridoma. new B cell anergic mouse model helps understand the phenotype of anergic B cells, and how to regulate anergic B cells to responding auto-antigens, and how immune tolerance broken down in autoimmune diseases. The work on B cell anergy can produce data on immunology of autoreactive B cells after stimulation, which will crossfertilize other fields, e.g. HIV vaccine development, where neutralizing antibody is derived from anergic B cells.

The project has potential benefits on clinic. The research about the effect of circulation for vaccination has the strong benefits to improve vaccine strategy on aged people. the treatment of various solid tumours. This active vaccine to induce polyclonal antibodies to auto-antigens has the potential benefits to the treatment of various solid tumours.

The project also has potential commercial
benefits. The improvement of vaccination on aged people could activate good antibody responses to vaccination and infection, which would benefit patients and the NHS. New reporter mice could improve the development of high affinity hybridoma, which has considerable potential effect on the monoclonal antibody production. Monoclonal antibody have been widely used on the basic research and clinic diagnosis, also have shown huge potential in cancer therapy. We are in the early phase of developing a cancer therapeutic vaccine by active vaccination to harness immune responses to auto-antigens in cancer. This vaccine strategy may be licensed and produced for the worldwide market for treatments of tumours, even potential benefit for the antibody mediated autoimmune diseases. This project has considerable potential to benefit the UK pharmaceutical industry.

How will you maximise the outputs of your work?

The output of project will be presented and discussed on national and international conferences. Outputs will be published in high quality open access journals and the UoB websites regularly updated. Manuscripts for publication will be prepared according to ARRIVE guidelines.

At this establishment we are in collaboration with colleagues who work on humans to study how B cell differentiation changes in the aged immune system, effect of circulation on antibody response, to improve the vaccine strategy on aged adults. We collaborate with industry to develop B cell reporter mice, and anergic B cell models. We start collaboration with colleagues who work on translational immunological research, and medical oncologists to address the B cell functions in autoimmune disease, cancer. We also collaborate with researchers from other institutes/Universities in UK or outside.

Species and numbers of animals expected to be used

- Mice: 30000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, mice will experience mild, transient pain and no lasting harm from immunisation by injection using standard routes or injection into the foot. Foot immunisation will be done under anaesthesia and lead to mild swelling that will not affect normal behaviour. Mice will be be reimmunised or injected immunomodulatory substances. No animal will be injected more than four times. Blood samples will be taken at the beginning of the experiments, before and after immunisation. Animals will be killed within 6 weeks of immunisation. The test substances will already have been tested to ensure that the dosing regimen does not cause toxicity. The final procedures will be undertaken under non-recovery anaesthesia where the animals will only be aware of the anaesthetic being administered and may experience mild distress and no pain.

A significant proportion of mice will receive repeat immunisations into the foot under anasthesia. Swelling after injection may result in mild pain, but should not result in obvious changes in behaviour.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Expected impacts are short-term stress and pain from animal handling and injections. Foot immunisation will often lead to foot swelling that can last a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect most animals to experience mild severity due to procedures such as ear-clipping, intraperitoneal or intravenous injections or taking of blood samples. 20% may experience moderate effects, mainly due to foot swelling after foot immunisation under anaesthesia, or occasionally when a larger numberthan three injections are necessary.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animal models to understand how antibodies are generated in response to vaccination. This process happens in lymphoid tissue that are very complex structures with many different cells types interacting and communicating with each other. In addition, these immune cells are in constant movement that allows them to interact with different partners at different stages of their development. These processes are so complex that currently no in vitro system is able to replicate this.

What was your strategy for searching for non-animal alternatives?

1. computer modelling of immune responses

2. In vitro models

Why were they not suitable?

1. Whilst computer modelling of immune responses is ongoing and improving these do not yet begin to replicate the complicated conditions and variables that exist in the immune system. Our use of computer models helps to confirm some of our data and provide testable hypothesis but is limited in scope and output to small aspects of the B cell response in vivo.

2. In vitro models are useful for very simple replication of immediate B cell stimulation and are used in our laboratory when appropriate but, again, do not replicate the immune system and the complexities

of the environment in which immune responses occur.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have consulted a statistician for power calculations using typical variations from our own earlier experimentation to calculate minimum numbers of animals to be used whilst ensuring that the results are statistically significant. Sample sizes for our experiments are estimated from past experiments, Power calculations using exemplary data from this study showed that group sizes of 8 are needed to achieve a power of 0.9 with alpha of 0.05 and effect size of 2. For experiments of central importance for the study we would work with alpha of 0.01, which would demand group sizes of 12. Typically, these group sizes are achieved by doing two independent repeat experiments. Most animals are generated during breeding and we have used historical data to estimate potential numbers.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice from local professional statisticians has been sought to evaluate proposed experiments for statistical validity and in the generation of power calculations. Numbers of animals necessary were calculated using our own historical data to estimated the expected variability of our experiments and to calculate the minimal number of animals necessary to generate significant results.

Further, we are continously refining our analytical methods in order to reduce variability, allowing further reduction in animal numbers. All relevant tissues where possible will be frozen and stored as input and controls for downstream experiments. Shared use of these will be offered for shared use by other groups working on related questions.

What other measures apart from good experimental design will you use to minimise numbers?

We will minimise use of animals by keeping colony sizes as small as possible. This may lead to experiments having to be split into two independent repeat experiments in order to generate sufficient power. New substances used on animals will be tested first in small pilot studies. Computer modelling may be used to predict experimental conditions that will show the largest effect sizes. At the end of the experiment we will harvest the maximal possible number of tissues. Tissues not immediately analysed will be archived frozen and will be made available to other researchers working on similar questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Some animals will be allowed to age in order to study the immune response in the ageing organism.

In order to induce gene expression in animals or deplete specific cells some animals will have receive substances via gavage, injection, or through food. Oral gavage or injection can be necessary in order to induce a rapid onset of gene expression. This will allow us to study processes that happen within short time periods of a few hours.

We will have to induce immune responses in order to study the response to vaccination. Animals will be vaccinated using methods similar to human vaccination, e.g. injection of substances under the skin, or by intraperitoneal or intravenous injection.

Some animal will have to be vaccinated into the foot, as this induces a strong response in local lymph nodes. This will be done under short term anaesthesia, however, the animals will suffer from temporary swollen foot for several days. This has not led to changes in normal behaviour in the past indicating that there is no major discomfort. If animals do show signs of behavioural change during the foot swelling phase, they will be treated with analgesic agents.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Non-mammalian animals are limited in their use because they either do not possess B lymphocytes or their differentiaiotn is too removed from the human immune system to provide relevant results. Embryos are unsuitable as their immune system is not mature and does not respond to antigenic stimulation in the way mature animals do.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Ageing animals will be carefully monitored by staff trained to work with ageing animals. Group sizes in ageing experiments will be increased to accommodate for loss of animals and to avoid single housing due to animal losses due to old age. Longer drinking spouts will be used, and animals will be monitored for adverse effects such as changes in weight, dermatitis, piloerection, paleness, changes in

mobility, lumps, eye defects, abnormal respiration or stools. If these are observed animals will be treated accordingly, and animals with that may develop severe effects will be killed humanely.

If gene induction or deletion is done for a new gene animals will be monitored closely in the days after induction. Mice will be weighed on a daily to detect weigh loss. If any mice have reduced activity, ruffled coat or hunched appearance they will be warmed and given glucose-saline (sub cut) to reduce heat loss and dehydration which may be a contributor. Flexible gavage tubes dipped in sucrose will be used to minimise damage to the oesophagus. Good handling and technical expertise will minimise any discomfort. Time and route of induction will be optimised in preliminary experiments for efficient induction of deletion of transgenes using the least adverse route of administration.

For all new models, new methods and new antigens we will consult with expert staff at our animal facility. Some methods, e.g. animals that are receiving new antigens or immunisation protocols, will be carefully monitored during the protocol and humane end points will be used if necessary in consultation with expert staff at the animal facility.

Immunisation will be done via injection of antigen. These vaccinations should only have transient effects and animals should return to normal behaviour within two hours. If new antigens will be tested, this will be discussed with expert staff at the animal unit. New antigens will be tested on small groups of animals first.

Some animals are immunised in the foot under short term anaesthesia. Foot immunisation may lead to foot swelling due to inflammation. This should not be strong enough to lead to behavioural changes. Mice that do show excessive inflammation or lameness will be treated with analgesics. Good handling and technical expertise will minimise any discomfort. Mice are not re-injected until fully recovered from previous injection and never at a frequently that causes them to display anything other than transient pain to discomfort. Foot immunisation has been refined by injecting substances under the plantar surface of the foot, away from the weight bearing walking pads. Further, injection of non-immunogenic substances will be done by hock injection.

LASA guideline will be followed regarding volume of substances to be administered.

Pathogens used are weakened or killed versions that should be non-pathogenic within the time-scale of the experiment. When pathogens are used, animals will be monitored appropriately. In the case of bacterial infection mice will be monitored for the first 48 hours following immunisation and also during the third week of infection which is the time of high susceptibility of secondary infection. The dose of bacteria administered is the lowest possible to obtain a response. Expert animal handling staff are aware of the course of the infection and adverse effects are expected to be noticed and dealt with quickly.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Experiments will be performed in line with LASA guidelines.

Will ensure that all experiments are designed to allow reporting in accordance with the ARRIVE guidelines. Our research will be published according to ARRIVE guidelines, regardless of whether a journal endorses this.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will regularly check information on NC3Rs, have signed up to the NC3R newsletter, and will meet with the NC3Rs Regional Programme Manager, and attend Regional 3Rs symposia.

Explain the choice ofspecies and the related life stages

We are using adult mice, because they are the only well studied mammal that has an immune system that is sufficiently similar to the human immune system. Only in mice have experimental methods been developed that will allow us to undertake our work.

NON-TECHNICAL SUMMARY

92. REDACTED

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Stroke is a life-threatening condition, occurring when blood flow to the brain is cut off. The treatment is to reintroduce the blood flow (e.g. by surgery or drugs). The re-introduction of the blow flow to the brain involves activated blood vessels, small chemical mediators and immune cells (collectively termed inflammation). Reducing, and ideally eliminating inflammation is critical for recovery from stroke – this process is called ‘resolution’. However, patients who already have other illnesses such as Sickle-Cell-Disease (SCD), a genetic disorder affecting red-blood-cells, are highly susceptible to stroke and show reduced recovery after stroke. Thus, the aim of the project is to induce a stroke in mice with SCD and administer drugs to resolve the inflammation and protect the mice against stroke.

A retrospective assessment of these aims will be due by 20 October 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work because stroke is one of the leading causes of mortality and the leading cause of disability worldwide. These studies will provide new insight into whether targeting inflammation (i.e. by promoting resolution) in stroke is protective.

What outputs do you think you will see at the end of this project?

Stroke limits the blood supply in the brain, resulting in death and inflammation. This is of particular significance in patients that are highly susceptible to stroke e.g. sickle cell disease (SCD) patients. This PPL builds work outlined in REDACTED. Specifically, during the course of this five-year PPL, REDACTED examine whether there is a disruption of endogenous pro-resolving pathways which may contribute to persistent chronic inflammation and may in part account for the fact that SCD patients are not only more susceptible to stroke but exhibit an exacerbated course of disease as well as clinically poorer outcomes New data obtained will be submitted and published in peer reviewed papers and presented at scientific meetings. Following on from this PPL, the longer term vision REDACTED, once mechanisms have been identified, REDACTED, particularly for patients with co-morbidities such as SCD.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This project will help us to obtain results that could help us to obtain possible therapeutic targets and drugs for the management of stroke, particularly in highly-susceptible patients e.g. patients with sickle cell disease (SCD).

How will you maximise the outputs of your work?

Throughout this PPL and beyond, collaborations are key to driving science forward. The knowledge obtained through the data collected in the PPL will be disseminated at scientific meetings and will be published in peer reviewed journals. Data will be deposited into repositories such as REDACTED and tissues may be available upon request. New methodologies will be sought throughout the course of this PPL and links with the NC3Rs rodent models of stroke network will be sought (https://www.nc3rs.org.uk/rodent-models-stroke).

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Our main objective is to understand the mechanisms behind stroke and why people with certain diseases (e.g. sickle cell disease [SCD]) are more susceptible to stroke and the outcomes of stroke. Thus, in order to study stroke in SCD, we will use mice that are genetically engineered to have SCD and induce stroke in these animals. The stroke model is one which is performed routinely and in many different laboratories including ours. Occlusion (i.e. blocking of a vessel in the brain) of upto 120 minutes will occur using a filament, after which time the filament will be removed so that blood flow can re-introduced (termed reperfusion). Where the reperfusion period is longer than two hours, the animal will be sutured and the animal allowed to recover from anaesthesia (an analgesic agent(s) [for pain relief] will be administered as per NVS recommendations, as clearly stated in the protocol).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

As is seen in the clinic with stroke patients, mice having had a stroke may experience pain, weight loss and changes in behaviour (due to the damage in the brain from the stroke), which typically occurs over 48h. Rigorous monitoring regimes have been put in place for post-operative care. Aseptic techniques will be performed along with barrier principles and environment management to minimise the risk of infection and analgesics will be administered, as appropriate after surgery. The advice from the NVS/NACWO will be sought as appropriate. All drugs/compounds will be made up in sterile conditions. Environmental enrichment will also be given.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The breeding protocols (protocol 1 and 4) are mild. Protocol 2 is severe due to the fact that like the clinical situation, stroke is associated with mortality. In our stroke model, this is typically around 20-30%. Protocol 3 is moderate due to the fact that several things could happen to an animal i.e. one blood sample taken, anti-inflammatory drug administration, cell depletion, inflammogen administration followed finally by thrombosis. Only 10% of mice on protocol 3 will have this. Typically, a blood sample will be taken, anti-inflammatory drug (and/or control) administration and thrombosis model will be performed. Up to ~750 mice will be used for protocol 1, ~1000 mice in protocol 2, ~1000 in protocol 3 and ~750 mice for protocol 4.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 20 October 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand what happens in stroke I will need to perform experiments in-vivo since some of the experiments described are not possible either in humans or in-vitro models. While we have previously used cell culture models to study some aspects of the cell-cell interactions elicited by inflammation, it is not possible to mimic all the complex, multicellular interactions that allow all aspects of a cerebral inflammatory response in stroke. Therefore, I have chosen to use mice since rodents are the lowest species in which stroke can be effectively modelled. Throughout this programme of research

I will ensure that I continue to adhere to the principles of reduction, refinement and replacement. I will share tissue samples with other researchers where possible and I will continually reassess possibilities for alternative or complementary experiments.

What was your strategy for searching for non-animal alternatives?

Human cells and in vitro tests.

Why were they not suitable?

In humans and in-vitro it is not possible to perform in depth analysis of all aspects of inflammation that occurs in the brain following stroke. Mice will therefore be used in these studies as rodents are the lowest species in which stroke can be effectively modelled. I will throughout the course of this PPL seek, review and incorporate any alternatives and other R's should they arise.

A retrospective assessment of replacement will be due by 20 October 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers have been estimated based on calculations performed from similarly designed studies (total 3500 mice), showing group sizes need to be in the range of 8-10 mice/group. However, these numbers are based on all experiments working, including the number of mice required for the different drug combinations. It is likely that considerably less animals will be used in this PPL e.g. if the anti-inflammatory drug REDACTED does not work at the concentrations chosen (based on in vitro data and EC50 values), then there will be no necessity in determining the mechanism of action e.g. co-administering the drug with a drug that blocks receptors known to mediate the effects of REDACTED (such as the pan antagonist REDACTED). A realistic number estimate of the number of animals. However, the numbers requested allow for flexibility with respect to the studies proposed i.e. so that we can pursue different avenues depending upon results.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice from local statisticians was sought, along with adopting helpful tips and advice form the NC3Rs.

What other measures apart from good experimental design will you use to minimise numbers?

I will share tissue samples with other researchers where possible and I will continually reassess possibilities for alternative or complementary experiments.

In general studies were performed blinded and randomised, with a key system to identify which animal/sample has undergone which treatment. Furthermore, compounds administered will be made by laboratory personnel other than the one performing the experiment. Controls will comprise of a vehicle (often saline) for the respective drug to be tested. Sham animals (i.e. animals that undergo the same procedure as the stroke animals but without the occlusion) will be set up alongside the stroke animals as sham mice are necessary to control against any findings associated with the surgery itself. Sham mice are still required for medium/longer term studies to ensure that the results obtained are true and not due to the surgery itself. There will be less than one sham per surgical occlusion model.

A retrospective assessment of reduction will be due by 20 October 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Clinically 85% of all strokes are ischaemic in origin. We propose to use two different models of ischaemic stroke (i.e. the transient middle-cerebral-artery-occlusion/reperfusion [MCAo/R] model or the bilateral common carotid artery occlusion/reperfusion [BCCAo/R] model). The MCAo/R model replicates an ischaemic stroke within the middle cerebral artery and the BCCAo/R model replicates global ischaemia (e.g. as seen clinically with cardiac arrest with reperfusion). This PPL will be split MCAo/R (~80%) and BCCAo/R model (~20%) because more strokes occur in the MCA region and as such our research focus will be directed more towards this area of research. However, it is important to study both clinically relevant models for possible therapy and stroke management.

Different reperfusion times are required because each model involves different being clamped or blocked i.e. BCCAo will be for upto 10 minutes and for MCAo, the MCA will be occluded using a filament for a period of upto 120 minutes

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Humans typically suffer a stroke in their adulthood. As such, to recapitulate the clinical setting in a mouse model, I need to be able to use mice that are at a more mature life stage. In addition, these mice cannot be terminally anaesthetised as I am studying the effects of stroke and drug treatment for the management of stroke in a murine model.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Ophthalmic ointment, appropriate anaesthesia (and possibly reversing agents if applicable) and analgesia will be given as advised by the NVS. Animals will be observed frequently and weighed daily. Animals will also be allowed to recover in specialised housing racks (Tecniplast DBS monitoring rack) in which post-operatively they will recover in a quiet area that will be clean, dry, warm and dimly lit. We will also monitor animals more frequently and outside of working hours, so we can take action quickly. As experiments will be performed on mice that are a model of sickle cell disease (SCD), it is highly likely that this intervention will increase the effects of stroke. All staff looking after these mice will be made aware of the additional risk and animals will be euthanized when indicated to prevent undue pain and suffering.

Compounds administered will be research grade and will have been tested in other in vivo models of inflammation.

In general, studies will be performed blinded and randomised, with a key system to identify which animal/sample has undergone which treatment. Furthermore, compounds administered will be made by laboratory personnel other than the one performing the experiment.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

I will adhere to the Home Office guidance of the Animals (Scientific Procedures) Act 1986 and the NC3Rs guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

New updates will be sought from the NVS, NCIO and AWERB at the REDACTED and from other agencies
e.g. the NC3Rs. Updates that are applicable to the PPL will be implemented where possible.

Explain the choice ofspecies and the related life stages

Fortunately, the biology of inflammation and thrombosis are similar in rodents and humans, thus mice will be used. As we are interested in the reasons why sickle cell patients are highly susceptible to thrombotic events and stroke, we will use mice that have sickle cell disease to study the mechanisms and possible therapeutic targets for reducing inflammation and thrombosis. Typically strokes occur in adulthood (although much younger in sickle cell patients), thus we will use adult mice in this protocol.

A retrospective assessment of refinement will be due by 20 October 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This research work aims to provide new formulations that may improve efficacy of already available therapeutic agents or vaccines, to facilitate the formulation of substances that might otherwise be inactive, and improve storage characteristics (e.g. increased shelf life, or heat-stability, thereby avoiding the need for cold-chain vaccine handling).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Identification and characterisation of drug and vaccine formulations and delivery systems that improve stability or biological action could lead to significant benefits in terms of contribution to healthcare quality worldwide. In real terms, we would expect that work done under this project will help to outline facets – such as techniques and the use of novel agents – of drug and vaccine delivery systems, that may provide the basis for further research and possible clinical trials. The benefits may include the dissemination of research from this project that results in the adoption of more effective formulation strategies – the development of knowledge through this project may lead to implementation of improved formulation strategies within the pharmaceutical area by publishing results based on these studies.

What outputs do you think you will see at the end of this project?

Identification and characterisation of drug and vaccine formulations of interest and delivery systems that improve stability or biological action.

We would expect a similar output to the previous Licence. It is hoped that specific candidate drugs, vaccines and formulations of interest that have been studied through the project may enter pre-clinical and clinical trials or go on to be manufactured to benefit the population.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The work has the potential for widespread improvement of human health, depending on the specific candidates analysed.

There remains a clinical need for safer and more effective medicines and vaccines, this project could lead to significant benefits in terms of contribution to healthcare quality worldwide both for animals (e.g.

TB and Rabies vaccines) and humans (e.g. TB, RSV and flu vaccines).

How will you maximise the outputs of your work?

Dissemination will be via delivery at conferences and peer reviewed publications.

We have several collaborators around the UK and of course all funders will also disseminate the outputs from the project.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

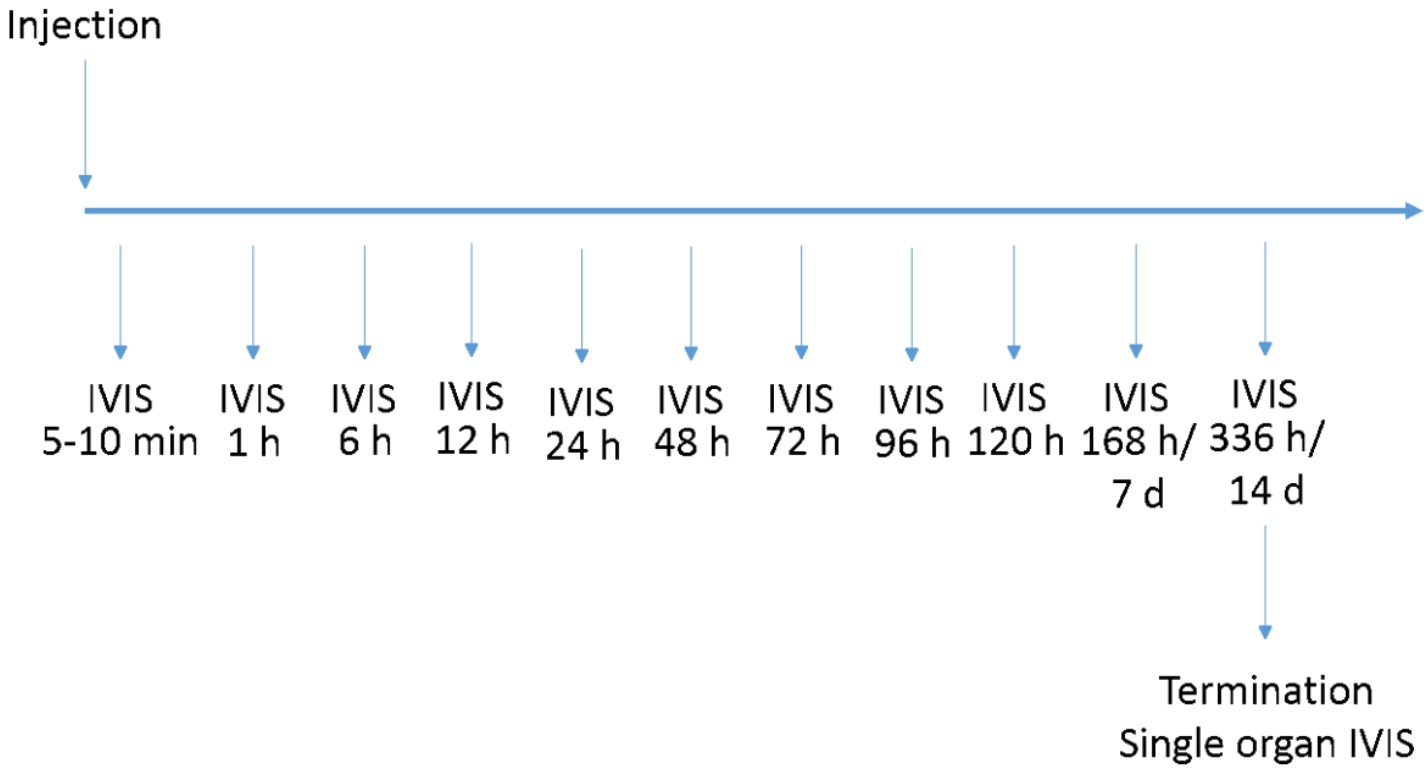
For protocol 1 animals will be administered substances (including radioisotopes) with or without anaesthesia, the route would be in the form of an injection (S/C, IM, IP, ID,IV), inhalation, intranasal dosing or oral gavage three times over the course of an experiment, on a once every two week schedule, this would be interspersed with taking blood samples 4 times (one before the first dose and then in the opposite weeks from the dosing). Animals will then be culled using cardiac punctures to obtain a good volume of blood for the study or a schedule 1 method will be used.

Schedules will involve inoculations no more than twice in any one week and no more than six inoculations within the duration of the procedure; and no more than three times in any one week and no more than seven oral inoculations within the duration of the procedure.

For protocol 2 animals will be imaged using the IVIS which requires them to be administered fluorescently labelled substances, this could be done without anaesthesia, by one or more of the following routes: Intraperitoneal, intramuscular (normally into the quadriceps), subcutaneous (normally into the scruff or at the lower back), oral (gavage), intravenous. Optionally, a suitable dye (e.g. pontamine blue) is administered by s/c. Alternatively, under general anaesthesia, substances may be administered via one of the following routes: Instillation by the intranasal and inhaled route, intradermal injection or intratracheal gavage.

IVIS non-invasive imaging involves anaesthetized animals being placed inside the IVIS imager for a limited time and then allowed to recover. Animals may occasionally be imaged for up to one hour, but typically for less than 15 minutes. Animals will be allowed to rest for a period of no less than 1 hour between imaging sessions. Any one animal may be imaged up to 15 times, with no more than 4 imaging sessions in one day (with the exception of pilot studies). A study may last 1 month, with imaging sessions spaced throughout.

During a pilot study this may be increased as shown below:



Chemiluminescent substances (e.g. Luminol) reacting with reactive oxygen species (ROS) may be administered to the animals via the i.p. route prior to imaging (10-20 minutes). The animals will be imaged using IVIS as described in step. 3 above. Animals may be inoculated up to two times with fluorescently labelled substance, though typically one inoculation will suffice. The inoculations will be at least two days apart.

Animals will then be culled to obtain a good volume of blood for the study or a schedule 1 method will be used.

Below shows the information within the establishments dosing guidelines for each likely procedure listed there, these will be the guidelinesfollowed.

Administration of drugs/substances: to reduce discomfort as much as possible, volumes administered will not exceed the recommended maximum volumes above. If there is a justified need for larger volumes, the Home Office will be consulted. The least invasive routes (i.e. oral in water or food and subcutaneous) will be used in preference to the other routes whenever possible.

General anaesthesia: momentary discomfort/fear; minimised by good technique. Risk of anaesthetic deaths estimated at less than 1%.

Intramuscular injections: can be painful in most species. This route will be avoided whenever possible and the subcutaneous route used instead. If the intramuscular route is used, injections will be administered into alternate sites and with the minimum volume possible. Any animal showing persistent lameness due to muscle damage will be withdrawn from study or will receive veterinary attention.

Intraperitoneal injections: momentary discomfort. There is a risk of damage to internal organs and peritonitis (rare event). The risk will be minimised by good technique. Any animal showing possible signs of peritonitis (weight loss, hunched posture, piloerection) will receive prompt veterinary attention or will be euthanased.

Subcutaneous injections: momentary discomfort; minimised by good technique. Very rarely, swelling and/or erythema. If these develop, or if there is skin ulceration, veterinary advice will be sought.

Intravenous injections: momentary discomfort. There is always a risk of haemorrhage, phlebitis, haematoma or thrombus formation (rare events). These risks will be minimised by good technique and by applying localised pressure to minimise swelling and bleeding. If any animal develops adverse effects relating to venous sampling, it will be withdrawn from study and brought to the attention of animal care staff.

Gavage: momentary discomfort. There is also a risk of oesophageal damage and/or inspiration of gavaged substances (rare events). This will be minimised by good technique. Any animal showing possible oesophageal damage (neck swelling, weight loss, hunched posture, piloerection, excess salivation) or aspiration of contents (acute dyspnoea) will be humanely killed.

Intradermal injections: can be painful. They will normally be carried out under general anaesthesia or sedation. Local erythema and swelling are commonly seen; ulceration is a possibility. If present, ulceration normally resolves within 1 week following onset of symptoms, without the need for treatment. If there are no signs of healing after 3-4 days or if there is secondary bacterial contamination or if the animal shows signs of pain or distress (e.g., scratching/licking), it will euthanased or will receive prompt veterinary attention. Good technique will be used and close observation following injection.

Intranasal dosing: short lived nasal irritation and mild increase in respiratory rate. Very rarely, severe dyspnoea. If any animal develops severe dyspnoea, it will be immediately killed.

All blood sampling will be done based on the establishments good practice guidelines. The guideline can be accessed in the establishment. If bleeding cannot be arrested or there is obvious bruising

causing irritation e.g. shown by the animal licking or rubbing the site or there is an obvious haematoma a veterinary surgeon will be called.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Protocol 1:

Drug Administration: There are no adverse effects anticipated as a result of the drug delivery systems administered.
However, when working for the first time with systems with unknown adverse effects, initial studies will be conducted using low doses and one mouse at a time to ensure there is no related toxicity issues. To reduce discomfort as much as possible, volumes administered will not exceed the recommended volumes stated in the establishments dosing guidelines. The most appropriate administration route will be chosen, taking into consideration the administered

substance.

Animals will not be allowed to lose more than 10% weight loss compared to an aged matched control.

Any animal exhibiting either partial pilorection / subdued behaviour / hunched posture / Oculo-nasal discharge for longer than 12 hours after injection will be humanely killed.

Advice will be sought from the NACWO & NVS for any animal giving cause for concern.

Blood Sampling:
Establishments good practice guidelines will be adhered to. The guideline can be accessed in the establishment. If bleeding cannot be arrested or there is obvious bruising causing irritation e.g. shown by the animal licking or rubbing the site or there is an obvious haematoma a veterinary surgeon will be called.

Radioisotopes: These will be administered at levels that are below therapeutic levels, and in our experience over 10 years appear to cause no adverse effects to the animals.

Mice injected with pontamine blue get a bluish tinge in the skin, especially at the nose, ears and paws. However, no adverse effects to health and behaviour in mice has been observed when applying pontamine blue.

How the adverse effect will be recognised:

Animals will be monitored for the above listed adverse incidents. If there are any doubts as to the severity of the clinical signs of animals undergoing procedures, the named persons will be consulted and advice taken as to whether or not the end-points as authorised in the PPL have been reached. In all cases, where adverse effects occur appropriate measures will be taken to minimise suffering, for example saline may be administered in order to reduce the effects of dehydration.

Anaesthesia: The level of anaesthesia will be maintained at sufficient depth for the animal to feel no pain. Deaths resulting from general anaesthesia are most uncommon in our experience (<1%) and will be kept to a minimum by ensuring accurate dosing during gaseous anaesthesia. The depth of anaesthesia will be monitored using indices such as the pedal reflex, corneal response and depth of breathing.

Intranasal dosing: Animals will be monitored closely following light anaesthesia for intranasal dosing to ensure a swift recovery. Following recovery, animals will be monitored for potential side effects.

Animals whose clinical signs exceed or are likely to exceed mild severity will be humanely killed by a Schedule 1 method

Protocol 2:

Drug Administration: As above with protocol 1

Whole Body Imaging: this is not an invasive procedure but animals need to be still during the scanning session and therefore an anaesthetic is required. During scanning, animals will be kept warm by means of a heated platform. Repeated general anaesthesia is stressful to the animal, therefore, the number and length of imaging sessions will be kept to the minimum possible to answer the specific experimental questions. Similarly, the longest possible interval between anaesthetics (to allow best recovery) will be used, depending on the experiment. Prolonged and/or frequent anaesthetics may result in dehydration. If necessary, subcutaneous fluids will be given to the animals in consultation with the NVS. Any animal showing signs of uncontrolled stress (e.g. losing body weight), or any other sign of ill health, will be brought to the attention of animal care staff or will be euthanized.

Any one animal may be imaged up to 15 times, with no more than 4 imaging sessions in one day. In pilot studies, imaging will be done more often to establish the window of interest (but not more than 15 times in total), which depends on the administration route and administered substance. Once this has been established, in subsequent studies, the number of imaging session will be reduced to the maximum of 4/day. A typical study may last 1 month, with imaging sessions spaced throughout.

If a study requires 2 to 4 IVIS sessions on the same day, the mice will be treated to e.g. Nutella after the imaging session as a means of positive reinforcement to minimize the stress from the anaesthetic procedure.

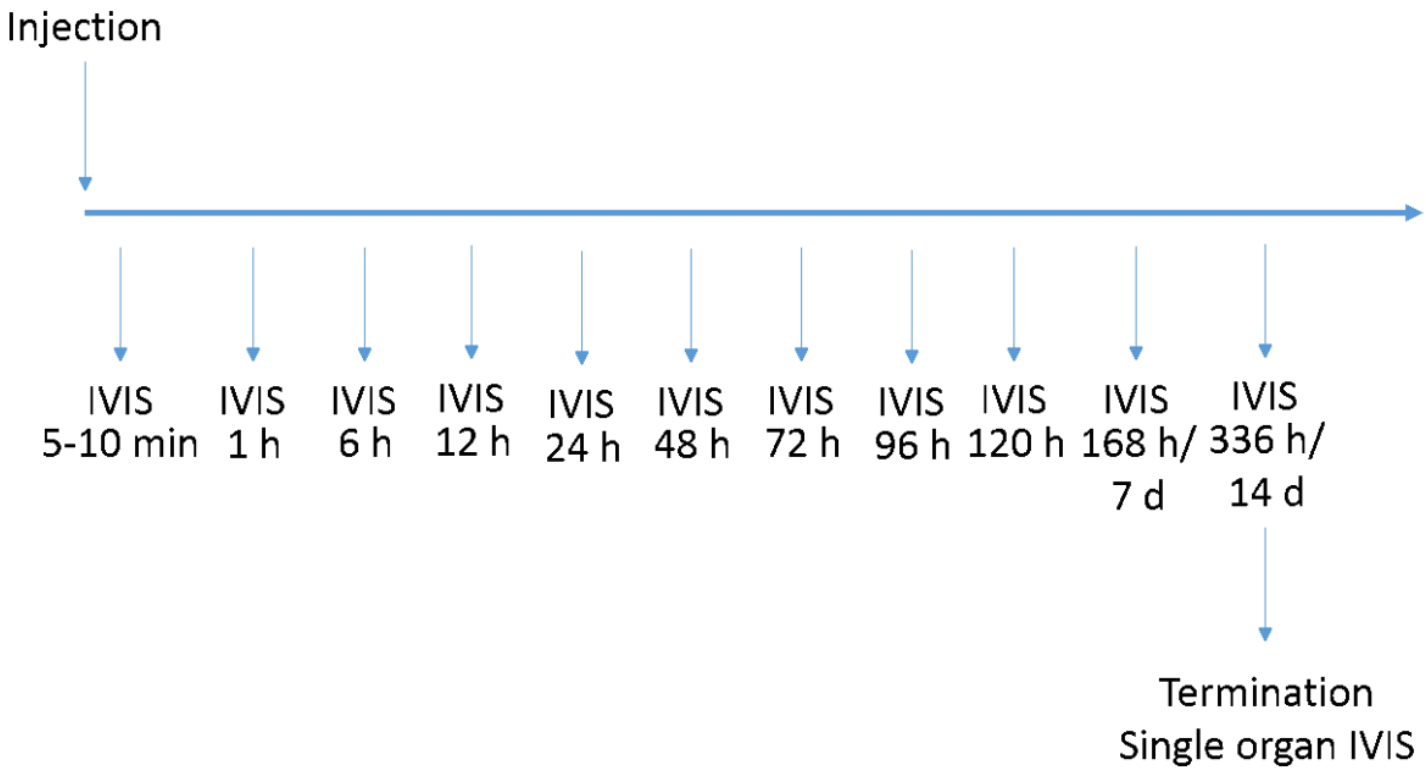


Fig. 1: Example of a study with one injection of fluorescently labelled substance followed by multiple imaging sessions. This is an example of a pilot study with many imaging sessions, fewer imaging sessions will be used in subsequent studies.

Anaesthesia: The level of anesthesia will be maintained at sufficient depth to achieve light general anaesthesia. Deaths resulting from general anesthesia are most uncommon in our experience (<1%) and will be kept to a minimum by ensuring accurate dosing during gaseous anesthesia. Prior to entry into the IVIS, the depth of anaesthesia will be monitored using indices such as the pedal reflex, corneal response and depth of breathing. During imaging in the IVIS, the animal is monitored via the screen, anaesthesia is monitored by observing body movement.

Intranasal dosing:
As above in protocol 1.

Blood Sampling: As above in protocol 1.

How the adverse effect will be recognised:

Animals will be monitored for the above listed adverse incidents. If there are any doubts as to the severity of the clinical signs of animals undergoing procedures, the named persons will be consulted and advice taken as to whether or not the end-points as authorised in the PPL have been reached. In all cases, where adverse effects occur appropriate measures will be taken to minimise suffering, for example saline may be administered in order to reduce the effects of dehydration.

Animals whose clinical signs exceed or are likely to exceed moderate severity will be humanely killed by a Schedule 1 method. Animals will not be allowed to lose more than 15% weight compared to an aged matched control.

Any animal exhibiting either pilorection / subdued behaviour / hunched posture / Oculo-nasal discharge for longer than 12 hours after injection will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Given there are no prospective adverse effects above mild for protocol 1 we expect that all animals would reach their stated severity.

Protocol 2 is assigned a moderate severity due to the possibility of up to 15 repeat anaesthesia sessions. This number will probably only be used at the start of tracking each substance. Therefore we would assess only 50 will be moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune systems and physiology of lower vertebrates are significantly different from humans, including restricted antibody diversity (Roman et al. 1995) that may be partly due to the fact that some immunoglobulin segmental elements do not undergo genetic rearrangement (for example in fish [Litman et al., 1999]) in the same way as that which is seen in humans (and that also seen in mice). In addition, for biodistribution studies and drug delivery, the murine model may be the model of choice for these studies as the mouse physiology, in terms of organs and systems, has many parallels to that ofhuman systems.

What was your strategy for searching for non-animal alternatives?

In conjunction with our in vivo studies, we have used these to develop of an in vitro testing model. REDACTED

of in vivo liposome efficacy'. In these studies we have quantified liposome uptake by phagocytes using the human continuous cell line THP-1. Fluorescence-labelled liposomes were co-cultured with THP-1-

derived macrophages at a final lipid concentration of 5 µg/mL. The proportion of

macrophages associated with fluorescent liposomes, and the relative amount of fluorescence associated, was quantified using flow cytometry. Our results shows the time-dependent uptake of liposomes after application to THP-derived macrophages at 37°C; with changes in formulation influencing cellular association in line with in vivo results we previously found. We are continuing with these studies and using previously published in vivo data to back-correlate with the in vitro studies with the aim of validating this in vitro tool.

REDACTED

Why were they not suitable?

At present it is impossible to recreate the biological environment in terms of biodistribution throughout complex physiological systems following the administration of a therapeutic or prophylactic agent. For this and the evaluation of biological effects in some systems (such as the immune system mentioned here) animal testing may be necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This has been estimated based on our experience of screening formulations. Normally we will start this a high-through put model where we screen up to 20 formulations for the physical attributes. Form this at least 10 of these will progress in vitro and we then down-select a maximum of 4 formulations to test and include 2 control groups. This gives us 30 to 36 animals split over two studies (to provide intra and interday variability). We would normally conduct 5 to 6 of these studies in rats over the course of the project (covering protocol 1 and 2).

For mice we use a similar design, however we have large research programmes working on vaccines. Normally we would conduct up to 12 to 14 of these studies per year (2 to 3 per researcher per year) (covering protocol 1 and 2).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In these and larger studies, good experimental design will ensure the combination of control groups and the comparison of multiple experimental entities or doses (or where appropriate, the utilisation of factorial experimental design).

The work conducted within these studies is based on improvement of formulations therefore control groups will be restricted to benchmark groups so that improvements can be tested and negative controls will be avoided unless absolutely necessary. All studies will be built on pilot data from either small group trials (n of 1 to 3) or based on previous data generated.

Advice on group numbers with reference to the data specific to our experiments will be obtained from the statistician responsible for advising the bioethical committee, who is experienced in statistics relating to animal experiments and peer review of proposed animal work.

What other measures apart from good experimental design will you use to minimise numbers?

IVIS is an alternative to performing biodistribution studies using radiolabelling of the administered substance. Because the imaging is performed under anaesthesia, the same animal can be used throughout the study, rather than having to euthanize animals at each analysis time point. In the long run, this can significantly reduce the number of animals used.

We will also only use animals when the lead compound shows activity in in-vitro tests.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Largely for reasons mentioned under ‘Replacement’ above, the mouse model is the most widely used model for initial vaccine immunogenicity evaluation and the initial in vivo assessment of developmental new drugs and delivery systems or formulations. The use of the mouse model enables cross comparison with other studies and hence more widely applicable results and context within which such results can be evaluated. We will draw on previous experience and the latest research to ensure doses of antigens and adjuvants are correct and we will set the earliest possible end point for the experiments. All protocols will be performed under the mild/moderate prospective severity limit and animals will be monitored to ensure they do not go beyond this point.

Similarly, in terms of drug delivery and biodistribution, a large number of studies have utilised the mouse and rat models and evaluation and comparison of the results across the literature is possible. The rat model may be appropriate only where it is deemed that the murine model may not generate sufficient data (e.g. in some biodistribution studies) or where there is a need for cross comparison with other studies.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The immune systems and physiology of lower vertebrates are significantly different from humans, including restricted antibody diversity (Roman et al., 1995) that may be partly due to the fact that some immunoglobulin segmental elements do not undergo genetic rearrangement (for example in fish [Litman et al., 1999]) in the same way as that which is seen in humans (and that also seen in mice). In addition, for biodistribution studies and drug delivery, the murine model may be the model of choice for these studies as the mouse physiology, in terms of organs and systems, has many parallels to that of human systems.

At present it is impossible to recreate the biological environment in terms of biodistribution throughout complex physiological systems following the administration of a therapeutic or prophylactic agent. For this and the evaluation of biological effects in some systems (such as the immune system mentioned here) rodent testing may be necessary.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Biodistribution studies using radiolabelled substances will focus on endpoint experimental data and will thereby be restricted to mild severity unlike some studies where prolonged procedures may lead to moderate severity.

Biodistribution studies using IVIS require several imaging sessions with anaesthesia, and therefore these studies are considered of moderate severity. These animals will be provided treats (nutella or similar) after imaging sessions to help with recovery and so they also have some form of positive experience from the procedure.

Based on previous publications, we will not use Freud’s complete adjuvant as a vaccine adjuvant control due to its potential for causing distress to animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The establishments good practice guidelines and the NC3Rs website. Also by ensuring that all training records are up to date and that all procedures are done by a competent person.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By checking in on the NC3R's website I can see of any new information from the source. As well as this, keeping up to date with current research advances could result in and of the 3Rs being improved. Also by raising any issues that arise with the NACWO, NVS and the technical staff with the aim to refine techniques to eradicate these problems.

Explain the choice ofspecies and the related life stages

The immune systems and physiology of lower vertebrates are significantly different from humans, including restricted antibody diversity (Roman et al., 1995) that may be partly due to the fact that some immunoglobulin segmental elements do not undergo genetic rearrangement (for example in fish [Litman et al., 1999]) in the same way as that which is seen in humans (and that also seen in mice).

For biodistribution studies and drug delivery the murine model may be the model of choice for these studies as the mouse physiology, in terms of organs and systems, has many parallels to that of human systems. At present it is impossible to recreate the biological environment in-vitro in terms of biodistribution throughout complex physiological systems following the administration of a therapeutic or prophylactic agent. For this and the evaluation of biological effects in some systems (such as the immune system mentioned here) animal testing would be necessary.

Home Office

NON-TECHNICAL SUMMARY

94. Investigating post-partum welfare of cows and calves

Project duration

2 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes.

Key words

Cow, calf, welfare, behaviour, parturition, NSAID

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The welfare of farmed animals is under increasing scrutiny from consumers as well as governmental and industry bodies. Millions of cattle experience parturition (giving birth) every year worldwide every year and although parturition is a necessary event for cows, research into the welfare effects of parturition and birth are lacking. Most parturition in cows proceeds without the need for human assistance, however assistance is required in a substantial minority of cases each year. The size of this minority has been reported be up to 50% by some authors, which for the UK dairy industry alone equates to up to 900,000 parturition events every year. There is some evidence that assistance at parturition is more stressful and more painful for cows than unassisted parturition however studies researching the effect of administration of pain relief are limited. There is a paucity of research studying the effect of assistance on calves and it is uncertain whether assistance at birth is painful for calves and whether administration of analgesia improves calf welfare. There is some evidence that calves born to assisted births have subsequently poorer health and production than their counterparts born to unassisted parturition. The aim of this work is to build on previous work to further determine the welfare and health benefits for dairy cows and calves of administration of pain relief immediately following parturition/birth, and whether animals experiencing assisted calving receive additional benefits.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The project will add to the current, limited knowledge base regarding any pain experienced and the welfare effects of parturition and birth in dairy cattle. The inclusion of analgesic intervention in the study will enable assessment of the welfare benefits pain relief to cows and calves in the post-partum period and has the potential to have far-reaching effects in improving post-partum welfare in cattle and calves. If pain relief is shown to be effective, it could be routinely administered by farmers to achieve significant welfare benefits for large numbers of animals.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use up to 300 calves and 300 cows over the course of the project.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The severity level of this project is mild and serious adverse effects are not expected. Animals will receive an injection of pain relief or placebo. Some animals may experience localised muscle trauma at

the site of intramuscular injection but the risk of this will be minimised by experienced personnel, appropriate restraint of the animals and correct volumes. Animals will be commercial dairy cows and calves, reared on a farm in the usual way, and following veterinary checks, they will be returned to the commercial herd after the study has ended.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

There are no alternatives to the use of cattle for this project because we are assessing welfare in this species. It is not possible to replicate parturition and birth in an *in vitro* environment.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We have carefully calculated the minimum meaningful numbers of animals required, based on previous studies, and this will not exceed 300 cows and 300 calves. A factorial design will be used to maximise statistical power and allow identification of interactions between our measures and causal factors, preventing the need for repeat studies and thereby minimising animal numbers.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our use of cattle is essential as we are investigating the welfare of this species. We have minimised the welfare costs to the animals by using a pain reliever known to be well tolerated in this species and by it being administered by experienced personnel. The severity of the project is mild and severe adverse events are not expected; however if unexpected severe adverse events do occur, veterinary attention will be sought immediately and appropriate action taken under direction of the attendant veterinary surgeon.

NON-TECHNICAL SUMMARY

95. Investigating the effects of sex hormones on heart disease progression

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project has two main aims.

Aim 1: to determine the sex differences in the cardiac responses to high blood pressure.

Aim 2: to determine the mechanisms whereby oestrogens and related compounds affect heart structure and function in health and in disease progression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heart failure (HF) can be considered to be the common endpoint of most types of cardiovascular diseases. As treatments for acute heart disease have improved, HF is becoming increasingly common. There are sex differences in the response of the heart and cardiovascular system during disease progression towards HF, particularly following menopause in women. The underlying reasons for differences in this "remodelling" response have escaped rigorous investigation with an assumption that treatments for high blood pressure and HF are equally effective in both sexes. This work will determine the sex differences in the responses of the heart to maintained high blood pressure, the effect of sex hormones on these responses and examine if established HF therapies benefit both sexes equally.

The stimulation of certain oestrogen receptors in the membranes of heart muscle cells leads to an improvement in the relaxation of the heart and decreases the chances of arrhythmias occurring. The actions of sex steroids on the heart are largely unknown and while the past notion that "oestrogens are good" is too simplistic, new evidence indicates their capacity for benefit in specific situations. The work in this part of the project will examine the effects of sex hormones on the heart.

This will result in knowledge necessary to develop ways of moderating disease progression and improving current treatment strategies and may have considerable implications for the optimal instigation of such treatments thereby allowing a more logical approach to their use.

What outputs do you think you will see at the end of this project?

Heart failure (HF) can be considered to be the common endpoint of most types of cardiovascular diseases. As treatments for acute heart disease have improved, HF is becoming increasingly common. We know some of the disease outcomes at the molecular level but we do not know the effects of progression of the disease on the function of key proteins involved in the electrical and mechanical functions of the heart. This work will characterise these.

Although sex differences in the remodelling of the heart in the progression towards HF have been

acknowledged, the underlying reasons have escaped rigorous investigation with an assumption that treatments for hypertension and HF are equally effective in both sexes. This work will determine the sex differences in the cardiac responses to a high blood pressure and examine if established therapies benefit both sexes equally.

The activation of certain oestrogen receptors improves the relaxation of the heart (so it fills with blood more easily) and decreases the likelihood of arrhythmias occurring. It is important to determine the mechanisms whereby sex steroids affect the anatomical and physiological changes that take place in the heart during progression towards HF. This will result in knowledge necessary to develop ways of moderating disease progression and improving current treatment strategies.

The results of this work will be presented at scientific meetings and will be published in peer-reviewed journals to ensure wide dissemination to the appropriate audience.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This work will lead to a better understanding of the mechanisms involved in the different responses of the two sexes to HF. At the level of the cardiac muscle cell this type of investigation has not been done before. Other REDACTEDs at our establishment will benefit from this knowledge and with publication and conference presentations, other groups in Europe and elsewhere. As a clearer picture of sex differences in the progression of heart failure emerges over the duration of the licence, interest from the pharmaceutical industry is likely because the results may influence a more tailored – and therefore more effective – approach to treatment strategies that may benefit both sexes.

How will you maximise the outputs of your work?

The results of this work will be presented at scientific meetings, will be published in peer-reviewed journals to ensure wide dissemination to the appropriate audience and these information routes will encourage further collaborations and potentially lead to translational opportunities.

Species and numbers of animals expected to be used

Guinea pigs: 650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will undergo constriction of the main artery that leaves the heart and this induces a pressure overload on the heart that mimics high blood pressure. The hearts undergo a gradual increase in growth of muscle cells, changes in their electrical and contractile characteristics and progress to failure and this takes about 150 days. The surgery is carried out under aseptic conditions and uses effective anaesthesia, analgesia and antimicrobial and fluid replacement treatments. Non-invasive ultrasound scans will be made on selected groups of animals after the post-operative recovery until the end of their study time to assess heart size and function.

Female animals may also undergo surgery to remove both ovaries which mimics the menopause. Drugs that are used therapeutically to reduce blood pressure and stimulate or inhibit oestrogen receptors may be administered to assess their effects during the progression to heart failure. The animals will be killed humanely and the hearts removed. From these we will isolate single heart muscle cells, or slices of heart tissue or use the whole heart. The cells or tissues are then subjected to a variety of electrophysiological, fluorescence and molecular techniques.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Short term impacts

(1) As with all invasive procedures, there is risk of operator error to cause trauma or even possible death. However, this procedure has been carried out successfully for over 20 years, with minimal (approx 4%) mortality due to surgical or anaesthetic error *per se*. The small number of animals affected will not suffer any distress because they will be fully anaesthetised.

(2) A number of animals (<15%) could develop acute heart failure (occurring between 6 – 24 hrs of the aortic constriction) if they fail to adapt to the constriction. This is the most common cause of peri-operative death and is more common in females than males. It is unpredictable in nature and preceding clinical signs are difficult to recognise over and above usual post-operative somnolence or drowsiness. Analgesia levels are high in the few days following surgery so animals will not experience pain.

(3) Some animals can scratch or pull sutures apart before the wound has healed and if this happens wounds will be cleaned and re-closed.

Most animals have an uneventful recovery and will be housed in groups to encourage social integration. Together with regular gentle handling and cage enrichment these measures minimise distress and alleviate boredom during the long-term studies.

Longer term impacts

In the longer term (>7 days after the constriction operation) there is myocardial remodelling that can give rise to disturbances in electrical impulse conduction and propagation, and to the mechanical cycle of contraction and relaxation. There is a risk that a small number of animals may die from sudden cardiac death that, like in the acute cases, is probably caused by lethal arrhythmias but the exact cause of death is uncertain. Such sudden death during the progression towards HF is a relatively rare event (approx 2 %), but is unpredictable in nature because there are rarely any preceding clinical signs, akin to the human situation.

In humans, oestrogen deficiency is a cause of bone loss occurring during the first two decades after natural menopause. Ovariectomized guinea pigs may have potential for some bone density reduction but studies in other species report that ovary removal does not have significant effects on the serum levels of calcium regulating hormones, parathyroid hormone and the vitamin D metabolites nor do they indicate changes in physical activity, or increases in bone fractures over the longest protocols to be used in these studies (up to 160 days). Careful observation of the general health and activity of the animals will assist in detecting unlikely, but possible, long term bone density-related ailments.

Animals will be monitored daily for signs of ill health such as weight loss, becoming pale, breathlessness, lethargy and fur standing up in a reflex response that can signal ill-health. The food and water intake will be checked by a trained, experienced technician.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For animals experiencing each protocol the expected severity is moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is no alternative to the use of animals for these investigations. We are investigating complex inter-relationships between various physiological systems i.e. blood pressure regulation, blood pumping by the heart and nerve and hormonal signalling which all contribute to the pathophysiology of heart failure. These inter-relationships would be too complex and ill-defined to be studied using computer modelling or cell culture models.

What was your strategy for searching for non-animal alternatives?

Long-term cultures of animal adult heart muscle cells and use of human heart cells were considered for this work.

Why were they not suitable?

Long-term cultures of heart muscle cells are not suitable for the *ex vivo* / *in vitro* studies because they cannot divide to form new cells. Adult heart muscle cells cannot be cultured for longer than 48 hrs because thereafter they revert to a fetal (ie not adult) form and lose the mature systems that couple the electrical excitation of the cell to the mechanical contractile response. These are the systems we are studying. The electrical and mechanical changes to large and failing hearts can only be carried out on cells that have undergone, or are undergoing, the cellular processes involved in these transitions.

Human cardiac cells can be obtained from valve replacement or heart transplantation surgery and can be used for these studies. However they are difficult to obtain consistently and the patient history and past treatments can produce many confounding variables. Acquiring control tissue is fraught with obvious ethical and resource issues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals needed is calculated using published information, previous experience (taking into account experimental difficulty and success rates) and the biological variation encountered in making some of the common measurements (e.g. electrical and contractile parameters). Our calculations account for different time points of study and give us assurance that our experimental methods will detect an effect (assuming one exists).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We follow the international PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines, have taken advice from our statisticians and have planned the studies to enable them to be published according to the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines which are intended to improve the reporting of research using animals and approved by the National Centre for the Replacement, Refinement and Reduction of Animals in Research also known as NC3Rs.

What other measures apart from good experimental design will you use to minimise numbers?

We are fully aware of the cost/benefit issues this work entails and constantly strive to refine techniques and maximise the quality of the experimental data. We minimise live animal use by capturing as much *ex vivo* and *in vitro* data as possible from each animal. Most of the experimental work is carried out *ex vivo*. The use of single cells and multi-cellular preparations allows different experiments to be carried out on one heart by the sharing of the heart tissue digest with different scientists so minimising animal use. In addition, *in vivo* echocardiography enables characterisation of the structural and functional changes occurring to the heart as a consequence of hypertrophy and heart failure in the conscious, rather than the anaesthetised, animal avoiding re-use and multiple doses of anaesthesia and so reduces animal numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We need to induce heart failure so that we can study the cellular processes that underlie the condition for a more tailored and effective approach to treatment strategies. Appropriate choice of animal model is crucial for meaningful scientific outcomes. We use an animal model that closely resembles the human situation. We produce heart enlargement and heart failure in the guinea pig by performing constriction of the main artery leaving the heart. This procedure replicates the extra load on the heart that it experiences in overcoming high blood pressure (common in humans), is well-described for the guinea pig and is well-established in our laboratory. The surgery is under aseptic conditions and incorporates effective anaesthesia, analgesia, and fluid replacement to minimise pain and suffering. End points are chosen so that distress is reduced to the minimum consistent with the symptoms of onset of the condition.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Adult guinea-pig is the least sentient species that importantly shares the physiological features that are under examination with human.

We are investigating complex inter-relationships between various physiological systems i.e. blood pressure, heart output and nerve and hormonal signalling which all contribute to the pathophysiology of heart failure and to sex differences in onset of the failure. These inter-relationships would be too complex and ill-defined to be studied using computer modelling or cell culture models or in immature animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have noted and incorporated a number of refinements to each protocol since we started to use the guinea pig 20 years ago. We continue to monitor animals closely, and with the Veterinary Surgeon constantly assess possible improvements in post-operative care, pain management, and animal environments.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We follow international PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines, plan and conduct studies according to the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines and use National Centre for Replacement, Refinement and Reduction of Animals in Research (NC3Rs) guidelines to ensure our animal experiments are as robust and reproducible as possible.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We read the monthly updates from the National Centre for Replacement, Refinement and Reduction of Animals in Research (NC3Rs) on their events and publications and their e-Learning resources all of which detail advances in replacement, refinement and reduction techniques and best practice and provide information how to put these in place.

Explain the choice of species and the related life stages

It is vital to choose an animal model that closely resembles the human situation. The guinea-pig is the least sentient species with which we could carry out these experiments and have confidence of achieving meaningful data. Among the small mammals commonly used in these types of study, the adult guinea-pig is the species of choice because in many relevant physiological aspects it displays similar features to the human. Our interventions in this animal produce well-defined changes to the lungs and chambers of the heart that mimic the clinical condition closely. The electrical and mechanical processes of individual heart muscle cells are almost identical to that of human. In terms of sex hormone balance and production, again the guinea-pig is similar to the human. Finally, we have long-standing experience with the cardiac physiology of this species providing us with a solid empirical reference point for our control groups.

NON-TECHNICAL SUMMARY

96. Investigating the genetic control of cancer

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

cancer, genetics

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Deaths related to cancer are the second leading cause of mortality in the UK, and the development of novel diagnostics and therapies remains an unmet clinical need. This project is aimed at increasing our fundamental understanding of the causes of cancer and the development of experimental preclinical

models of human cancer that will accelerate the translation of novel therapies into the clinic. It is now clear that genetic status is fundamental to altered predisposition to cancer, cancer progression and response to therapy. Understanding the biological mechanisms associated with these genetic changes will be vital to facilitate new treatment strategies for human disease. In this project we wish to approach these subjects using existing strains of GA mice in novel combinations and also generate new GA mice to investigate the importance of certain genes during cancer in vivo. This will allow us to achieve three primary goals: Firstly to understand the function of certain genes during cancer with regards to how they regulate important cellular functions such as growth, cell death and migration, secondly to generate more accurate mouse models of cancer to better mimic human disease, and thirdly to use the tools and knowledge obtained in the first two aims to identify and test novel therapeutic strategies and targets.

A retrospective assessment of these aims will be due by 18 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project aims to investigate the function of genes implicated in cancer, for example observed in high levels in tumours compared to surrounding normal tissue. This genetic information provides a powerful tool to understand the requirement for a particular gene during cancer and therefore identifies if it will be an attractive target for therapy. For example, if we identify that gene X is up in cancer and then develop a new GA mouse to delete that gene which results in smaller tumours this would lead us to then try and inhibit gene X by a therapeutic strategy using drugs. This is particularly relevant to the treatment of cancer, as at present there are relatively few new options available in the clinic to modulate the course of disease, and therefore new, effective therapies are desperately required. We furthermore hope to gain an understanding of the degree by which genetic status determines the response to a range of therapies. The majority of clinical benefits are likely to be long term; our principal hope is that by identifying candidate genes and candidate genetic pathways we will be able to refine and accelerate drug development for human therapy. There will also be short term benefits, primarily from the testing of novel drug therapies within our models. This latter approach has the potential to directly and immediately modify clinical practice. Finally, the development of new, more accurate mouse models of cancer will provide a powerful research tool for other scientists to directly inform clinical trials and accelerate translating our findings in animal models into the clinic.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice are the species to be used. Mouse numbers have been extrapolated from the current funding awards held. Funding bodies require full power calculations to justify mouse numbers and sometimes

compulsory use of the NC3Rs experimental design system, and thus the numbers are as accurate as possible and we estimate that we will require 21,500 mice over the 5 year period of this PPL.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

During the project, we will generate and analyse mice with both increased and reduced predisposition to cancer. This will involve the use of transgenic procedures to modify the genetic status of mice. The techniques we will use are such that we can control genetic status through exposure to chemicals or through exposure to viruses. We will also use these GA mice which are predisposed to develop cancer to model anti-cancer therapy in the clinic. This will be achieved by exposing mice to therapeutic agents and monitoring the response of normal and tumour tissues to these therapies. Monitoring will be performed both by live imaging mice and by analysing tissue samples at death. The adverse effects will therefore be the development of cancers and the negative side effects of anti-cancer therapies. In terms of severity, these will be mostly moderate. All animals will be killed at the experimental end point.

A retrospective assessment of these predicted harms will be due by 18 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We aim to investigate the genetic control of cancer development and the responses of cancers to a range of agents including therapies. The extremely complex nature of such *in vivo* responses makes it impossible for these studies to be completely recreated in artificial systems in vitro. However, we have been pursuing the establishment of alternative procedures that have the potential to at least partially replace the use of animals. Most prominently we have been developing 3-dimensional culture systems for both normal tissues and tumour counterparts. To date we have established these for gastrointestinal tissues and have begun to develop this approach for prostate tissues. Where possible and appropriate, we are using these *in vitro* approaches to inform our *in vivo* studies, with a view to replacing some in vivo studies and reducing and refining others, for example by establishing more precise hypotheses which can be directly tested in vivo.

A retrospective assessment of replacement will be due by 18 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

Our studies make use of the known available genetic models of disease and novel highly specific genetic models. By using such precise genetic models, we have enhanced the specificity of experiments permitting us to investigate precise genetic pathways and mechanisms. This reduces the overall numbers of animals required. We will also continue to introduce methodologies, such as novel imaging technologies, to increase the amount of data obtained from single animals and therefore reduce total animal requirement.

A retrospective assessment of reduction will be due by 18 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The approaches we will use are fundamentally a refinement of using mice, as the creation of appropriate precise genetic models ensures that the work carried out will have the most accurate and useful outcome. We will also derive multiple data from a single animal , principally by the use of in vivo imaging to allow tumour progression to be monitored over time within the same animal - so reducing the requirement for multiple timepoints and thus animal usage. To minimise welfare costs to the animals we will monitor and examine animals on a daily basis and respond to any change in health status as appropriate. We will also adopt techniques wherever possible to minimise physical intervention. For example, we will maximise the use of genetic approaches that do not require chemical injections to induce the desired genetic change and we will use non-invasive approaches (such as imaging) wherever possible. To attempt to avoid single housing of males, every attempt will be made to biopsy animals at 2 week, in order to group house at weaning.

A retrospective assessment of refinement will be due by 18 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

97. Investigating the neural circuits of hearing-in- noise

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to better understand the neural circuit(s) that underlies hearing-in-noise. In addition, we aim to understand how hearing-loss and aging affect the function of this circuit(s).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our ability to hear-in-noise substantially declines with hearing loss and as we age, this makes it difficult for sufferers to engage with the world and can leave them socially isolated and lead to a decline in mental health. This work is important as it seeks to enhance our understanding of the neural circuit(s) of hearing-in-noise (a critical skill for communicating as most environments contain noise). In addition, we aim to better understand how neural hearing circuits adapt with age and hearing loss. By understanding how these circuits change we may be able to provide critical insights into how we can maintain normal function in these circuits, allowing people to have normal hearing for longer.

What outputs do you think you will see at the end of this project?

We will advance our understanding of the neural mechanism(s) of hearing, specifically hearing-in-noise and how these pathways are affected by age. These results will be disseminated through conference proceedings and peer-reviewed published articles. The data described in these publications will also be made publicly available for other researchers to use.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Short term: We will use these results ourselves in our studies of hearing loss to inform subsequent work. In addition, these data will be directly shared with collaborators to improve models of auditory function.

Medium term: We anticipate that others will also use these results for a variety of purposes related to studies of basic auditory processing and efforts to model and simulate the function of the auditory system.

Long term: These results could form the early foundation of the detection of specific sub-types of hearing loss, e.g. dysfunction of descending auditory feedback, and potentially lead to research targeting treatments to reduce the impact of hearing loss.

How will you maximise the outputs of your work?

We will seek at every stage to collaborate with computational modellers, this will allow experimentation in silico, substantially increasing the range of hypotheses that can be tested. Work will be disseminated at conference both by ourselves but also through our collaborators. Where possible we will aim to pre-register publications allowing us to publish the work even when unsuccessful, reducing the amount of duplication in the field.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, mice will have an intracranial injection of viral vector (AB, recovery surgery, ~47% of animals) and then 4-6 weeks later undergo physiological measurement under terminal anaesthesia (AC) and perfusion. A subpopulation (~36%) of animals will also have hearing loss induced (AB) followed by a wait of typically 4 weeks and then have their hearing function measured (AB), then another wait of at least 3 weeks before having the viral vector injected (AB, recovery surgery with a 4-8 week wait) and then physiological measurement under terminal anaesthesia (AC) and perfusion. The remaining animals (~17%) will undergo physiological measurement under terminal anaesthesia (AC) and perfusion.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Intracranial injection: May rarely lead to infections in animals recovered from this procedure. This will be treated with antibiotics or if necessary the animal schedule 1 euthanised. The duration of effects should be brief (<2 weeks).

Stitches or bonding glue may become loose: If this occurs the wound will either be fixed immediately or the, if not possible, the animal euthanised. If the wound is resealed and comes loose a second time the animal will be euthanised.

Recovery surgery: May cause post-operative pain and discomfort. The first 3 days after surgery will be treated with analgesic. If signs of pain appear after suspension of this treatment postoperative analgesic will be continued (through consultation with the NVS).

Induction of hearing loss: Noise exposure may, very rarely, cause ear discomfort from inflammatory

reactions to noise-induced cochlear damage. We will administer post-procedure analgesic but if this problem persists the animal will be euthanised.

Ageing mice up to 15 months: Mice may attack one another when co-housed for long periods. If this is detected the aggressor may be single housed, if this single housing produces stereotypic behaviour it may be necessary to euthanise the animal.

Animals expressing fluorescent proteins: Cre recombinase or opsins will be used. The animals with fluorescent proteins or CRE inserted in their genome proposed here do not usually express any obvious detrimental phenotype and have no apparent disabilities. However, unexplained deaths do occur in both wild type and GA litters.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mouse = Mild (17%), Moderate (83%)

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to understand the function of specific neural pathways formed by auditory circuits. To understand how these pathways, respond to sounds we need to be able to record from them while sound is being presented. This requires a normally functioning ear and brain as well as a way to monitor neural function at the cellular level. At present the only way to do all of these things is through in vivo physiology. In addition, to establish the causal role of these pathways we need to be able to functionally manipulate them, this can only be done (in a specific manner) using transgenic techniques. Taken together these two points mean that animal use is unavoidable.

What was your strategy for searching for non-animal alternatives?

Sensory neuroscience research generally relies on four main approaches to answer questions: 1) non-invasive behavioural experiments, 2) computational modelling experiments, 3) in vitro physiology 4) in vivo physiology. All of these approaches were considered as potential tools for addressing the aims of this work.

Why were they not suitable?

Non-invasive techniques work on a gross population level and do not offer cellular and circuit (i.e. within a cortical column) level measurement of function. In addition, they do not allow specific functional control of parts of the neural circuit and so cannot answer fine grained circuit level questions. Computational techniques can work at the cellular and circuit level and allow modelled functional control. However, to make these models more than conceptual (i.e. biologically plausible) parameters within the model need to be constrained by biology. At present there are large and fundamental gaps in our knowledge about projections from auditory cortex including: the basic parameters needed to model their intracellular dynamics, how they respond to sound, how they connect (motifs) to their targets, how they modulate function in their targets and how they change with age. The only way to gain this knowledge is to study these projections in real brains. In vitro physiology allows study of actual brain function at the cellular and circuit level and also allows functional control of real neural populations. However, this work aims to study the involvement of the neural circuit in listening behaviour. This means animal use is unavoidable because brain slices lack the real sensory inputs from the outside world and connections from other parts of the brain.

However, within these limitations, both computational and in vitro methodologies will be used wherever possible to inform the in vivo studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to ensure reasonable estimates of the required animal numbers we used data from existing research papers as a guide to the potential size of changes to neural firing rate that we might expect to observe. We also used our previous experience of these types of experiments to help us estimate the number of neurons we might reasonably expect to measure in each animal. Taken together this was sufficient to create an estimate of the total number of animals required for each experimental condition and controls, to ensure the experiments were designed to be able to deliver statistically robust results. It should be noted that all animal numbers reflect the maximum number of animals that might be needed. The results of objective 1 and 2 could dramatically reduce the number of animals needed. For example, the results of objective 1 could remove the need to study brainstem projections (therefore a maximum of 4 pathways would be investigated in objective 2), likewise, objective 2 could further reduce the number of pathways under investigation (i.e. if the critical pathway has already been found).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experimental design: We will re-derive power calculations after the first few experimental animals, this will help improve estimates and probably reduce the number of animals we will eventually use. We will work through the pathways systematically; this means if a particular pathway is yielding results this will become the primary region of focus for these studies. We feel this approach could dramatically reduce the number of animals investigated. We will consult widely within the department, with the NC3Rs Regional Programme Manager and use NC3Rs resources (e.g. I currently use instructional videos like "How to pick a mouse" to help train staff) within the NC3Rs resource hub to ensure good experimental practice is used. Finally, when selecting the projections to target we will work methodically from most to least probably involved in hearing-in-noise.

Animals: Where possible we will use animals from one experimental group as sham surgery controls for other experimental groups. Projection neurons can be broken down into subtypes, we will use "catch all" transgenic lines and use strategically placed injections to gain specific control of subpopulations. This approach means that multiple subtypes can be accessed in the same animal, which in turn means fewer animals will be used.

Brain imaging: When possible we will employ brain imaging prior to recordings. By imaging prior to recordings we will be able to map out the known subdivisions of auditory cortex. This means more accurate positioning of recording electrodes increasing the data yield, improving the precision of the data and reducing the number of animals used.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be employed to test the feasibility of or improve the quality and efficiency of future studies. Where possible tissue will be archived for potential later use (particularly in older animals).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Viral vector injection: At present the most humane way to target specific sub-types of cells (e.g. specific subtypes of projection or inhibitory neurons) is to use genetic approaches combined with viral vector injections. In some cases, e.g. with projection neurons, it is possible to use wild-type mice to specifically label projection neurons and so this approach could be used if transgenic lines were not possible. However, this approach requires two invasive surgeries (two sets of intracranial injection) rather than the one employed here and hence represents more pain, suffering and distress to the animal. To avoid this transgenic REDACTED will be employed.

Induction of hearing loss: Animals will be anaesthetised during hearing loss induction and monitored closely after surgery for any signs of discomfort (which will be treated with analgesics if found). The only other way to produce noise induced hearing loss would be in conscious animals, therefore, this approach is the most refined.

Measurement of hearing function: Hearing function could also be assessed using chronically implanted electrodes, however, this approach would require much more handling of the animal and an invasive surgery (moderate procedure). For the approach used here the animal will be anaesthetised during the procedure, will not need to be regularly handled and it is a mild procedure.

Mouse model: We will use transgenic REDACTED that either originate from or are backcrossed with C57BL6 REDACTED to help ensure no harmful phenotypes are encountered. In addition, this mouse model is known to develop premature hearing loss. In fact, hearing loss generally associated with old age can be observed in healthy adult mice. By using this model we do not need to age mice to the point where they develop noticeable health problems.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice represent the only animal model with "normal" mammalian hearing and that allow this level of specificity of control of cortical circuits. Alternate transgenic models exist, for example drosophila melanogaster, however these animals do not have mammalian style hearing organs (i.e. a cochlea) and so it is difficult to translate findings in this animal model to human hearing. In addition, in vitro work does not allow the inclusion of a functional ear (critical to the type of work proposed here).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Protocols have been written to allow, time permitting, either measurement or induction of hearing loss under the same anaesthetic. This will reduce the number of anaesthetics needed for each animal and reduce overall suffering.

Animals will be monitored for several days after surgery and induction of hearing loss to increase the speed at which any potential problems may be discovered. In addition, daily weight records will be made for several days following these procedures. This will increase the probability of picking up problems quickly, allow careful monitoring of the recovery trajectory (animals will be "tagged" during surgeries to allow individualised care for group housed animals) and reduce the amount of suffering experienced by each animal.

Long gaps in time (minimum of two weeks but typically longer) will be left between procedures to allow for full recovery and reduce the possibility for interaction between anaesthetic events or procedures.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use LASA “Good practice” guidelines throughout. In addition, we will also follow ARRIVE guidelines when designing and carrying out the studies and publishing work.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay abreast of developments and advances in 3Rs guidelines by visiting the NC3Rs website periodically. I am subscribed to the NC3Rs newsletter and have (and will continue to) engage with the NC3Rs Regional Programme Manager to develop ever improving research methods.

Explain the choice ofspecies and the related life stages

Our hearing ability changes during our lifetime, therefore, we will use mice with normal hearing, i.e. in the age range of juvenile to early adulthood (p10-50) and also mice with hearing loss, i.e. middle/old age (p51-540). This range of ages is necessary to monitor the development of auditory cortical circuits and capture how their function changes throughout the lifetime (and allow sufficient time to allow hearing loss). This will allow us to understand the critical developmental steps that underlie hearing-in-noise and also the critical function that is lost as we age.

Transgenic mice are critical to this work as they offer the control of highly defined cell types, when combined with viral vector injections, within specific brain regions. This is critical to allowing specific subtypes ofauditory cortical projection neurons to be targeted.

NON-TECHNICAL SUMMARY

98. Investigating the pharmacology of advanced drug delivery technologies and conventional medicines

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

advanced formulation strategies, nanotechnology, long-acting

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult
Hamsters	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to improve the effectiveness of medicines by developing better ways of delivering the drugs to the sites in the body where they are needed to work. Drugs investigated will include currently used drugs and new drug candidates with potential application in Covid-19 and other diseases. New drug formulations, (the way in which drugs are combined with other substances) and drug delivery devices will be created. We will use animals to measure the concentrations of drug in the blood and other tissues following administration of the drug, and we will be able to predict which drugs would give us the best results in humans. The data using animals will be used to inform computer models which will inform future human drug trials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work undertaken in this project will improve our understanding of what factors in the body can influence how an administered drug works. An exciting area of research in this project will be the continued investigation of the benefits of using advanced formulation strategies (e.g. nanotechnology) to improve the effectiveness of drugs treating human diseases. Novel formulations can improve the ability of the drug to enter the body and to allow for long-acting treatments. This reduces the need for patients to take multiple pills and can also lower the cost of treatment. It is hoped that our research completed during the last 5 years will be the foundation for this project to continue this important field of research and continue to prove the application of novel formulations in humans, including in repurposing existing medicines for Covid-19 treatment and prevention.

What outputs do you think you will see at the end of this project?

At the end of this project we would expect a number of peer-reviewed publications in high impact journals that guide clinical practice in the treatment of diseases important to public health, chronic diseases and resistant organisms.

At the end of this project we would like to see a change to currently available products for the treatment of diseases such as SARS-CoV2, malaria, TB, HCV and HIV. These products should be made

available in low and middle income countries as well as high income countries to ensure those with the highest need have access to safe and effective treatments.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The work undertaken in this project will improve our understanding of what factors in the body can influence how an administered drug works. If we understand the factors influencing how a drug works in the body, we can work with chemists to design drugs that work more effectively, or to improve current drugs using advanced drug delivery systems. These changes to how drugs work in the body can improve a patient's experience of taking their medication, potentially by decreasing side effects, changing how often they have to take the drug, etc.

Peer reviewed publications will be produced throughout the duration of the project to ensure that the research we carry out informs the scientific and clinical community as soon as possible, this ensures the data is relevant and any changes made are based on up to date data analysis.

Any products generated as an outcome to this project will take longer to make an impact as they will have to undergo rigorous regulatory testing and clinical trials before they would be available products on the market. However, the data from this project and early phase clinical trials will be published.

How will you maximise the outputs of your work?

We aim to generate publications for high impact journals to ensure the data are widely distributed throughout the scientific community. We will also generate publications to demonstrate unsuccessful approaches, allowing the scientific community to use our data to inform their future experiments or techniques.

As a group we lead a consortium of scientists investigating long-acting medicines for the treatment of malaria, TB and HCV and we have been working on improving HIV treatments for over 20 years. Recently, as an antiviral group, we have used our resources to help the global effort to find a therapy for COVID-19, working closely with other scientists locally as well as throughout the UK and the world.

Our group has close links with the wider scientific community, including funders, regulators and community advocacy groups to help achieve the aims of the project as well as disseminate the information generated via international scientific meetings and community action groups.

Our group will expand over the coming years to allow for the recruitment of PhD students and scientists to use the data generated from this project to inform future scientific directions, enabling collaboration and further knowledge into the future.

Species and numbers of animals expected to be used

Mice: 1300
Rats: 1200
Rabbits: 430

- Hamsters: 700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

For the majority of animals used for this project an experiment will last between 1 and 90 days depending on the nature of the regimen to be tested.

For medicines which will be assessed for their distribution after a single dose animals will usually be in an experiment for 24 hours. Animals will be administered a medicine either by an injection (into the tail vein or flank for example) or by administration using oral gavage and placed back in the home cage. At specific time points after administration

- Rodents may be placed under anaesthesia for blood to be withdrawn via cardiac puncture and then administered an overdose of anaesthetic agent (usually the case for mice).
- Rodents may be placed in a heatbox to dilate veins and then placed in a restrainer for blood to be withdrawn from the lateral tail vein before being placed back in the home cage.
- Rabbits would be placed on a heated table and ears would be rubbed gently to encourage blood flow, a butterfly needle would be inserted into the ear vein to withdraw blood.
- Animals will have blood withdrawn a number of times in 24 hours but the total volume withdrawn is a maximum 10% of circulating blood volume in any 24 hour period.
- Animals will be anaesthetised usually using isoflurane prior to an overdose of an injectable anaesthetic.

For long-acting medicines assessment will follow the same pattern as above except time points for blood withdrawal will be spread across up to 90 days, ensuring the total volume withdrawn is a maximum 10% of circulating blood volume in any 24 hour period and 15% in any 28 day period. Long-acting medicines are typically administered via injection into the leg muscle, by microarray patch or by implant and in most cases this will be completed under inhalational anaesthesia.

Experiments to investigate medicine distribution in the bile and other sanctuary sites will involve surgery and animals will be administered a medicine, usually orally, and will be placed under anaesthesia for the entire duration of surgery. Animals will not be allowed to recover from surgery and will be killed using an overdose of anaesthetic so as to minimise any pain, suffering or distress.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals may experience some discomfort, abnormal behaviours, significant weight loss or other indicators of poor health, but these will not prevent normal feeding and drinking or other normal activities other than for short periods. These experiences are not expected in any animals and work carried out prior to animal work will inform the experiments as much as possible to minimise the discomfort experienced by the animals.

The most likely expected adverse effect on animals in this project is pain during a procedure. For example, pain during insertion of a needle when administering a medicine intravenously or when inserting a needle for blood withdrawal. This pain will be very short lived and transient and will not affect the animal's overall wellbeing. Any administration of a substance that is thought may cause longer lasting pain, for example intramuscular injection, will be completed under anaesthesia and pain relief will be administered at the same time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol 1 - non-recovery - 100% of mice and rats used will experience this severity

Protocol 2 - Moderate - 60% of mice, rats and rabbits used in this protocol are likely to experience a moderate severity

Protocol 3 - Moderate - 75% of mice, rats and rabbits used in this protocol are likely to experience a moderate severity

Protocol 4 - Mild - 100% of mice, rats and rabbits would experience this severity

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are required to achieve the aims of this protocol because they have genetic and biological characteristics closely related to humans, making them a good model for the evaluation of drug characteristics. They allow us to simulate tissue sub-compartments of relevance for human disease, especially sanctuary sites such as the gut, central nervous system and rectal associated lymphoid tissue.

What was your strategy for searching for non-animal alternatives?

We use a combination of in vitro, ex vivo and in silico techniques to investigate the pharmacokinetics and distribution of medicines and novel formulations of active pharmaceutical ingredients (APIs). We also use *Galleria mellonella* to investigate long-acting drug release and depot architecture. We are also developing an in vitro muscle model to invetsigate the pharmacokinetics of medicines which show long-acting capabilities in cell culture experiments.

Why were they not suitable?

These models are not suitable as they have the following limitations:

1. Inability to simulate tissue sub-compartments of relevance for human disease (especially sanctuary sites such as the gut and rectal associated lymphoid tissue and central nervous system)

2. Inability to faithfully simulate human biology and the processes that are involved in the absorption, distribution, metabolism and excretion of API's

3. Immune cells examined ex vivo may not faithfully simulate the situation in vivo

4. Available models may not include all the cell types or immune molecules that may have an important impact on the medicine exposure or response relationship

5. *Galleria mellonella* are proving difficult to extract medicine from to measure drug concentrations and as they do not have the same level of genetic similarities with humans as animals, these would only be a preliminary screening tool

6. An in vitro muscle simulation is in its early phases of development and at the moment cannot be used to investigate long-acting injectables

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We tend to use groups of 3-4 mice to obtain an estimate of central tendency (usually the mean) and variance. These estimates are adequate for the downstream analysis to be completed. We know on average how many experiments we are likely to complete per year based on our previous work. We have also taken into account the current pandemic as this will likely increase our animal numbers as experiments are being completed at a much faster rate than usual to respond to the global need.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have an in depth understanding of the variance structure around much of our data, which has helped us design our studies. We use the following general principles:

1. We attempt to define exposure-response relationships using in vitro models to reduce the numbers of animals required to establish these relationships.

2. Simulations of pharmacokinetics are employed when appropriate to inform in vivo experiments in order to minimise the number of animals used and to maximise the data generated from each experiment.

3. We have altered the length of studies if later time points do not provide any additional information. This reduces the number of animals that are required.

What other measures apart from good experimental design will you use to minimise numbers?

- We debate study design as a collective to ensure we arrive at the best possible design.
- We seek statistical help and critique for our model design.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rats and mice will be used. Rabbits will be used for validation purposes only. Some will only experience being administered a general anaesthetic, after which the whole experiment will be

completed under anaesthetic and the animals will be killed without recovering consciousness. Other animals will receive doses of the potential new medicines being tested after which blood and urine samples will be taken at intervals to assess how the animals re-distribute the medicine within their bodies and how long it takes for it to be eliminated eg in urine. Body tissues will be collected at the end of the experiment after the animals have been humanely killed. The medicines to be given are not expected to cause the animals suffering and the sampling methods do not involve more than transient discomfort. Some animals will be anaesthetised in order to give the medicine by certain routes eg into the muscle. At the end of the experiment some animals will be anaesthetised so that a larger volume of blood may be collected and then the animals will be killed without recovering consciousness. No animal is expected to experience more than what is regarded as 'moderate' adverse effects and most will experience only mild and transient discomfort.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In cases where it is appropriate and in some protocols within this project animals will be used that are terminally anaesthetised so as to minimise any discomfort. Mice will be used rather than rats where appropriate and rabbits will only be used for validation purposes. Mice are the lowest sentient animal we can use in order to mimic the human response.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

- Animals will be monitored very closely after administration of a drug to ensure no acute reactions take place.
- Animals will be kept in the procedure room for monitoring at this early stage to ensure an anaesthetic machine is available if needed to minimise any suffering that may occur.
- Animals will be checked regularly throughout the day of the experiment by both the REDACTED and PILs and animals will be humanely killed if deemed necessary.
- Animals are kept in a post-operative room after any surgical procedure and monitored by a PIL.
- Animals will be administered pain relief if needed and will be administered pain relief prior to any surgical procedure.
- Animals will be transferred in the enrichment tube when possible to decrease distress.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

- NC3Rs website

- Diehl et al, J Appl Toxicol, 2001, 21(10):15-23
- Laboratory Animal Science Association (LASA) Guidelines
- Understanding Animal Research website
- Recent publications in our field of study

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We regularly attend NC3Rs conferences and meetings held at the establishment and nationally to update our knowledge and ensure techniques used are in the best interests of the animals. Any information from these meetings is disseminated to the group at weekly group meetings and changes will be put in place, led by myself or my 'deputy'.

Any PIL leading a study will check the NC3Rs website, as well as other relevant literature, to ensure that the procedures necessary for the study are carried out using techniques that are in the best interests of the animal's welfare. PILs will also seek advice from the REDACTED team, including the NACWO and NVS.

Explain the choice ofspecies and the related life stages

Rodents such as mice, rats and hamsters have genetic and biological characteristics closely related to humans, making them a good model for the evaluation of drug characteristics. Rodents allow us to simulate tissue sub-compartments of relevance for human disease, especially sanctuary sites such as the gut, central nervous system and associated lymphoid tissue as described in this protocol. Rabbits are important as a model of validation in a second species. Rabbits are an important species for prodrug validation as rabbits are a more representative model of hydrolase activity compared to a mouse or rat. Hamsters are especially important for investigation into Sars_CoV2 virus as they have been found to be a very good model of the disease.

All rodents will be used at a weight of between 20 - 25g which correlates as between 5-7 weeks old, therefore, they are at the adult stage. Hamsters will be used at 80-120g (approximately 5-8 weeks of age). Rabbits will be used at 3kg (approximately 14-18 weeks of age), this ensures that growth of each animal has stabilised.

Home Office

NON-TECHNICAL SUMMARY

99. Investigating the Regulation of Glucose Transport

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The single most important action of insulin is to promote glucose transport into skeletal and cardiac muscle and fat. This is achieved by the regulated trafficking of glucose transporters from intracellular storage compartments to the cell surface. We seek to define the mechanism(s) responsible for this trafficking.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Insulin-stimulated glucose transport is impaired in people with Type-2 diabetes. There are > 420 million people living with diabetes. Diabetes is a major cause of blindness, kidney failure, heart attacks, stroke and lower limb amputation, is the 7th leading cause of death world-wide and costs the UK £10billion/year. Defective glucose transport lies at the heart of this disease and our work seeks to define the impairment in mechanistic terms.

What outputs do you think you will see at the end of this project?

Understanding how glucose transport is regulated in physiologically relevant cell systems is key to the development of novel therapeutics and/or identification of new potential drug targets to treat diabetes, ameliorate its consequences or assist in patient stratification.

Our work will:

- Identify novel potential mechanisms for the enhancement of our basic understanding of insulin action
- Offer new targets for therapy,
- Potentially help with stratifying patients with diabetes [Type 2 diabetes is a heterogeneous disease, and improving classification is considered essential if precision medicine is to be developed for this condition].

We will seek to publish our findings in peer-reviewed open-access journals and to disseminate our work via STEM-events, peer-peer networking, Twitter and Diabetes-UK-led outreach events.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This work may have potential benefits to people living with diabetes, as it may identify new therapeutic targets or help stratify the disease. However, this is basic science and as such a translational end point is likely to be many years in the future.

How will you maximise the outputs of your work?

The applicant has participated widely in outreach and public-facing activities to publicise his work. These include REDACTED-led events, Diabetes UK led events such as talks with patient support groups, and he has also participated in the REDACTED International Science Festival (twice).

We collaborate widely within the Glucose Transport field, participate in regular meetings and actively seek to publish our work in a range of journals which reflect the 'highly visible' output of exciting new findings, to the 'solid' output of important but arguably less novel data that nonetheless provide the field with important insight and comparative data.

Species and numbers of animals expected to be used

- Mice: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

All work proposed here will use transgenic mice. The typical GA mouse in question expresses a fluorescent protein tagged glucose transport in muscle and heart and exhibits no adverse effects as a consequence.

Groups of 10 mice will be placed on high-fat diet or 10 on a normal diet for up to 20 weeks (but some may be used from week 12 depending on body weight gain and blood glucose levels) as only around 2 mice can be used per week because of limitations on cell processing discussed above.

Blood samples will be collected to confirm development of insulin resistance; a difference between control and high-fat fed animals of >0.7 mmoles/l will be used as a cut off, or an increase in body weight of greater than or equal to 20%.

At no longer than 20 weeks after the start of the experiment, animals will be humanely killed using a Schedule 1 or a non-Schedule 1 method.

Up to 50 mice in total will be on a high fat diet and a corresponding number will be used as control mice.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The reporter gene the mice have does not cause them any health problems and mice don't exhibit any adverse phenotype. Breeding animals are kept for a maximum of 12 months of age.

Cardiomyocyte isolation and intact muscle dissection will be performed once the animal has been humanely killed.

Some animals will be placed on a high-fat in order to induce insulin resistance, for a maximum of 20 weeks. Mice on this modified diet will be inspected daily and are likely to become obese, they will also be monitored for signs of ill-health, including changes in respiration, dehydration, activity, unkempt appearance, abnormal posture, and trembling.

Repeated micro blood sampling will be carried out whilst animals are on the dietary modification experiment, and this is classed as Mild.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Breeding of colony – Sub Threshold.

High-fat fed induction of insulin resistance - Moderate.

Blood sampling classed as Mild.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Insulin action, and defects associated with diabetes and obesity, are multi-system diseases. This intra-organ communication cannot be replicated in any cell culture-based model.

The analysis of the plasma membrane dispersal of glucose transporters using digital stochastical optical reconstruction microscopy (dSTORM) requires the use of fluorescently tagged transporters. To achieve this in primary cardiomyocyte or skeletal muscle culture systems requires post-isolation infection with a virus to drive expression of the transgene. In our hands, the time taken to drive the

transgene is too long for the cells to maintain insulin responsiveness and they de-differentiate. Hence, the use of a transgenic mouse strain expressing the tagged transporters obviates this step and represents the only viable experimental system available to us.

Moreover, the ability to modify the insulin resistance status/diabetic status of the animal is not possible in any cell-culture based system.

What was your strategy for searching for non-animal alternatives?

Preliminary work has employed cultured cell lines, which have paved the way for this work.

Why were they not suitable?

None of the cell culture lines come close to recapitulation of cardiomyocytes isolated freshly from intact hearts. Our attempts to use primary cardiomyocytes from other species have failed as a consequence of the need to over-express a gene which cannot be achieved in cardiomyocyte cultures in vivo as the cells do not survive. The transgenic line we propose to use was developed to circumvent this issue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All work proposed here will use a specific transgenic mouse unless other similar GA mice offering a better model become commercially available. The mouse in question expresses a fluorescent protein tagged glucose transport in muscle and heart and exhibits no adverse effects as a consequence. Details of the strain are at: https://www.jax.org/strain/027496 A breeding colony will be established; the animals are homozygous so genotyping is not required and there will be fewer waste animals.

Much of the work proposed will involve the development or refinement of imaging approaches which depend on the reagents used (e.g. in tissue digestion for optimal cardiomyocyte isolation, different batches of enzymes need to be evaluated before experimental work can begin) and experimental set-up on the microscopes.

Our estimation of numbers is based on a planned use of 1 mouse per week in the development phase

(months 0-24), and then groups of mice for specific experimental hypothesis testing, once optional conditions for analysis are established.

1 mouse/week months 1-24; it is anticipated these will be from the maintenance breeding colony. The colony will be maintained at approximately 3 pairs with 4 breeding stock held. Breeding will be staggered to reduce overproduction and wastage.

If conditions from the development studies indicate that methodology and analysis can be achieved, then we will also examine the impact of diet-induced obesity/insulin resistance.
Groups of 10 mice placed on high-fat diet or 10 on a normal diet for 20 weeks.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

One animal per week in the initial period of study will allow us to develop/apply methods developed using cultured cells and will supply sufficient material for considerable experimental analysis. Cardiomyocytes will be isolated using standard procedures and intact muscles will be isolated from the same animal post-mortem. Thus each animal will contribute tissues to both plasma membrane dynamics analysis and whole tissue transporter Mesoscale morphology analysis, reducing the numbers required for the project.

What other measures apart from good experimental design will you use to minimise numbers?

One animal per week in the initial period of study will allow us to develop/apply methods developed using cultured cells and will supply sufficient material for considerable experimental analysis. Cardiomyocytes will be isolated using standard procedures and intact muscles will be isolated from the same animal post-mortem. Thus each animal will contribute tissues to both plasma membrane dynamics analysis and whole tissue transporter Meso-scale morphology analysis, reducing the numbers required for the project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

All work proposed here will use a transgenic mouse. The mouse in question expresses a fluorescent protein tagged glucose transport in muscle and heart and exhibits no adverse effects as a consequence. Details of the strain are at: https://www.jax.org/strain/027496 A breeding colony will be established.

Most procedures will be performed under terminal anaesthesia without recovery.

We will induce insulin resistance by feeding a high fat diet to mice, this is a well established way to create a diabetic mouse.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The specific use of this particular transgenic mouse is required. No other model is available which can answer the scientific questions of this project as well as this one.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

This strain of GM mice is bred specifically for analysis of transporter biology in muscle cells. It imposes no harm or disability to the animal which are by all measures assessed normal and healthy with no ill effects.

Animals fed a high-fat diet in order to induce diabetes will only be kept on the modified diet for a limited period of time (max 20 weeks) and thus are not expected to develop significant adverse effects. They will be given plentiful access to water and their bedding will be changed frequently so as to keep them dry and comfortable. Their glucose levels and general condition will be closely monitored and if any develop defined adverse clinical signs, they will be humanely killed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Local guidelines for blood sampling will be used and the NC3Rs website will be regularly consulted.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Training courses are provided regularly by local staff and external colleagues. I will keep up to date with more refinements via the NC3Rs website.

Explain the choice ofspecies and the related life stages

Transgenic mice, as outlined above, offer the only viable route for these kinds of experiments. The starting age of 5 weeks of age is the recommended one for this model.

NON-TECHNICAL SUMMARY

100. Investigation of epigenetic reprogramming in male germ cell development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project is to identify factors (genetic or non genetic) that direct epigenetic reprogramming (epigentics refers to non-genetic influences on gene expression), and development of the male germline, during sperm development and early life.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Germ cell development, for the most part, unfolds during embryonic life, when germ cells are present in small numbers and are extremely difficult to access for manipulation. The consequences of any defect during this process has long-lasting and destructive consequences, reducing one's ability to produce offspring and/or resulting in birth defects in future offspring. Although our study primarily focuses on the basic biology of germ cell development, a better understanding of the processes could have an impact on both reproductive medicine and treatment of rare non-genetic hereditary diseases. While it does not pose any immediate health risk, infertility has a deep impact on the life of an individual, his/her family and, more broadly, society. Worldwide, 15% of couples of reproductive age (15-44 yrs) have experienced problems conceiving a baby. The cause will be different (genetic defects, surgical removal of the testis/ovaries, sterility inducing treatments e.g. chemotherapy, unknown factors), but they often result in either a failure to produce functional gametes (sperm/eggs) and / or difficulties in carrying a pregnancy to full term. To date, approaches for the in vitro differentiation of gametes from patient derived stem cells have not been fully successful, mostly due to large grey areas in our knowledge of the events directing this key developmental process. At the same time, the underlying cause of several hereditary diseases still remains unknown in most cases, due to an inability to identify the causative genetic mutation(s). The absence of a known cause has therefore greatly impaired the development of treatments, which often have been targeted to alleviate the symptoms rather than reversing the primary issue. Understanding how non-genetic hereditary diseases are passed to offspring could provide a new framework in which to identify and investigate the causes, and the origins of these.

What outputs do you think you will see at the end of this project?

Completion of this project will offer new insights on the dynamics, mechanisms and relevance of epigenetic reprogramming in directing germ cell development. Although all the cells of an organisms share the same genetic information encoded in genomic DNA, different cell types are defined by the expression of different sets of genes. This is controlled by a second layer of information called epi-genetics ("epi" is a Greek prefix for "on top of"), whose functional elements are chemical modifications of the DNA bases or the histones (the proteins that "wrap" the DNA. It is key for the proper development of an embryo with a full compendium of tissues and cell types, that the content of the epigenetic landscape from both the egg and the embryo is rest to a blank state to avoid any developmental bias. In particular, we will focus a large part of our efforts and resources to obtain a better understanding of the events leading to the specification of Spermatogonial Stem Cells (SSCs), the sole contributors of gametes in the adult testis. Since SSCs are ideally positioned to be relay points of hereditary information transmitted to the next generation, data on the mechanisms guiding this fate decision may offer novel insights into how and when epigenetic traits can be transgenerationally inherited in mammals.

We foresee publications in peer reviewed journals to arise from the project proposed here.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term, the impact of these outputs will mostly be seen in fuelling basic research on the mechanisms of germ cell development and the mechanisms by which non-genetic traits can be inherited through generations. Such increase in knowledge may lead to uncovering the causes and mechanisms of rare diseases, possibly guiding the development of new therapeutics.

By identifying the events that guide immature germ cells to commit to Spermatogonial Stem Cells, in the long-term this work may provide the theoretical basis for the development/refinement of therapies aimed at treating male infertility by promoting the production of functional sperm using drugs or other treatments. This project could also provide unique insights on the local niche of developing germ cells, it is plausible to expect a similar application of the scientific outputs to generate healthy sperm from patient derived stem cells in a petri dish.

How will you maximise the outputs of your work?

We will be open to collaborate with other laboratories that have interesting models, data or questions where our methods can be applied. Moreover, all the knowledge and expertise generated with this project will be spread through talks, conferences and publications.

Species and numbers of animals expected to be used

- Mice: 11800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Throughout this project we will produce mice, often with a genetic modification. In most cases we expect the genetic modification to cause only male sterility (possibly associated with a reduced female fertility). Any other effects of the genetic modification for new lines of mice may be unknown (except in the case of reporter mice where there would be only labelling of a gene, and no additional effects would be expected). We do not expect the modifications to be harmful for the mouse. In some cases we will produce embryos (instead of live full term animals) by allowing the mice to become pregnant. A mouse may experience injections of chemical agents at locations appropriate to each agent. This may typically require 2- 3 times in the lifetime of an animal. The mouse will then be killed later on in the time course of the experiment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Our intention is to carry out this project without adverse effects on the mice, however in a small number of cases mice may experience weight loss or show signs of abnormal behaviour. This should last for no more than a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority will be mild, as they will only experience the breeding protocol. Of those being used on an experimental protocol (approximately 3% of the total animal proposed), < 5% may experience a moderate severity if they suffer adverse side effects to any agent we deliver.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Germline development is a highly integrated process involving constant cross interaction between germ cells and their surrounding cells (within the gonads), Development from a germ cell to a fully functional sperm cell proceeds via a series of signals from both the germline and also surrounding cells, part of which are still left uncharacterised. For these reasons, it is necessary study germ cell development in an in vivo setting.

What was your strategy for searching for non-animal alternatives?

Previous work of our laboratory attempted to establish a protocol to reproduce male germ cell development in vitro with the goal of driving mouse embryonic stem cells to acquire the identity of mature germ cells, also referred therein as in vitro differentiation. In such protocol, we would solicit the generation of germ cells either via series of chemical induction events alone or in combination with co-cultures of in vitro differentiated germ cells and primary non-germ supporting cells sourced from mouse testis.

Why were they not suitable?

Unfortunately, our efforts proved unsuccessful because we were unable to obtain fully and robustly differentiated germ cells. After careful consideration, we attributed our failure to two main factors. First, in vitro differentiation protocols mostly rely on strong and acute inductive signals that fail to recapitulate the highly integrated and dynamic developmental process
that cooperatively define a true germ cell as it appears in vivo, and for some of which we still don't have a comprehensive understanding. Second, in vitro differentiation protocols are extremely sensitive to experimental variability (e.g. different batches of reagents, experimental conditions and timings), whereas living organisms have evolved strategies to actively ensure robust and reliable physiological processes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For each experiment in each of our objectives, we have carried out a statistical sample size calculation which is detailed in the project plan. In general, we have based our estimate of the size and variance of the data that we expect to acquire on similar experiments performed by our laboratory in the past. Where this has not been possible we have clearly specified so in our project plan, and we will perform a pilot study to better characterize the data which will inform a proper statistical calculation of the sample size.

We have also consulted in house statisticians for guidence.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have attempted to follow the best available guidelines on experimental design, including these listed on the NC3R website. In addition, we screened the existing literature to inform ourselves on the best standards currently applied in terms of sample size determination.

Wherever possible, we have attempted to perform multiple measurements from the same dataset (applying the appropriate corrections) and to compare multiple treatments to the same control, reducing the number of control animals required.

We based our sample size calculations on estimates of effect size and variability from previous data of our laboratory. However, this is just an initial estimate, and we fully expect that our understanding of the data will increase over the project. As this happens, we will refine our sample size calculations and either use less animals, if possible without reducing scientific significance, or seek permission to enrol more animals in the study if we realize that a higher number of replicates is needed.

What other measures apart from good experimental design will you use to minimise numbers?

We aim to use efficient breeding stratagies and seek to use tissue from each animal for as many different data analyses as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use laboratory mice of several different strains, some of which are genetically modified in order to either i) tag certain cells of the body with a fluorescent molecule or protein tag or ii) to induce sterility, in order to study the development of germ cells. None of these modifications will cause harm to the animals. In order to study the behaviour of germ cells within their biological context in the gonads, we will use chemical agents to trace them throughout development or to specifically label molecules within these cells at specific times. These agents are frequently used and well tolerated and we expect very few animals to display unwanted side effects.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are the least sentient , and most understood (in terms of gene modifiying and cell labelling) animals that represent mammalian development. Some of our data will collected from adult mice as we require full biological development of the animal.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will use several strategies, refined over the course of our previous work, to minimize suffering for the animals. While producing transgenic animals, we will use methods and breeding schemes that maximize the number of animals with the correct hereditary traits that are produced, this will ensure that as few as possible transgenic animals are born unnecessarily. The facility creating the transgenic mice now use a more refined methodology with far improved success rates over those used previously. When administering substances to neonates, we will leverage on the expertise of other users in the institute how they have refined the route, volumes and protocols for dosing.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the guidelines listed within the public resources available from the NC3Rs website. We will follow all of these, as well as several other standard operating procedures that were developed by a team of specialists at our institute for the explicit purpose of minimizing animal suffering, and are periodically updated. While designing experiments. we will follow a series of guidelines existing in the literature to design and report our experiments, in addition to the ARRIVE and PREPARE guidelines from the NC3Rs, and will consult with an on-site statistician to ensure that we’re using as few animals as possible for our study.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our institute routinely circulate advances in the 3Rs and we will always seek to identify ways these can be incorporated in our project, while ensuring they do not effect the (statistical/ biologically relevant) consistency of our data collection.

Explain the choice ofspecies and the related life stages

We are using mouse models to understand the mechanisms that direct the correct development of germ cells in the testis to produce healthy and fertile sperm. Previous work from our laboratory and others has shown that the mouse male germline closely recapitulates the same key events and processes that drive human germ cell development in men, with very few exceptions that will not interfere with our proposed work. Since most of the epigenetic reprogramming of the germline, the focus of our project, unfolds during embryonic and early postnatal life, our study will require the use of embryos, pregnant females and neonates in addition to adult individuals that will represent the end time point of the process of our interest.

Home Office

NON-TECHNICAL SUMMARY

101. Investigation of influenza virus and avian REDACTED disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
Embryonic forms: Avian embryonated chicken, duck, turkey eggs	embryo, juvenile, adult
Pigs	juvenile, adult
Cattle	juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this licence is to improve animal health and welfare by researching influenza and REDACTED viruses in order to limit the impact of disease. Research will focus on areas including detection of infection, characterising viruses of concern e.g. highly pathogenic strains, identifying risk pathways and developing intervention strategies.

A retrospective assessment of these aims will be due by 30 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Animal influenza and REDACTED viruses can have severe impacts on animal health and on agriculture, food security and the economy. It is particularly important to research viruses that cause outbreaks of notifiable avian disease, such as highly pathogenic avian influenza (Bird Flu) and Newcastle Disease, caused by certain strains of REDACTED. The research to gain further understanding of how these viruses cause disease and therefore develop mitigation strategies, is underpinned by this licence. Other animal influenza viruses, notably those infecting swine (Swine Flu), may also have the capacity to infect humans, and so can have a Public Heath impact. Indeed, pandemic influenza is included in the UK National Risk register of Civil emergencies.

This licence therefore provides the essential capability to safeguard the UK by enabling research into important viral diseases that have potentially significant risks including the ability to cause notifiable disease outbreaks in agricultural species and pandemics in humans.

What outputs do you think you will see at the end of this project?

This project licence will promote an improved understanding of influenza and REDACTED viruses. These viruses are known to adapt and evolve in nature with the result that the diseases they cause can alter in different hosts and cause sporadic outbreaks. Of particular concern are emergent viruses that are

associated with increased disease in livestock or risk to animals and /or humans. Research questions to be addressed will include the pathogenesis and transmission of virus infections in susceptible host species, drivers of increased virus virulence and strategies to limit the impact of disease, including the use of vaccines.

The research programme will be used to address knowledge gaps ‘known unknowns’ that are of concern to stakeholders e.g. the mechanisms and drivers of virus diversification and assessment of new risk factors e.g. vaccine escape.

New information will be disseminated in the form of research papers and presentations, or may be provided as expert reports to stakeholders, the agricultural sector or other external organisations REDACTED. Data obtained will also be used to underpin risk and epidemiology assessments and will thereby contribute to mitigating disease risk by informing veterinary disease control or intervention strategies. The work conducted under this licence will also potentially provide evidence on which to base future research and diagnostic strategies.

In some cases, this work will require a dynamic, rapid response during the active phase of a disease occurrence, to address issues of national and international importance for veterinary and public health. The study questions may be ‘unknown unknowns’ requiring reactive data generation in order to support timely disease interventions to help reduce the impact and dissemination of disease, thereby benefiting livestock, the agricultural sector and society.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This licence supports the programme of work delivered by the group in accordance with the objectives of the establishment. The activities and impacts of this work will directly benefit the health and welfare of livestock species, through providing research outputs to assess approaches to mitigating influenza and avian orthoavula- virus diseases through improved prevention, detection and mitigation strategies.

Consequently, this work will also support of the wider national and international animal and public health communities by providing data to support policy and risk assessments. These beneficiaries include departments, organisations, governments and competent authorities. The work will also ultimately benefit trade and food security, the economy, taxpayers, consumers and society in general.

How will you maximise the outputs of your work?

The outputs of this work can be maximised through participation in collaborative studies with external organisations. As detailed, the establishment already has representation on several organisations and also have joint-funded projects that are active or in negotiation. This allows co-ordination of research efforts and good use of animals. Research findings are presented at external meetings and published.

The establishment ensures dissemination of knowledge to stakeholders, REDACTED. In the case of notifiable

disease or increased risk information is disseminated through expert reports and disease risk assessments.

The establishment ensure active engagement with stakeholders, for example through the UK species expert groups and through the organisations evidence and policy teams.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided
- Other birds: No answer provided
- Pigs: 650
- Cattle: 45

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of procedures to be done are blood and swab sampling as well as inoculation of virus or immunological reagents (e.g. vaccines or antigens) by injection or instillation. Some studies will require introducing animals into a virus-contaminated environment or co-housing of healthy animals with infected animals (e.g. to assess virus transmission and infectivity in the environment).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The main potential adverse effects are the clinical signs resulting from infection. Often the subject of study is a novel virus strain, and the expected adverse effects are unknown. Clinical score sheets are applied to ensure humane endpoints and minimise suffering. Transient mild adverse effects may also be experienced as a result of restraint, during sampling or inoculation. Anaesthesia will be applied if anaesthesia is not more severe than the procedure itself.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Chickens

Mild 65-70%

Moderate 10-15%

Severe 20-25%

Ducks

Mild 85-90%

Moderate 5-10%

Severe 1-5%

Turkeys

Mild 45-50%

Moderate 25-30%

Severe 25-30%

Gamebirds (Pheasants and Partridges)

Mild 60-65%

Moderate 1-5%

Severe 35-40%

Pigs

Mild 98%

Moderate <2%

Cattle

Mild 99%

Moderate <1%

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 30 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Only selected viruses of scientific importance will be selected for full assessment in animals. A complete biological system is frequently required to study the course of clinical disease and the whole body response to infection. For example, the mechanisms of virus transmission from one animal to the next and disease interventions such as protective immunity from vaccination cannot be studied in non-animal alternatives. Non-sentient embryonic forms e.g. embryonated avian eggs, will be used where possible.

What was your strategy for searching for non-animal alternatives?

In vivo studies are conducted when it is necessary to answer complex scientific questions relating to infection dynamics in the biologically relevant host. For these studies, a whole animal response to virus infection needs to be assessed eg the host's immune response to virus infection, virus virulence in the host species as well as virus shedding and transmission. For studies where it is appropriate to do so, we do use continuous cell line cultures or organ tissue cultures. For the studies conducted in animals under this project licence, however, the nature of the hypotheses prevents non-animal alternatives.

Why were they not suitable?

These alternatives are suitable to address some, but not all research questions. Alternatives to animals cannot be used, for example, to address questions such as virus-host interactions, mechanisms of disease induction by a virus (pathogenesis) or vaccine efficacy.

Modelling of risk pathways in agricultural settings e.g. in poultry barn or free-range housing and assessment of risk or mitigating approaches also requires live animals.

A retrospective assessment of replacement will be due by 30 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals in each research area have been estimated based on previous research programmes and project licences. These estimates considered of the number of virus strains studied, the outbreak incidents researched and the research commissioned to address scientific and stakeholder concerns. THe study outcomes will be used to inform the scientific and policy communities on potential changes and improvements to control strategies in the field. The estimates in this licence are projections to cover future disease outbreak scenarios and the anticipated research required. Numbers of animals estimated per research area also include animals that are needed for pre-screening to ensure appropriate for enrollment on a study. If not enrolled, they will be used in another protocol or another licence.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The use of a statistically valid minimum number of animals per study will be determined based on expert advice from a professional Biostatistician. Animal studies will be designed in a consistent manner so that inter-study comparisons and data analysis can be performed.

What other measures apart from good experimental design will you use to minimise numbers?

Animal studies will be designed to maximize collection of biological materials and, where feasible, run in parallel. This will potentially reduce the number of control groups required and therefore increase the data output and research questions that can be addressed.

A retrospective assessment of reduction will be due by 30 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This programme does not use animal models. Viruses are studied in the biologically and agriculturally relevant hosts.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Where possible, less sentient forms are used e.g. avian embryonated eggs that have been incubated less than 48h before hatch and are defined as not being sentient. In studies involving study of virus-host interactions, it is not possible to use less sentient animals as study requires use of the biologically and agriculturally relevant host.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The species chosen are those for which the disease is most relevant in the field. Avian viruses are studied in the most relevant bird species, and swine influenza viruses in pigs as the biologically relevant host. Pilot experiments are used to refine protocols e.g. dose, route and timeline of infection required to establish infection and transmission. The Establishment strives to continually improve clinical score systems and environmental enrichment.

All species have their own specific and disease-relevant clinical observation criteria and score sheets. No animal will be allowed to progress beyond the described humane end point using a 2-3 times daily monitoring system. On site veterinary teams and animal welfare officers (NVS and NACWO qualified) participate in each study. Clinical signs serve as study endpoints when the scientific objective does not require progression of disease.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Best practice guidance is obtained from NC3Rs, ARRIVE, IAT and the RSPCA. Publications and articles are also reviewed during the approval process prior to each individual study. Where specialist training is required, inter-institutional exchanges and training visits are organised.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The Establishment is a signatory to the NC3Rs and applies the Culture of Care in animal studies as well as the ARRIVE guidelines. Staff from the Establishment frequently attend or organise external symposia on laboratory animal welfare e.g. RSPCA and IAT meetings. Staff attending these meetings provide meeting feedback reports locally. In addition, the Establishment has a Species Group Care and Use Committee where all PILs are invited to attend. Specialist topics are presented and refinements, such as environmental enrichment, are communicated and opportunities are used for implementation. In addition, specialist knowledge exchange is organised by field and lab exchanges with other organisations e.g. PHE and Universities.

Explain the choice ofspecies and the related life stages

The species used are the biologically relevant hosts appropriate for the viruses being studied. Where possible, an alternative to live animals is sought, for example cell or organ culture. Also, where possible, non-sentient embryonic forms (avian embryonated eggs) are used. However, for certain scientific questions where complex virus-host interactions need to be studied, it is not possible to replace a live animal. For example vaccine efficacy investigations require study of the complex interactions between virus and the full repertoire of a host’s immune system.

A retrospective assessment of refinement will be due by 30 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

102. Investigation of pathways regulating tumour progression and regression

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To understand the cellular processes that contribute to cancer and identify components within these processes that might be potential targets for therapeutic intervention.

A retrospective assessment of these aims will be due by 18 November 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite dramatic improvements in the treatment of some cancers, many remain stubbornly refractory and even those that initially respond frequently relapse. Relapse generally results from evolutionary selection of subclonal populations of tumour cells that carry mutations conferring drug resistance or by adaptive compensatory rewiring of functional redundant intracellular pathways. The ability to interrogate simultaneously individual signalling pathways and model the evolutionary trajectory of tumours from benign mutant pre-cancerous cells to a malignant and aggressive cellular mass capable of rapid and continual evolution will be invaluable for the development of novel cancer therapies, preventative strategies and early detection.

What outputs do you think you will see at the end of this project?

Advances in fundamental knowledge

Cancer is a disease that arises because of accumulating errors (mutations) in the genetic instructions that regulate and control how the cells in our tissues replicate, spread and die. In normal tissues the processes of cell gain and cell loss are maintained in an exquisite balance: cells only replicate in the right place, at the right rate and at the right time. The process is controlled by genes that promote cell increase (oncogenes) and genes that prevent it (tumour suppressors) – these act as, respectively, accelerators and brakes. Mutations in many different oncogenes and tumour suppressors contribute to the different kinds of human cancers. Moreover, because these mutations occur and accumulate randomly, each cancer is different from every other and even within the cancer of a single patient there are many genetic variants. It is this complexity and diversity of human cancers that confounds our ability to contain and treat the disease.

However, just because cancers harbour many differences from each other does not necessarily mean that they are functionally different. Although a particular make of car may have many drivers, all those

drives operate the same, common, engine. Our research aims to explore the provocative idea that certain underlying processes (engines) are shared across many, perhaps all cancers even though the mutations (drivers) that power those engines are different from patient to patient. In this regard, the huge number and diversity of cancer drivers are a distraction. Instead, our aim is to identify the common cancer engines, determine what they do and how they work, and ascertain the therapeutic benefit of targeting them with drugs. Our ultimate goal is to foster the development general anti-cancer treatment strategies that may be administered to patients irrespective of what type of cancer they have.

Our hypothesis is unorthodox and counters the prevailing dogma that cancers are irreducibly complicated. It is also backed by several decades of our research work that has identified aberrations in the function of two pro-cancer oncogenes – a molecular switch called Ras and a molecular regulator of genes called Myc – and in one pivotal tumour suppressor – a stress and damage sensor called p53 – as common to many, perhaps all human cancers. However, none of these is yet targetable by drugs. Hence, our only means for deciphering the roles of these cancer engines is to use sophisticated, switchable mouse genetic models. These models allow us to reversibly switch Myc, Ras and p53 on and off in normal and neoplastic tissues and thereby directly determine what the roles of these engines are in the genesis and maintenance of different cancer types. Over the past few years, our principal focus has been on the Myc "engine," whose diverse activities appear to be absolutely fundamental to the genesis and maintenance of diverse cancers. We have painstakingly identified and mapped the web of interactions that link Myc activity to control of the tumour itself, as well as the pathogenic inflammatory and immune-suppressed tissue that surrounds and supports the tumourin its midst. Our mouse models also allow us to assess the therapeutic consequences of manipulating such common cancer engines: would interfering with their function be therapeutically effective? If so, why? And how toxic might the side effects of such interference be for a cancer patient. In this way, we will establish in principle what are the most effective and tumour-specific cancer therapeutic targets, so informing pharmaceutical strategies for future cancer therapies. We will also test existing therapies in these same controlled and reproducible disease models. The data so generated will be used by chemical engineers to guide the design of completely new drugs of general applicability across a wide range of neoplastic diseases.

Production of valuable resources

We have developed and validated some of the core regulatable genetically altered mice that we will utilize in our future studies. Additional novel mouse strains will be developed and used in conjunction with existing strains and with those available to us from commercial sources or from collaborators. Given our proven track record in the development of novel switchable genetics in mice, we are highly likely to generate significant results. Our results will be published in influential peer-reviewed journals and disseminated through scientific seminars. Novel regulatable genetically altered animals developed during the course of this project will be made freely available to other researchers interested in the functions of the target proteins in normal adult tissue and in cancer and other diseases.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

It has always been our strict policy and practice to freely distribute all data and reagents, including genetically modified mouse strains, without conditions and prior to publication. This policy will also

apply to scientific outputs covered by this project. We are investigating the possibility of depositing our mouse strains with the European Mouse Mutant Archive (EMMA/Infrafrontier). There will be no moratorium on presenting our research at national and international scientific meetings and via bioRxiv (https://www.biorxiv.org) prior to submission to open access peer-reviewed journals.

Sequence data will be maintained by the host institution and, in addition, RNAseq and ChIPseq data will be submitted to publicly accessible databases such as ArrayExpress (http://www.ebi.ac.uk/arrayexpress/). Other data such as mouse strain, husbandry and genotyping are stored on local databases but relevant information will be made available in suitable formats on request.

Where data are not available through public databases, interested parties will be provided with a secure digital links to the requested data via the host institution.

In the longer term, our hope is to stimulate increased academic, biotech and pharma efforts towards inhibiting the Myc oncogene and identify Myc effectors, crucial for initiation and maintenance of tumours, that are potential therapeutic targets.

How will you maximise the outputs of your work?

All our research will be routinely presented at national and international scientific meetings and via bioRxiv (https://www.biorxiv.org) prior to submission to open access peer-reviewed journals. Our group participates in many collaborative endeavours, some of which use mouse models developed under our existing PPL. In addition, the applicant and other lab members are frequently invited to present at scientific meetings throughout the year at which expertise on the animal models is freely communicated.

Species and numbers of animals expected to be used

- Mice: 41000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, non-toxic gene/protein activating agents will be administered to genetically altered mice, either in drinking water or in the diet. In a minority of cases such agents will be administered by gavage or injection (usually intraperitoneal). Administration of such substances induces tumour development. In some cases, a potential therapeutic compound is administered at the same time to determine its effect on tumour development. In addition, a small number of mice spontaneously develop tumours after

several weeks/months. Our experiments last a few days/weeks and we aim to limit the tumour size to minimise suffering prior to switching off the activity of the gene/protein and/or administering a therapeutic agent to assess tumour regression. One important hypothesis, for which we already have convincing preliminary evidence, is that tissue-specific programmes that instruct tissue regeneration and resolution in response to injury are hijacked by oncogenic proteins. Thus, some animals will be subject to tissue-specific injury to understand these processes and how oncogenic proteins are involved. For example, liver is the principal organ involved in de-toxification of hazardous compounds and, as a consequence, has evolved a remarkable capacity to regenerate. Continuous chronic assault on liver from hepatotoxic agents such as alcohol, mycotoxins or natural alkaloids drives a sustained cycle of damage and repair that is thought to contribute both to liver failure and liver cancer. We will use controlled, sub-lethal doses of CCl_4 to elicit acute liver injury and then monitor the roles of Myc and Ras oncogenic signalling pathways in instructing the rapid repair and regeneration of the organ. Pancreas is another tissue of interest where overlapping molecular programmes appear to underpin both repair of pancreatic injury and pancreatic adenocarcinoma, a cancer with dismal prognosis. Acute or chronic injury in pancreas will be induced by intraperitoneal injections of cerulein, a cholecystokinin (CCK) analogue that enhances secretion of digestive enzymes from the pancreas acinar cell and acutely induces mild to moderate acute interstitial pancreatitis. Recovery from each cerulein dose is rapid and involves regeneration and remodelling of pancreatic exocrine tissue that transiently shares great mechanistic overlap with pancreatic adenocarcinoma. Similarly, naphthalene is rapidly metabolised into a number of reactive epoxide and quinone metabolites by lung epithelium-specific cytochrome P450s (CYP2A5 and CYP2F2) and thereby induces acute lung injury that triggers rapid regeneration of the damaged lung epithelium. In all these instances, injury is transient, rapidly repaired, and all mice recover within a few days. At the end of the experiment the mice are humanely killed and molecular analyses conducted on multiple tissues.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Our experimental models are designed to induce tumours in lung, pancreas, skin, breast and B cells or tissue damage in lung, pancreas and liver of mice that will cause the least suffering for the shortest period. Nonetheless, the nature of the experiments (tumourigenesis and tissue injury) will cause inevitable adverse effects and mice may suffer transient weight loss, tumour development (which in the lung may lead to respiratory distress) and pain (largely confined to pancreatic tissue injury).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Our aim is to minimize animal suffering commensurate with directed scientific experimental design and statistically valid output. Indeed, we would argue that animals experiencing persistent pain are not a good experimental model. Nonetheless, our experimental models are designed to induce either tumours in lung, pancreas, skin, breast and B cells or tissue damage in lung, pancreas or liver of mice, and this will likely cause at least transient suffering. Since the majority of our genetically altered animals harbour switchable alleles, we can accurately and reproducibly switch on (and off) key proteins that govern tissue regeneration/tumour progression and wound resolution/tumour regression, allowing us unprecedented accuracy in predicting the kinetics of tumour growth (and regression). This allows us

to either kill the animal before severe adverse effects are manifest or initiate tumour regression and thereby forestall any adverse impact. The majority of animals, such as the 60% used for breeding, will not exceed mild severity. Experimental animals will experience moderate severity (20-30%) and some animals (<2%) may experience severe adverse effects. For experiments designed to induce tissue damage in a single organ (lung, pancreas, liver) we aim, via reductions in dose, to induce the minimum damage that initiates a regenerative response. The damage inflicted is acute, tightly controlled and transient and the mice recover within a few days. Lung damage: we intend to administer naphthalene by inhalation (West et al. 2001. Toxicol Appl Pharmacol 173, 114-119) rather than injection and will seek local expertise on this method. Pancreas damage: cerulein is a cholecystokinin (CCK) analogue that enhances secretion of digestive enzymes from the pancreas that induce a form of self-injury. Cerulein-induced damage to the pancreas may be acute or chronic and, while widely used to cause pancreatic damage and induce pancreas inflammation and injury (akin to the human condition pancreatitis), the effects on the tissue and adverse effects to the animals can be variable and a small percentage (<10%) of animals may experience severe effects for short periods (before being killed). Toxin-dependent liver damage causes short-lived moderate adverse effects and the liver very rapidly recovers both function and fom.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 18 November 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to elucidate the contribution of Myc to tumourigenesis, tumour maintenance and normal physiology and to validate Myc as a potential therapeutic target for cancer. Since in vitro studies cannot adequately recapitulate the physiological and systemic context and interactions in which cancers evolve it is necessary to employ animal models. For example, interactions between the tumour cells and several different types of stromal cells that constitute the "tumour microenvironment" are crucial determinants in tumour evolution, growth and survival. Inhibition of the soluble paracrine signals that inhibit these interactions is a promising basis for tumour therapy whose impact and tumour dependence can only be investigated in the whole organism, particularly since some of the key stromal cell types (i.e. lymphoid and inflammatory cells) are recruited to the developing tumour from distant organs.

What was your strategy for searching for non-animal alternatives?

Where possible, our animal studies are replaced and/or complemented by cell/tissue/organoid culture experiments using both commercially available and mouse-derived established cell isolates. These studies are invaluable in investigating the cell autonomous nature of cell signalling and cell processes but cannot address complex interactions between multiple cell types. We will consider the use of 3D organoid models that have been developed for lung, pancreas and liver (three prominent tissues in our studies) but these still fail to address the inherent difficulties of modelling complex and highly tissue-specific interactions between tumour and normal cells that we know is critical to cancer growth and response to therapy *in vivo*.

Why were they not suitable?

Cells in culture are subject to an environment very different from that *in vivo*. They experience a variable and abnormal oxygen tension that is only poorly controlled and defined, are usually cultured in a vast excess of glucose and ill-defined mitogenic growth factors, survival factors, cytokines and chemokines of (typically) bovine origin. Their rapid proliferation in culture is abnormal and facilitates rapid evolutionary selection (e.g. for cells that proliferate faster and/or are more resistant to cell death). Although organoid cultures offer some improvements, they are severely limited by the rather crude and unrepresentative matrices (e.g. Matrigel) that must be used and which do not reconstruct the complex interaction of multiple cell types. For example, a functional dynamic immune and inflammatory system that responds to, and is instructed by, the tumour cells - a central mechanistic tenet of our research - cannot be reconstituted *in vitro*.

A retrospective assessment of replacement will be due by 18 November 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The aim of this project is to elucidate the contribution of Myc to tumourigenesis, tumour maintenance and normal physiology and to validate Myc as a potential therapeutic target for cancer. We will use well-validated mouse models with which we have extensive experience. There is considerable overlap in our experimental design that serves to reduce total numbers of animals used.

Mice will be randomly allocated to experimental groups, maintaining a comparable segregation of age, size and gender. All animals will be maintained in the same environment. Details of the random allocation will be retained by our existing chief animal technician, who is not directly involved in this project. The same person will administer experimental agents (or control substances) and retain a key to identify recipient mice. This key will only be accessed after analysis has been completed .

For most experiments we calculate that 5 - 6 animals are required per group to generate biologically meaningful and statistically valid data. This is based on a range of considerations agreed with our advisory biostatistician.

Since most of our studies are based on the dynamic changes that follow Myc activation, we will generally require 3 time points per experiment (typically, but not exclusively 1, 3 and 7 days) making a total of 30 animals per experiment. In this case the choice of the test of interest might be to compare with and without treatment, at different time points, and across time points (all treated). Again, all known statistical considerations will be implemented to be sure to derive the maximum usable data from each experiment.

Since many of our experiments require animals with complex genetic makeups, we will carefully plan breeding strategies to minimize the number of animals of incorrect genotype. For example, some experiments require animals with a specific combination of 5 or more alleles. Hence, more than 65% of the animals will be involved in breeding protocols only.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Calculations are informed by reference to Festing, MF and Altman, DG, 2002 (ILAR J 43, 244-258) and NC3Rs Experimental Design Assistant (https://eda.nc3rs.org.uk/eda/landing) and with assistance from the in-house statistician dedicated to optimising use of animals in experiments.

What other measures apart from good experimental design will you use to minimise numbers?

Since most of our experimental animals have complex genotypes we have carefully planned breeding strategies to maximize the number of suitable experimental animals and control littermates. All animals will be humanely destroyed at the end of experiments and tissue samples taken for further experiments. Where possible (eg where tissues can be used as controls for other experiments) mouse tissues will be shared amongst the research group. This will maximize the amount of information that can be acquired from the minimum number of animals. Where appropriate pilot studies will be conducted to determine feasibility and efficacy.

A retrospective assessment of reduction will be due by 18 November 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

One of the problems with classical transgenic and xenograft mouse cancer models is the unpredictable and highly variable time it takes for tumours to emerge. In such instances, it is unknown why some animals take longer to exhibit disease than others. For this reason, all animals have to be constantly monitored and their state of health inferred indirectly by external signs. Such unpredictable variability makes minimisation and mitigation of adverse effects much more difficult. The great variability in the time to tumour presentation in such classical mouse models also means that the critical events that eventually drive overt outgrowth of tumours, and timing and sequence of such events, are very poorly defined, making it almost impossible to establish the cause-and-effect events that cause the cancer.

By contrast, our sophisticated switchable genetic technologies allow us to regulate expressionor activity of key cancer genes at will, in real time in target mouse tissues. This triggers tumour formation and regression with highly reproducible, consistent, predictable and rapid kinetics. This allows detailed assignment of which, when and how the various oncogenic events accumulate to cause cancers while greatly reducing numbers of animals needed in each cohort to achieve statistically valid data. Moreover, because of the highly predictable latency and rate at which our models develop tumours, we are able to terminate most experiments at a very early, incipient, stage when tumours are small and have not yet spread or metastasised. Consequently, most mice exhibit only moderate adverse effects and the small number that perhaps exhibit severe effects can be killed immediately
.

Our studies on the role played by the Myc protein in tissue regeneration, and its relationship to cancer, requires animals in which different single tissues are deliberately damaged. Although not causing lasting harm (the tissues rapidly and efficiently regenerate), these models may generate transient suffering and pain. Where possible the pain is mitigated by analgesics.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Our scientific goals rely on being able to model the development (and regression) of adult human cancers in the mouse. Thus, it is not possible to use more immature stages or terminally anaesthetised animals. Mouse physiology is sufficiently similar to that of humans to generate passable representations of the human disease. This is facilitated by detailed knowledge and comparison of mouse physiology and genetics. Tumourigenesis is a dynamic process, taking several years in humans - in the mouse, we can speed up and precisely regulate this process using a number of genetic manoeuvres such as reversibly switchable protein activity and/or gene expression.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will continue to use rapidly switchable models that allow short-term, consistent and predictable outcomes that allow us to limit welfare costs to the animals.

For example, in some experiments we employ the commonly used pdx1-Cre allele to activate expression of oncogenic Ras and Myc proteins specifically in the pancreas. However, we have observed extra-pancreatic expression in this mouse model leading to collateral adverse effects, specifically hyperplasia and neoplasia in the intestine. For this reason, we developed a replacement mouse model in which expression of Ras and Myc is tightly restricted to the pancreas and extra-pancreatic adverse effects do not occur.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We adhere to the guidelines published in Workman *et al*. (2010) Guidelines for the welfare and use of animals in cancer research. BJC 102, 1555 - 1577 and the NC3Rs ARRIVE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are advised of advances in the 3Rs via regular correspondence (email). Furthermore, our dedicated technician attends relevant 3Rs - sponsored meetings. Information is disseminated to the rest of the group. REDACTED

Explain the choice ofspecies and the related life stages

The aim of this project is to elucidate the contribution of the Myc protein to tumourigenesis, tumour maintenance and normal physiology and to validate Myc as a potential therapeutic target for cancer. Since cells cultured *in vitro* do not adequately recapitulate the cellular context and interactions in which cancers evolve it is necessary to employ animal models. For example, interactions between the tumour cells and several different types of non-tumour (stromal) cells that constitute the "tumour microenvironment" are crucial for tumour growth and survival. Inhibition of the soluble signals that drive these interactions is a promising basis for tumour therapy that can only be elucidated in the whole organism, particularly since some of the stromal cell types recruited to the developing tumour originate in distant organs. All of the proposed animal experiments involve mice. The mouse is the most suitable model system in which to perform these studies. Our major interest is in adult human tumours (particularly those arising in the lung, pancreas and liver) and our experimental mouse models generate tumours in these organs of adult mice that closely resemble the human disease. Moreover, the mouse genome is well characterized and can be manipulated by gene targeting and there is extensive knowledge on the breeding and husbandry of rodents. The animals will be maintained in Home Office

approved facilities offering rigorous guidelines to ensure the best welfare and so that animal numbers are kept to a minimum.

A retrospective assessment of refinement will be due by 18 November 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

103. Investigation of the factors involved in the development and maintenance of myeloid malignancies, and ways to target them therapeutically

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

In this project, we want to understand why specific blood cancers start and develop. These cancers, called myeloid malignancies are more frequent in older persons, but the reasons for that are unknown. Our goal is to understand why the elderly develop myeloid malignancies more frequently, how to identify people at a particularly high risk of going on to a more severe condition and how to prevent or block the disease from progressing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The blood cancers called myeloid malignancies (MM) are increasingly common with age. With a frequency of more than 15 cases per 100,000 people per year, they represent an important health issue and with the ageing of population worldwide, the number pf patients will largely increase. The majority of patients still die from their disease as treatments have not improved over the years. The main obstacle to improving the treatments is a lack of understanding of how these diseases begin and progress to more severe forms. There is therefore an urgent need to develop new therapies, and this is one of the main goals of our project.

Due to the current lack of effective treatments of myeloid malignancies, another approach is to prevent them. Prevention was not an option until recently for MM as the patients often get ill suddenly, without any earlier signs of the disease. However, recent work by our team and others has found that we can identify people at high risk of developing these cancers many years in advance. Therefore, an early detection may be possible which opens a field to a search for preventative methods. Prevention of myeloid malignancies is another main goal of this project.

Myeloid malignancies origin from haematopoietic stem cells (HSCs), the cells responsible for blood cell production. Under daily pressures, HSCs acquire mutations in their genetic material which changes the information contained within it. Whilst the vast majority of such mutations do not affect HSC behaviour, certain mutations can equip an HSC with advantages. In consequence, this HSC will increase production of its daughter blood cells out of proportion, a situation known as clonal haematopoiesis (CH). Clonal hematopoiesis is driven by a group of Mutations associated with Myeloid Malignancies (MMM). Importantly, CH becomes increasingly common with age and is detected in more than 30% of people aged 70 years and older. Most people with CH do not develop myeloid malignancies, however, they are at an increased risk.

Apart from mutations changing the behavior of HSCs, it is clear that other factors influence their behaviour. There is now increasing evidence that the pace at which an HSC and its daughter cells grow, is affected by ageing and factors such as infection, inflammation, diet, exercise, sleep and the microorganisms co-living inside the human bodies. The impact of ageing is particularly strong for some of the mutations, as the blood cells with these mutations are only able to over-grow out of proportion in old but not in young people.

It is not known how the ageing and the other factors affect blood cells with a mutation. In this project we aim to find which early events enable HSCs with different MMM to begin its uneven growth and progression to malignancy. Preventing and blocking these processes are the main objectives of our work.

What outputs do you think you will see at the end of this project?

This project will provide new knowledge about the factors involved in the initiation and progression of a group of blood cancers called myeloid malignancies. This new knowledge will enable to develop new laboratory and bioinformatic tools to test people at increased risk of myeloid malignancy and predict their disease progression. Furthermore, we aim to find new or existing drugs to prevent and treat myeloid malignancies (cancers), in order to improve patient survival and quality of life.

The new knowledge gained in this project will be shared with the scientific community though conferences and publications. We will also remain involved in public engagement activities to increase awareness about our research to the wider public.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short-term, the medical, scientific and pharmaceutical communities will benefit from our research by using our findings to develop new strategies to identify, prevent and treat myeloid malignancies.

To the rapid benefit of patients, we plan to work along with other scientists, medical doctors and biomedical companies to speed up the application of our findings into new testing methods and new treatments. We have a good experience in such processes and we are already advanced with trials of drugs discovered through similar studies.

In the longer term, we hope that our work will lead to the development of new methods for the prevention and treatment of myeloid malignancies and related blood cancers. Prolonged survival and a better life quality of patients with myeloid malignancies and their families will be the most direct and measurable benefits from our research. In the broad sense, ensuring a better treatment options will have a positive effect on society at many levels.

Our groups have a longstanding interest in public engagement activities and we will remain actively involved in these to promote the understanding of our research in line with the programme of public engagement proposed by our institution.

How will you maximise the outputs of your work?

Our findings will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings. The generated data will be archived and made openly available to other researchers around the world via the European Nucleotide Archive (ENA) at EMBL-EBI. Our new animal models as well as viable cells collected from the mice will be valuable to other scientists studying the myeloid malignancies. We will distribute our mice and other tools freely to non-commercial establishments after publication. Pre-publication access will be extended to other scientists as part of collaborative studies. We have already exported a number of our mouse models to several leading universities and institutes worldwide. We will also aim at share and use tissues from aged mice using SHARM (https://www.sharmuk.org).

Species and numbers of animals expected to be used

- Mice: 33100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most methods and procedures required for this project are well established in the field of blood cancer research and in our group; we have successfully used them in the past to characterise different mouse models of leukemia.

In practice, mice will be bred to generate offspring with changes of interest in their genetic material, so-called genetic alterations. Frequently, to achieve an active state of the genetic alteration, a mouse will need a specific **induction** procedure involving a single or repeated injection of a substance that will turn on or off the genetic alteration. Some of these experimental mice, after activation of genetic alteration, may undergo **ageing** up to 125 weeks. Throughout this time we will perform **blood collection** from mice on one or multiple occasions to assess how the number of blood cells change as one of markers for the disease progression in response to various treatments.

Frequently, the treatments will aim to mimic the exposures normally encountered by humans during their lifetime such as low-grade inflammation following infection or poor choice of diet. The treatments may last up to 12 weeks and are expected to produce long-lasting but virtually undetectable changes, in the same way that occurs in humans. To this end, mice may undergo a **pro-inflammatory or anti-**

inflammatory treatment with different substances to modify the behaviour of the changed blood cells or their normal body environment. The treatment may involve a single or multiple administrations of a substance (e.g. bacterial cell elements) by different delivery routes (e.g. in the food, injected under the skin). The frequency of these treatments and volumes used are not expected to harm the animals in the long term. Similarly, mice may undergo a procedure of **behavioural modification** to indirectly influence the activity of blood cells. To this end, mice may undergo a change in their dark-light cycle, receive a modified diet or may be provided with exercising equipment.

Some mice will undergo irradiation to compromise or remove their own blood system before a **transplantation** of blood cells from another mouse. Transplantation will be performed only once in the life time of a mouse. Often, **preconditioning (e.g. irradiation)** of an animal may be necessary to facilitate growth of transplanted cells. Depending on the amount of irradiation, mice may experience post-irradiation illness but our advanced care plan will effectively limit this condition. Where relevant and available, human blood cells may be transplanted into mice to confirm the findings from studies in mice.
Frequently, the transplanted cells may be pre-manipulated "in a dish" prior to transplantation to modify their potential to generate leukemia in mice.

On occasions, the pre-manipulation on cells "in a dish" may enable emission of a bioluminescent light by the cells to enable **imaging** of the cells growth within the body. Upon injection of an imaging substance in the mice, this light can be captured from the living mice placed in the imaging system. To enable stress-free restraint of the mice for imaging, they will undergo a **short term anaesthesia** for a brief period and are expected to recover from anaesthesia without longterm harm.

Anti-leukemic treatments may be administered to the mice to prevent, slow down or eliminate leukemic cells. Examples of leukemia-targeting substances include drugs that have been shown to effectively inhibit tumour cell growth when tested "in a dish". Frequently, the treatments may involve repetitive handling of mice for a brief moment to administer the substance by injection. However, the frequency of these treatments and volumes used are not expected to harm the animals in the long term.

On occasions, a large volume of blood may be required for analysis and to obtain this, a mouse may be induced under **terminal anaesthesia** (a state of deep sleep terminated by euthanasia) to enable a collection of a **terminal blood sample**. Similarly, terminal anaesthesia may be used in an animal to perfuse it (supply through circulation) with fixative solution for preservation of its organs for further analyses.

Mice will be killed by one of the approved humane killing methods. Upon killing of a mouse, we will collect different organs (e.g., bone marrow, spleen, liver) to analyse multiple parameters such as proportions of different cell types, gene expression, protein expression etc.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

General health monitoring is performed for all mice by trained personnel in the animal facility and members of our research team. According to our long-standing experience with our mouse models of blood cancers, we understand in-depth the possible adverse effects of our experimental designs and can enhance animal care for the mice at increased risk of ill-health. Any mice showing signs of ill-health

or noticeably reduced activity for more than 24 hours will be humanely killed. In addition, when visible signs of compromised wellbeing are observed, enhanced monitoring and support will be put in place according to the care plans included in this license.

During our project we will use different procedures and experimental setups which are expected to have a various level of impact on animal wellbeing as listed below.

1. Breeding of genetically altered mice is not expected to cause harmful effects. Nearly all of the genetic changes used for our project will be seen in the adult animals used for our experiments. Therefore, the majority of the animals used for breeding will not experience adverse effects which might arise from changes in their blood system.

2. Induction treatments are meant to activate genetic alterations. Activating substances will be injected in mice up to 7 times every day or every other day. A mild weight loss up to 10% of pre-treatment weight may appear in relation to biological effects of injected substances. These adverse effects will decrease or stop once the induction period in finished and will not affect the mice long-term.

3. Blood collection will be used to obtain samples for tracking of a disease progression and other analyses. This will be done up to 20 times during a life time of a mouse with at least 2 weeks between the bleedings. The bleeding may lead to a short-term discomfort and stress but is not expected to affect the animal in long-term.

4. Blood cancer will develop in some of the mice. Over the weeks or months, these mice usually show gradual changes in the number of blood cells, which may cause an increase in the size of the spleen and occasionally, in liver size. Infrequently, other tumours may appear. Their growth will be judged by external signs such as swelling of the tummy or appearance of masses under the skin. Mice may appear hunched (a specific posture with a hump in the back), their hair may stand on end and they may show reduced activity at the advanced stages of the disease. These signs will be humane endpoints.

5. Transplantation (a transfer) of blood cells will be done into some of the mice. This is a standard method to assess the potential of cells under challenging conditions. Tail vein will be used most frequently to inject the transferred cells. A transient discomfort and stress due to temporarily holding an animal, as required for injection, may lead to a short-term discomfort and stress behaviour. However, the procedure itself is not expected to negatively affect the animals in the long term.

The injection of abnormal blood cells into the cavity in a long bone (thigh bone) may be used in specific cases to improve the outcome of the transplantation or modify the experimental outcome. This is a surgery and is discussed below under a paragraph 7 about surgeries.

6. Preconditioning (preparation) may be needed for some mice before they get a transplantation. Irradiation will be used most frequently but other methods may be used as well. Irradiation may induce a post-irradiation illness and a level of the illness depends on the amount of irradiation (a dose) received by a mouse.
The doses will be always adjusted to ensure the least dose is used therefore limiting animal suffering.

- Low dose of irradiation may cause a mild drop in weight of mice (up to 10% of pre-irradiation weight). The reason for this is a decreased interest in food and water. The activity of mice should remain unchanged. Irradiated animals will be checked daily and weighed at least twice weekly to monitor their

health. An enhanced pre- and post- irradiation care plan will be provided if necessary. Our experience and the published data show that the mice recover fully from the irradiation-related adverse effects within 7-10 days. The mice should return to their weights within 7-10 days post-irradiation.

• High dose of irradiation leads to a long-term failure of blood system and therefore, the irradiation illness is more pronounced. Mice may drop in weights up to 15% of their pre-irradiation weight. Moreover, mice may be less active. The mice should return to their weights and activity within 7-10 days post-irradiation.

Sometimes, only a part of a mouse body will be irradiated. These mice will be put under 20-30 minutes of anaesthesia (a state of a deep sleep). This short anaesthesia will not result in long-term adverse effects.

Preconditioning will be done only once in a lifetime of a mouse.

7. Surgeries will be done in germ-free conditions to prevent infection and under anaesthesia (a state of a deep sleep). Following surgery, mice will be kept warm until they are fully recovered and moving freely around the cage. The mice are expected to recover form anesthesia within 20-30 minutes at most and no long-term effects are expected. Medication to relieve any pain will be administered to the mice while they are anesthetised for the surgical procedures. Mice should be fully active within 2 hours from surgery. Surgeries should not result in long-term adverse effects. Difficulties to regain activity beyond 2 hours post-anaesthesia or signs of more than mild pain and distress will be humane endpoints.

8. Imaging may be performed on some mice to visualise a cancer growth. Injection of a substance for imaging will be done before each session. Each session will last up to 45 minutes. At most, we will do 9 sessions three times a week. Imaging will be done under anaesthesia (a state of deep sleep) and the mice are expected to be fully active within 20-30 minutes post-anaesthesia. Imaging is not expected to result in long-term adverse effects.

9. Different anti- or pro-disease treatments will be used to change the progression of the blood cancers under study. We will use only substances with known properties and known to cause up to moderate adverse effects such as reduced activity, decreased feeding and weight loss up to 15% of pre-treatment weight. These adverse effects may persist throughout the whole period of treatment. The mice may receive the substances in drinking water, food or by injections.

10. Physiological anti- or pro-disease treatments will be used to mimic states normally met during a human lifetime. Examples of such treatments include a high-fat or a nutrient-deficient diet, a free exercise, inflammation, infections, changes in intestinal bacteria and disruption of the light-dark cycle. These treatments may result in mild disturbances to the normal condition of an animal such as mild changes in their activity and weight gain or loss up to 10% of their pre-treatment weight. These treatments will last up to 12 weeks.

11. Ageing as a physiological process is not expected to have more than mild effects on mice. General physiological features of ageing such as reduced activity, a weight change, hair loss or blindness may appear and persist until the animal is killed. The ageing mice will benefit from an enhanced care plan and killed immediately if they experience any signs of suffering. Rarely, different cancers may develop in the oldest animals and an existing blood disease may progress faster in aged mice.

Unless otherwise specified, the work in this licence will be undertaken in accordance with the principles set out in the Guidelines for the welfare and use of animals in cancer research. British Journal of Cancer (2010) 102, 1555-77.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Below is the summary of animal numbers used on different severity protocols:

Moderate severity, 12100 mice:

protocol 3: Embryo recipients 1000 - all mice will reach moderate severity

protocol 4: Vasectomy 100 - all mice will reach moderate severity

protocol 6: 4000 moderate, 75% predicted to reach moderate severity (3000)

protocol 7: 3000 moderate, 75% predicted to reach moderate severity (2250)

protocol 9: 4000 moderate, 75% predicted to reach moderate severity (3000)

Mild severity, 21000 mice:

protocol 1: superovulation 2000 - all mice will reach mild severity

protocol 2: generation of founders 1000 - all mice will reach mild severity

protocol 5: breeding 15000 (this number includes animals that will be moved to other protocols)

protocol 8: 3000 mild, 75% predicted to reach mild severity (2250)

What will happen to the animals at the end of the study?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are particularly interested in the biology of blood cells carrying different mutations (i.e. changes in the genetic machinery that controls the cell) causing a specific type of blood cancers called myeloid malignancies. In myeloid malignancies, blood cells with mutations escape the normal regulation of blood system and out-grow other types of blood cells leading to an unbalanced blood production. According to studies from ourselves and others, this process of unbalanced growth is strongly linked to the ageing but it is not known how.

In many ways, human and murine ageing are physiologically similar, which allows to use results from research on human and mouse interchangeably and validate the research relevant for human in mouse models.

Regulation of blood system is not fully understood. It is of particular interest, but highly challenging, to address the regulatory environment controlling the blood stem cells (i.e. the cells that will produce all subsequent cells) and all the produced downstream types of blood cells. Multiple approaches have been proposed to re-create "in a dish" the interactions between blood cells and their regulatory factors. However, these attempts have not been fully successful and only a limited number of known regulatory clues can be combined. Only a living organism provides a complete structure required to study biology of normal and diseased blood system.

Due to the technological progress, mice can be used to generate models of mutations found in patients with blood cancers. Blood system of mice has been thoroughly studied and therefore, it offers a well-validated resource to research on development and function of normal and mutated blood cells. Of note, differences between normal and diseased cells are frequently subtle and animal studies may provide a more restrictive test condition.

Studies in mice have a strong track record in facilitating basic and translational (patient-oriented) cancer research in ways that cannot be pursued in "in a dish". Our work moves increasingly in a therapeutic (treatment based) direction and it is essential for us to test potential treatment approaches in a living animal. This step in necessary before we are confident that the tested therapy is appropriate for humans.

What was your strategy for searching for non-animal alternatives?

In our project, we combine different approaches to answer different questions. The majority of our work is performed "in a dish" where we grow immortalised cells (cells that do not die) as established cell lines. Equally, we use in cultures a material obtained directly from mice e.g, different types of blood and blood-supporting cells.

Human material from healthy people and from patients plays essential role in our project and we have in place arrangements to obtain fresh and archived samples. Human blood and blood-supporting cells will be used for cultures and for different direct analyses.

Newly generated data as well as existing datasets are analysed using bioinformatics (the use of computers to analyse and interpret animal and human data). This helps us to solve our research questions as well as to propose new directions.

Why were they not suitable?

Due to the limited knowledge about regulation of blood system within both mice and humans, it is not possible to re-create the physiological conditions to culture blood cells "in a dish". Once removed from the body, blood cells rapidly lose their properties and their biology cannot be fully studied "in a dish". The culture systems are a simplified and unphysiological context, where only specific questions are studied without the full picture. By contrast, studies in living animals allow scientists to draw physiologically relevant conclusions. Findings from cultured cells always need to be tested in living animals to validate their relevance.

Bioinformatics analysis of our own and publicly available data is extremely important for our research and three members of our team work full time as bioinformaticians. Their work helps us to direct our research towards specific questions and goals, but we will always need to validate their conclusions in cellular systems, living animals and humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Keeping the numbers of animals to a minimum is an important goal that we constantly strive to achieve. This begins during the planning of an experiment. We use results from previous experiments and statistical calculations to accurately estimate the maximum numbers of animals required to answer our different experimental questions. We understand that underestimating animal numbers can be just as wasteful as overestimating them.

In our project, almost half of all the animals will be used for breeding to generate animals for experiments. For some of our research questions, we need 3-4 different genetic alterations to be present within one animal. Obtaining such mice often requires a number of breeding steps and therefore, we expect a large number of animals to be used for breedings. We will always aim to keep the breeding schemes as efficient as possible.

Regarding the numbers of experimental animals, we base our estimates on past studies within our groups. We will calculate the numbers of the mice required for different types of experimental designs using statistical tools appropriate for the purpose and with an adequate power. For example, in experiments designed to test therapeutic effect of an anti-leukemic drug, we will estimate a number of animals using calculators designed specifically to match the data output required. In experiments where we compare changes with a normal distribution, we will use calculators using t-test statistics.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In general, we will consider the PREPARE guidelines to formulate a study and to control the quality of each of its parts. According to a good laboratory practice, we will write a protocol for each experiment including a description of the experiment and number of animals per group. Researchers will be advised to design their experiments using the NC3Rs Experimental Design Assistant (EDA). Online tools, for example easy-to-use spreadsheets, may be used as a guidance to estimate the number of animals for particular types of experiments (https://www.bu.edu/researchsupport/compliance/animal-care/working-with-animals/research/sample-size-calculations-iacuc/ spreadsheet) or http://www.biomath.info/power, recommended by the 3Rs-Reduction.co.uk website http://www.3rs-reduction.co.uk). In case of doubts, we will search an advice from an expert statistician.

Experimental plans will be clearly communicated to the animal facility staff to ensure a straightforward operation. Experiments will be conducted to enable publication of results in open access journals and in accordance with the ARRIVE guidelines. We will consider publication of negative data to avoid unnecessary duplication of the work by others. Sequencing or genotyping data will be archived at EMBL-EBI's European Nucleotide Archive (ENA) which is openly accessible to any researcher around the world.

We have and will keep updated with methodological advances; reduce the numbers of animals needed to design statistically sound experiments, as for example using single cell technologies or bioinformatic analysis tools as they are developed. To reduce the numbers of animals needed, we will also use cells from the same animal to answer different experimental questions.

Where there is any doubt, advice from a professional statistician will be sought.

What other measures apart from good experimental design will you use to minimise numbers?

Wherever possible, we shall import existing mice strains with altered genes of interest or obtain animals from other project licences with authority to transfer animals rather than generating new ones, as this will reduce significantly the numbers of mice used in the generation of new genetically altered mice. However, if there is strong justification for different variant of a gene or a different genetic background, we will generate the new model using the most efficient technology.

We frequently require mice with a combination of two up to four genetic modification. Generation of a mouse with such complex genetic image (genotype) requires a high number of mouse pups to be born. We adapt mating strategies to maximise the numbers of mice born with the required genotypes. We have adapted our mouse mating strategies to maximise the numbers of mice born with the required genotypes, and whenever possible, we will use mice homozygous (i.e. have two identical genes) for mutation if these animals are fit and fertile.

We will interact closely with the staff of animal facility to ensure that the breeding of our genetically altered REDACTED is as efficient as possible. We will carry out regular reviews to check that only required REDACTED are kept alive. If there are no plans to use a mouse line for at least a year to come, the line will by cryopreserved (reproductive material collected form mice will be deep frozen for storage). To improve recovery rates from frozen material, cryoprotective additives will be used during

freezing according to the current best practice. Historically the cryopreservation of sperm from some mouse strains, has been highly problematic due to post-thawing recovery rates. Additional media constituents allow us to use sperm as a suitable archiving option. By utilising this option we can again minimise the numbers of females used at this stage of the process.

Furthermore, cryopreservation will allow saving REDACTED in case of a large-scale problem affecting the animal facility, e.g. disease outbreak.

Our REDACTED will be available for sharing with the wider scientific community. This will help reduce the number of animals used to generate lines by other scientists.

To reduce the number of animals required to detect a true biological effect, we will aim to use litter-mates without genetic alteration as controls. Such control litter-mates coming from the same parental pair have their genetic material most similar to test animals and are exposed to the same environment. Their usage counterbalances the problem of variability between mice from different litters, and therefore, it decreases the overall number of animals needed to reach valid results.

Whenever possible, we will maximise the amount of data obtained from the same experimental animal by collecting different types of samples and information (e.g., organ size, blood counts, tissue). This will enable combining of different types of results on a per mouse basis, helping to reduce variability.

When planning new types of experiments, we will search through literature if any data on similar approaches is available and we will contact other researchers for expert advice.

Ageing of experimental mice is essential for our project and we will aim to efficiently use the aged animals. We will collect different types of samples form aged mice and we will share unused tissues through ShARM UK.

We will equally publish negative data to inform the scientific community about inefficacy of tested treatments to avoid others doubling the animal work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Throughout this project we will use mice with different mutations (i.e. changes in their genetic material) to study why specific blood cancers start and develop. These blood cancers are called myeloid malignancies as they result in cancerous overgrowth of myeloid blood cells.

There are over 30 mutations linked with myeloid malignancies and our groups have previously generated and studied a number of mouse models carrying these mutations. Over the years, we have developed extensive expertise in these models and in the types of studies which we intend to carry out. Therefore, we understand how to obtain valid experimental outcomes in mice with progressing blood cancers without causing unnecessary suffering to animals.

In most of these models the mutation is not active and the animal will not experience any harm. Once the mutation is turned on by an appropriate treatment, the mouse is expected to gradually develop signs of abnormalities in the blood system. As the timing of mutation activation is under our control, we are able to date when the disease should begin. This way, we can intervene early to minimise adverse effects. Most of mutations that we study will lead to diseases with a slow progression which again, enables us to keep progression of adverse effects to minimum.

In this project, we will continue to study our mouse models in a new perspective of ageing. To this end, we may use mice with genetic alterations resulting in ageing features. For example, mice with genetic alterations in immune or nervous systems or with changes in metabolic functions may be used. Whenever introducing a new model to our studies, we will collect all the information needed to assess any special needs of the new model. According to this information and if needed, we will design an appropriate care plan.

Lastly, most of our studies are based on material collected from animals post-mortem and therefore, will not involve animal suffering.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Blood cancers that we study affect mostly aged people. However, according to data from us and other researchers, mutations responsible for these cancers may appear in middle-aged people many years before the patients start to show the disease. Furthermore, only a small part of people with mutations will develop the cancer. In consequence, our research questions are, firstly, why only some people with mutations go on to the cancer and secondly, how advanced age promotes the disease. Furthermore, blood cancers of our interest have slow progression and therefore, passage of time is essential to model their development. Mice, due to their similarity to human physiology and their life time to around 2 years, allow to address our questions in a physiologically complete system within a feasible time frame.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

In this project, we will perform different types of experimental procedures. The highly trained staff at the animal facility offers significant assistance and ideas for refining protocols.

In general, post-procedure checks are put in place to monitor the condition of animals in the hours after they have undergone a procedure. For each procedure, we will put in place an appropriate care programme to minimise harms to the animals as described below.

Surgery

Surgeries, for example intra-bone injections (directly into a bone), will be done under general anaesthesia (a state of deep sleep). After surgery, mice will be kept warm until they return to their normal activity. Mice will receive medication to relieve any post-surgery pain.

Ageing

Wellbeing of ageing animals will be carefully monitored by regular checks of their condition. The standard check will include observation of their activity, skin and fur condition, teeth, posture and weight. The observations will be crosschecked with the previous report to detect any sign of deterioration. When deterioration in the condition is observed, appropriate countermeasures will be taken and may include: supportive diet, additional cage enrichment or specific treatments (e.g. medicaments applied on skin) upon consultation with animal care specialists.

Housing

Mice will be maintained in individually ventilated cages (IVC) where clean filtered air is provided in a controlled way to reduce anxiety in mice. To satisfy natural social instinct of mice, they will be kept in groups. Group sizes will follow the regulations to avoid the cage overcrowding. Separation and housing of single mice will be introduced only when aggressive behaviours are found.
Each mouse will be marked by its earmark and will be tracked in the computer system to enable easy access to all the information about the mouse.

Enrichment

Mice will be kept in deep bedding and will be provided with nesting materials and ‘play tunnels’.
Particularly sensitive mice will receive an additional cage enrichment to reduce their stress levels.

Genotyping

Genotyping is performed to confirm presence of genetic alterations in mice. As material for genotyping, we will use ear-clips taken for identification of mice.

Cancer models

In most of the cases, genetic alterations causing the cancer will be activated in mice only upon a specific treatment. As the timing of the alteration activation is under our control, we are able to predict when the disease should begin and intervene early to minimise adverse effects.

Treatments to mimic ageing-related conditions

We will mimic ageing-related conditions by multiple approaches including induction of mild inflammation, infection, disturbed dark-light cycle or changes in diet. These treatments may lead to weight drop as an adverse effect. The weights of mice will be checked at least twice weekly. To counteract the weight drop, mice will receive enriched diet before and throughout the treatment period to keep their feeding.

Irradiation

Irradiation is a standard method to prepare mice before transplantation. Following irradiation, the mice suffer from post-irradiation illness where decreased food and water intake are main adverse effects and may lead to weight drop. With higher doses of irradiation, the symptoms may be more pronounced. Mice will be weighed before irradiation and every other day to detect weight drop as a sign of ill-health. Weighing of mice will continue until the weights are stabilised. To prevent the post-irradiation illness and weight drop, mice will always receive enriched diet at least two days before irradiation and during the post-irradiation period until their weight is stabilised.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Webpage https://www.nc3rs.org.uk is our reference for the best practice in animal research. Various aspects of work with animals such as handling, anaesthesia, analgesia, blood sampling, euthanasia and welfare assessment are covered there under the link:

https://www.nc3rs.org.uk/topic-specific-resources-0

Equally, we will refer to http://www.lasa.co.uk/ where under the tab: current publications we find "Guiding principles" for different aspects of working with animals. Particularly rich information can be found there regarding the principles for aseptic surgery:
http://lasa.co.uk/PDF/LASA_Guiding_Principles_Aseptic_Surgery_2010.2.pdf

To generate numbers of animals matching our experimental needs, we will follow the assessment framework available form Home Office under the link:

https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf

For the best practice, all experiments will be planned in agreement with PREPARE guidelines (https://norecopa.no/prepare) and we will follow ARRIVE guidelines (https://norecopa.no/3r-guide/arrive-guidelines) to report our animal research.

All PIL holders working under this PPL will be strongly encouraged to research through and implement these resources in their experiments.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed about advances in the 3Rs by following information in the newsletters prepared periodically by our establishment Named Information Officer. I also have an account at https://nc3rs.org.uk/ to receive updates from NC3R and equally I follow information published in the Lasa forum https://www.lasa.co.uk/current_publications/ and use the Establishment’s 3Rs Search Tool.

All team members will be encouraged to become acquainted with these resources. Additionally, any information relevant to the welfare of the mice under our care will be forwarded to all group members during our lab meetings and as brief handouts. We will always aim to set a good example to our colleagues. We will work closely with staff in animal facility to ensure the best care for our animals.

Explain the choice ofspecies and the related life stages

Mice are widely used for biomedical research due to their anatomical, physiological and genetic similarity to humans. Furthermore, they are easy to maintain in laboratory environment. The enormous progress of technology over recent years enabled us to efficiently generate mouse models useful to study myeloid malignancies which are our main research interest. Our mouse models carry changes in their genetic material (mutations) copying or resembling the changes in genetic material of patients with myeloid malignancies.

Myeloid malignancies are a group of blood cancers affecting mostly aged people. Consequently, effects of the ageing on the blood system are essential part of our project. In many aspects, the ageing of mice resembles the ageing of humans and therefore, mice are extremely useful resource to understand the human ageing. The life-length of a mouse averages to 125 weeks which allows to complete the project goals within a reasonable time-frame. Equally, we will use young adult mice as a reference for results obtained with aged mice.

Our work is focused on blood system and will benefit from a well-established mouse-specific range of methods. For example, blood cells can be easily analysed and separated by flow cytometry, a method where a set of the cell molecules is specifically marked to emit light under certain conditions and subsequently used to describe the cell for further analysis.

NON-TECHNICAL SUMMARY

104. Investigation of vitamin D biology in companion animals

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The important role vitamin D plays in maintaining healthy bones has been known for nearly a century. However, there is increasing interest in the potential health benefits of vitamin D beyond the skeleton in both humans and animals.

My research group studies the role vitamin D plays in maintaining and regulating the health of dogs. Our previous research has found that vitamin D status of dogs is dramatically altered in numerous diseases and we now wish to understand more about why this happens and then define the importance of these changes.

In particular, we are keen to establish whether vitamin D influences the immune system of dogs. Our previous research in mice has shown that vitamin D metabolites can dramatically alter the nature and behaviour of immune cells. Importantly, we found that high doses of active vitamin D metabolites can block the development of inflammation in the brain following the activation of immune cells. Consequently, we now wish to examine whether vitamin D can alter the immune response in healthy dogs.

We also wish to examine how vitamin D is metabolised in healthy dogs in order to understand how commonly used treatments, such as administration of fluids directly into the vein, can influence vitamin D status.

We also intend to understand more about vitamin D biology in patients who attend our hospital with diseases that develop spontaneously. We are keen to study diseases which develop naturally in patients to avoid the need to induce disease in healthy dogs. In addition, induced diseased in healthy dogs is unlikely to mimic all aspects of the spontaneous diseases we diagnose in our clinics. In particular, we wish to examine why dogs with severe gastrointestinal diseases typically have very low vitamin D status and whether this causes ill health in body organs beyond the intestines. In addition, we want to define how best to treat dogs with intestinal disease in order to improve treatment outcomes.

A retrospective assessment of these aims will be due by 13 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

A deeper understanding of vitamin D biology in dogs is likely to lead to development of superior treatments for client owned dogs with spontaneous illnesses. In addition, a better understanding of vitamin D homeostasis in dogs may offer a better understanding of the important diseases in humans.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will use 56 dogs in our studies.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The procedures undertaken in this study will include blood sampling, diagnostic imaging. The expected adverse effects will be limited to, and not be noticeably more, than the standard diagnostic tests and normal treatment for the conditions and will be managed by an experienced team of onsite veterinary specialists

Adverse events may include minor skin bruising from site of blood sampling. Other less common potential adverse events include high concentrations of calcium following vitamin D administration. This is very unlikely given the dose of vitamin D which we will use in our studies. Other potential adverse events include administration of intravenous fluids, extended anaesthesia times and exposure to diagnostic radiation. All of these are standard clinical procedures with a very low level of adverse events. If any adverse events occur we are ideally placed in our multidisciplinary hospital to deal with any eventualities.

A retrospective assessment of these predicted harms will be due by 13 September 2025

The PPL holder will be required to disclose:

> What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Our aim is to better understand vitamin D biology in dogs. We believe this approach is the epitome of best practice on compliance with the 3Rs since we are studying disease processes which have already developed rather than inducing them in otherwise healthy animals.

There are no pre-existing datasets which allow us to deliver our proposed programme of work. There are no non-animal approaches which allow us to understand how vitamin D modulates health in dogs.

A retrospective assessment of replacement will be due by 13 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

As the animals will develop the disease spontaneously, we are avoiding the need to induce illnesses in otherwise healthy animals. Control, healthy animals will be used as controls, where appropriate, to facilitate the meaningful interpretations of data gathered from the spontaneously ill dogs. For each experiment, we will use the minimum number of animals required to address the scientific question of interest. Where there is pre-existing and relevant preliminary data, power calculations will be performed to guide the numbers of patients which should be recruited for each experiment.

A retrospective assessment of reduction will be due by 13 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our aim is to better understand vitamin D biology in dogs. We may identify further diseases of relevance to these species that require improved scientific knowledge in order to produce effective treatments for them and thus the need to include dogs in this licence. Wherever possible, we will undertake procedures, notably blood sampling, at the same time as clinical procedures. Clinical procedures will be undertaken by a veterinary surgeon or nurse to ensure animal suffering is minimised and all procedures are done to RCVS standards.

A retrospective assessment of refinement will be due by 13 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

105. Investigative & Enabling Safety Assessment Studies

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	juvenile, adult
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project is to generate data to support the development of potential new medicines, with the following key elements:

1. Characterisation of functional and toxicology liabilities related to a specific agent/compound, a pharmacological target/class or a chemical series to allow selection of optimal candidate drugs for further progression, refine drug discovery strategies and provide appropriate animal models to enable effective candidate drug selection.

2. Investigate drug development strategies or mitigate observed unexpected toxicities. This may include, for example, investigating novel dosing strategies to improve agent/compound tolerability and effectiveness or combination strategies where potential new medicines may be dosed alongside existing therapies.

3. To provide support to development of new medicines and improved welfare through Method Development or Enabling work in the following ways:

- Method development to enable an investigation.
- Method development to increase the predictability of in vivo studies.
- Method development to validate new/existing techniques in literature or in other laboratories.
- Bespoke studies to assess potential refinements for animals e.g. evaluating specific enrichment methods

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Studies performed under this project licence will contribute invaluable data to support and progress the development of potential new medicines where there is a clinical unmet need. These studies will be fundamental to the elucidation of a safety risk associated with a target/agent early in its development, and therefore support decision making with respect to the progression of a candidate molecule towards the clinic.

Drug development is a long and costly process. It is therefore desirable to avoid unnecessary expenditure of time, money and resources as well any unsubstantiated use of animals on substances that are not suitable for development as potential medicines. This can be achieved by testing

agents/targets early in the drug discovery process, leading to early removal of unsuitable agents/targets from the pipeline or making a scientific assessment of an agent/target safety risk, alongside a strategy to mitigate observed toxicities whilst still delivering benefit to patients.

Furthermore, it would be unethical to administer novel substances to humans before making every effort to ensure that they were safe. In all disease therapy areas, developing novel agents with any associated toxicity into a new medicine can ultimately limit the benefit to the patient. This is particularly relevant to cancer patients where such toxicities may be dose limiting, i.e. they cannot tolerate higher doses of agents to improve efficacy because of adverse effects.

What outputs do you think you will see at the end of this project?

Data generated from studies performed in support of discovery and early candidate selection will be used internally to allow decision making on whether to develop drug candidates and, with other preliminary studies may help to define doses for subsequent studies. Data from studies will enable the investigation of safety liabilities identified through *in silico* (computer program simulated tests) and/or *in vitro* (in cells) methods and will be pivotal to the progression of novel anti-cancer agents and other therapeutics. Data from experimental studies will also be used to develop ways to mitigate, monitor or manage unwanted effects in the clinic, for example, by changing dosing regimen, previously intolerable adverse effects can be reduced, allowing a patient to continue with a beneficial treatment. Some studies will typically be performed to provide data in support of dose selection, typically tolerability and/or toxicokinetics (levels of drug in the blood or tissue), or to build/validate a new or different methodology thereby enabling other parts of the safety evaluation programme to proceed with best possible outcomes.

For all of the above, data will feed back into programmes for future compounds to refine discovery and development strategy and thus avoid unnecessary animal use and expenditure.

For compounds which progress, these studies may be included in regulatory submissions as supporting studies.

Data from studies may be included in peer review publications or presented at internal and external meetings and conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Early indications of safety and toxicity liabilities, including functional endpoints where appropriate, will allow early detection of unsuitable molecules and thus support decision making with respect to the progression of the a novel molecule, ultimately supporting the development of only the best new medicines towards the clinic for the benefit of patients where there is a clinical unmet need.

How will you maximise the outputs of your work?

Data from studies performed under this licence will feed back into research programmes for future compounds to refine discovery and development strategy and thus avoid unnecessary animal use and expenditure.

For compounds which progress, these studies may be included in regulatory submissions as supporting studies where they have informed for example a more effective dose selection for regulatory studies.

Collaboration with external scientific groups and organisations enables us to explore the use of developing technologies and capabilities such as proteomics and metabolomics platforms, allowing us to extend data sets further from within an individual study.

Data from studies may be included in peer review publications or presented at internal and external meetings and conferences to share new knowledge and learning in the wider context of drug safety assessment and development.

Species and numbers of animals expected to be used

- Rats: 9000
- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Studies will be conducted by dosing routes similar to those used in man, e.g. by mouth (orally) or by injection. The animals are then observed regularly to monitor changes in appearance and behaviour. Procedures carried out during these studies include:

a) Weighing: as a loss in body weight is often an early sign of harmful effects in animals

b) Blood sampling or collection of urine for measurement of different components, as changes in these may serve as early indicators of toxicity. Doctors, for similar reasons, often take blood and urine samples from humans.

c) Electrocardiography (ECG) monitoring to assess changes in heart function (e.g. number of heartbeats per minute). This technique is also used by doctors to assess heart function in humans.

d) Animals may undergo surgical procedures, for example to implant telemetry devices for non-invasive, longer term, cardiovascular monitoring; for implantation of vascular cannulae, or for non-recovery investigations

e) A degree of restraint or confinement may be required for some of the various dosing, sampling or assessment procedures such as those required to assess motor co-ordination (balance), muscular strength (ability to grip) or visual assessments.

At the end of the study, the animals are humanely killed by an overdose of anaesthetic. Where appropriate animals may be re-used for subsequent investigations. Samples of various organs are taken and examined under a microscope to ascertain whether the potential new medicine has caused changes that would rule out administration to humans.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

From experience, some animals are expected to have mild adverse effects such as slight weight loss. Animals may show more significant (moderate) adverse effects e.g. more marked weight loss, or changes in appearance (e.g. ruffled fur in rodents) or behaviour (e.g. reduced activity) indicative of moderate severity. Humane end-points are applied, under veterinary guidance as necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The maximum severity for both mice and rats is expected to be moderate. It is estimated <70% of animals will reach moderate severity, with the remainder reaching either mild severity or being non-recovery in nature.

What will happen to the animals at the end of the study?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Prior to studies within this programme of work, a number of in vitro (in cells) and/or computer programme simulated tests will have been used to establish early safety liabilities and risk associated with a target or novel agent. Only by using animals as part of a hypothesis-driven experimental design can we evaluate the impact of these in vitro /simulated findings on disordered physiological processes and pharmacology in a whole animal system, and ultimately the potential for adverse effects in humans.

What was your strategy for searching for non-animal alternatives?

We are continually investigating alternative in vitro systems that may be utilised to assess certain end points and thus reduce the number of in vivo studies required. For example, specific types of hazards, predictive of potential to changes in blood pressure ans heart rate, can be detected using in vitro systems and these assays are performed early in the safety assessment programme. “Organ-on-Chip” technology is extensively used, particularly to understand liver and bone marrow toxicology. These are self-contained units containing living human cells. The human cells recreate the physiological functions of organs without using animal models.

Why were they not suitable?

In silico and in vitro approaches are becoming increasingly powerful tools in the deign and development of new medicines and are used extensively to understand potential adverse effects. These approaches can help in understanding various isolated aspects of a new drugs safety profile and these methods are used to screen out those that clearly do not have the desired properties. However, because the safety profile for a given drug is multifactorial, it is not always possible to mimic the entire breadth of physiological responses and any interactions as seen in a whole animal (in vivo) system and to this end, such studies performed under this licence remain necessary.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers for all protocols have been calculated on an estimated workload derived from the previous tenure of this licence over a 4.5 yr period. These numbers are not definitive and could change in relation to the target/therapeutic disease area needs.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The numbers of animals used for each experiment will be set after consultation with a professional statistician to ensure all animal studies use the most appropriate design to answer the primary objective and to avoid bias. Animal numbers are kept to the minimum commensurate with meeting the objectives, and the endpoints being measured.

What other measures apart from good experimental design will you use to minimise numbers?

The following approaches will optimise the number of animals used, obviating further studies being performed as stand-alone studies under this licence:

- Where possible, additional sampling (e.g of tissues at the end of a study) may be included in planned studies thus deriving more data from one experiment.
- Samples may often be stored awaiting the development of a suitable assay, for examples the use of samples to obtain a measure which is a similar measure to that used in patients.
- Where possible, control or vehicle-dosed tissue may also be used for other experiments.
- If a new technology or concept is to be used within this Project, small pilot studies will first be performed to validate equipment and gain confidence, expertise and experience, prior to committing to larger studies.
- Studies employing a dose escalation design will be staggered to prevent unnecessary suffering and animal losses; once maximum tolerated doses are reached, further dosing will cease.

Other steps taken to ensure minimal animal use include the use of databases and computer modelling. Data generated under this project will be uploaded to a corporate database. This is critical to reducing the number ofanimals used and allows:

- Rapid access to data by all scientists and avoids requests and repetition of studies.
- Other research scientists carrying out evaluation of the same test compound may design their studies at appropriate dose levels, routes etc.
- The refinement of computer models to predict pharmacokinetic (PK) properties utilises software to simulate multiple dose PK (level of drug in the blood or tissue), rather than repeat dosing animals, and is critical to selection of appropriate doses for toxicological evaluation.

Other approaches that reduce animal numbers used include:

- Crossover study design may enable all dose phases to be performed in one animal – typically used for studies measring heart rate and blood pressure where re-use enables the same animals to be used for multiple evaluations.
- Increased assay sensitivity and the development of microsampling has enabled serial sampling in mice where full PK profiles are generated in single animals rather than the multi animal approach utilising 3 animals per time point. This approach reduces animal numbers used and reduces data variability across cohorts.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The species, models and methods used within this licence are widely accepted and have a proven record in generating translatable preclinical safety data. There is a wide knowledge of the response of rats and mice to various chemical entities and a wealth of background safety data in the pharmaceutical industry. Typically, the rat is the rodent species of choice unless it is known to be an inappropriate model for man for the test substance or target-related toxicity. Mice may be used where they are considered a more appropriate species than rats e.g. for kinetic reasons and/or presence of pharmacological target.

The scientific objective of this Project is to assess the early safety risk of novel medicines. To enable this assessment, agents will be administered at doses that may result in moderate bodyweight loss and clinical signs. The severity limits are those considered to be the minimum commensurate with achieving the study objectives. In all studies conducted under the authority of this licence, the upper severity limit will be moderate.

Blood volume taken for measures will be minimised by using microsampling techniques which significantly reduce the volume of blood removed from each animal, but still produce high quality data.

Best practice, for example the use analgesics after surgical procedures will be employed to minimise suffering.

Adverse effects will be kept to the minimum to achieve the objectives. Animals will generally be housed in groups and provided with specific materials to provide environmental enrichment.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Generally, the rat is the rodent species of choice unless it is known to inaccurately reflect man for a particular compound. There is a wide knowledge of the response of rats to various chemical entities and the translatability of these responses to man is more defined in the rat than other species due to a wealth of background data in the pharmaceutical industry. Rats are big enough to provide repeated blood samples for toxicokinetics, thus requiring significantly fewer rats than mice to achieve the same objective. However, mice may be used where they are considered a more appropriate species than rats e.g. for kinetic reasons and/or the presence of the pharmacological target.

As part of safety assessment profiling a molecule may be assessed for effects on complex functional / behavioural observations such as visual acuity, co-ordination / CNS effects or cardiovascular parameters in telemetered animals. These tests evoke responses in rats and mice that can be readily translated to man and the clinic. These assessments are more difficult in species that display more limited behavioural repertoires.

Studies are performed in animals that are terminally anaesthetised, where appropriate. However, many toxicological responses and pathologies evolve over time with repeat dosing.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Where possible, all animals will be group housed. The use of the REDACTED for rodent infusion work enables group housing of surgically cannulated rats between infusion cycles where previously this was not possible.

The majority of rats are housed in cages which offer a diverse environment divided over two levels, which encourages natural rat behaviours such as “rearing” and gives a greater floor area for exploration, AND ARE provided with specific materials to provide enrichment, including a selection of nesting materials, chew blocks, refuges/hiding places and foraging. All animals will receive a minimum of 7 days acclimatisation before use in experiments.

We are fully committed to NC3R recommendations for single needle use for parenterally (non-oral) administered substances ensuring that undue pain and suffering linked to the use of blunt needles is not experienced. As described above we are also heavily involved in non-aversive handling techniques for mice and have begun to ensure this is applied as "best practice". Training regimes to acclimate mice to “cupping/tube handling” techniques are underway to reduce stress in mice and therefore improve the integrity of data generated.

Blood volumes taken for measurements will be minimised by using microsampling techniques which significantly reduce the volume of blood removed from each animal, but still produce high quality data.

Adverse effects will be kept to the minimum to achieve the objectives, and will be closely and regularly monitored during and after regulated procedures.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Best practice, for example the use of analgesics after surgical procedures will be employed to minimise suffering.

FELASA guidelines are used as a baseline to ensure experiments are conducted in the most refined way. Historically, guidelines such as those produced by FELASA have been used to define the upper limit for bodyweight loss at 20% in safety assessment studies. Our organisation has actively contributed to a global collaboration that used evidence to define the upper limit for body weight loss in maximum tolerated dose (MTD) studies (conducted at contract research organisations). We have extended this guidance to studies run in-house under this and previous Project Licences, meaning that a gradual bodyweight loss limit compared with baseline (pre-dose) and/or age matched controls, will be commonly less than 15% over a period of one week.

The dose selection principles outlined in the LASA/NC3Rs guidance on dose selection for pharmaceuticals will be used where appropriate.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Advances in the 3Rs are regularly shared throughout our organisation and establishment network via e-mail or the internal intranet system, as part of the named person structure implemented by the Act (NTCO, NVS, NIO, HOLC, PIL, PLH).

Specific 3Rs based objectives are regularly included as part of an individual's yearly performance goals and are assessed as part of that individual's performance. In addition to this, we promote an annual presence at industry-focused meetings (IAT, FELASA) with the sole purpose of attaining and sharing 3Rs based knowledge with other companies and institutions. The "cupping/tube handling" technique for mouse handling is such a technique that has been introduced from these activities and is currently being implemented, validated and reviewed across our global sites as part of our continuous commitment to animal welfare improvements. One of the functions of this licence application is to enable the introduction and review of new techniques or technologies that may be applicable to the 3Rs. The use of the REDACTED for rodent infusion work enabled group housing of surgically cannulated rats and is one example of this protocol in use.

Explain the choice ofspecies and the related life stages

Rats and mice have a well characterised pathophysiology, and are a widely accepted species to measure safety/toxicity effects.

Home Office

NON-TECHNICAL SUMMARY

106.Invivo profiling of novel compounds

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

pharmacokinetics

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of the project is to give support to the discovery phase of research projects for external clients, ensuring that potential medicines with suitable pharmacokinetic – what the body does to the drug (PK) and pharmacodynamics – what the drug does to the body (PD) properties can be selected for further development to treat human disease effectively. PK is investigated by studying how potential

medicines are absorbed and distributed in the body as well as how they are broken down (metabolised) and excreted. PD is investigated by the affect a compound has on the cardiovascular system

Typically a medicine that is given orally is dissolved in the gut, absorbed into the blood and then the circulated around the body. It may be metabolised, usually in the liver, and it, and/or its break down products (metabolites) excreted in urine and faeces. Some medicines cannot be given orally: for example, due to poor absorption from, or breakdown in, the gut and another route must be used. Other medicines, such as those given by inhalation, do not need to go into the blood stream in order to elicit the desired pharmacological response and/or are more effective when directly delivered to diseased tissue. Confidence in predicting pharmacokinetic properties in man is gained by studying the action of the potential medicine in more than one animal species.

The information gained from studies carried out under this licence will help to;

1. Understand and then improve the way the compound is given so that there is sufficient information available to treat the disease effectively.

2. Understand and then improve the length of action of the compound so that it is likely to stay in the body long enough when given in a dosing routine that is easy for patients to use. Potential clients are required to disclose any previous in vivo investigations done on their compounds, to avoid any unjustified duplication of procedures.

To acheive these goals animals will be dosed, usually only once, with the candidate medicine and then small blood samples taken in order to assess how the candidate medicine’s concentration changes over time and whether this affects its ability treat a disease.

Dose concentrations will be kept as low as possible to ensure any adverse effects associated with the candidate medicine are minimised. Blood sampling methods will favour the least invasive possible to minimise any distress associated with taking blood samples.

Whilst we cannot predict unforeseen circumstances, but we only anticipate ‘mild’ to 'moderate' levels of severity in the licence.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Work under this licence will assist our clients in selecting compounds with an expectation of suitable properties in man and thus reduce the risk of exposure of human volunteers and patients to compounds that would be unsuitable as therapies. The work will enable clear decisions by our clients to progress or halt compounds at key project milestones. Data generated will assist in designing appropriate regimens and limit unnecessary use of animals for pharmacological and toxicological studies.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Rats, mice and guniea-pigs will be used on this licence. It is expected that no more than 11250 rats, 12300 mice and 600 guinea-pigs will be used over the life of the licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Adverse effects (eg piloerection, mild sedation and salivation) are those associated with routine routes of administration, sampling and those associated with general anaesthetic. In these cases, the likelihood of occurrence is estimated at <1%. The administration of test compounds/ substances will have the potential to affect all animals. Close monitoring and use of pilot studies, will help to keep the incidence of adverse effects to a minimum. Animals will be humanely killed at the end of all protocols.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

There are no non animal tests (in vitro - in glass) that completely mimic and predict many key aspects of the work described in this licence eg: does the drug get to the target tissue or organ and does it affect blood vessels. These aspects are often the result of the interaction of many individual biological processes and these interactions cannot be reproduced by in vitro (non animal) alternatives. For most organs there are currently no in vitro models that predict organ clearance and only an intact animal can provide an adequate integrated system. Consequently, animal testing is essential to achieving the overall objective of this licence.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Certain properties of drugs can be studied using a range of in vitro (‘in glass’ or ‘test tube’) and in vivo (‘in life’ or ‘in animals’) studies. It is standard practice to conduct the major proportion of testing in vitro using cells and tissues obtained from humans or animals. This strategy makes a vital contribution towards minimizing animal usage. In our experience, fewer than 10% of compounds tested in vitro are progressed to in vivo studies. In addition to in vitro testing, the properties of compounds are also predicted based on knowledge of their structure (‘in silico’). Whilst in silico (using computers) predictions or in vitro studies can provide a wealth of information on individual body systems, eventually studies in living animals are needed. Animals offer suitable models to replicate the interplay between different processes that can influence the disposition (what happens after it is given to the patient) of the potential medicine.

Once in vivo work is deemed necessary, there are a number of approaches adopted in order to minimise the numbers of animals used;

Typically group size is 3 rats
Refinements in sampling in mice, reducing overall numbers required.
Consideration of statistical analysis, to use the smallest group sizes possible, yet maintain adequate precision.

In pharmacodynamic studies the minimum number of animals required to detect effects of scientific interest will be determined using sample size calculations.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Purpose bred, adult free living animals of assured health and genetic status will be obtained from commercial suppliers or from breeding colonies. Most studies will be conducted in rats; this is supported by in vitro testing which shows the relevance of this species to man. It is necessary to use other rodent species, for the purpose of this project mouse and guinea-pig if these species are more relevant to man for a particular research project or if more than one species is needed to build further confidence in predicting to man.

Animal suffering will be minimised by the following;

Competent personnel will perform all studies on this project licence and adverse effects resulting from regulated procedures will be minimised by careful handling and the application of good technique.

Guidelines on the limit of volumes of administration of substances and blood sampling will be strictly adhered to.

A refinement in sample analysis has led to the reduction in total blood volumes required, now typically 20µl sample size. Thus reducing the burden further.

Home Office

NON-TECHNICAL SUMMARY

107. Ion regulation in cardiac, skeletal and vascular smooth muscle

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes.

Key words

Exercise, heart, heart failure, skeletal muscle, sodium

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Heart failure and high blood pressure go hand in hand in the elderly. Approximately 70% of men over the age of 70 show some evidence of having a large heart (hypertrophy) and almost the same proportion of men also have high blood pressure. Large hearts do not contract (or relax) properly and so this process of hypertrophy is a prelude to heart failure. These problems are not confined to men. One recently described type of heart failure is called HFpEF – this is where the heart does not relax properly between beats. HFpEF (like other forms of heart failure and high blood pressure) affects both men and women however it is particularly prevalent in post-menapausal women who have other comorbidities (ie diabetes, obesity etc). There is now a large amount of evidence suggesting that changes in ion regulation (sodium, calcium, potassium etc) inside heart and other muscle cells may contribute to hypertension, hypertrophy, heart failure and even skeletal muscle fatigue. The objective of these studies is to learn more how disease processes, ageing and gender all interact to affect outcome. Our aim is to understand more about the role of ion regulation in these diseases and to identify and develop new ways to treat heart failure, skeletal muscle fatigue and hypertension (high blood pressure).

A retrospective assessment of these aims will be due by 10 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The objective is to learn more about the disease process and to develop new ways to treat heart failure, skeletal muscle fatigue and hypertension (high blood pressure). We propose to test new drugs designed to treat both heart failure, hypertension and the skeletal muscle fatigue that so often accompanies the later stages of heart failure.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We propose to use rats (<1,000) and mice (<4,000) over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Under general anaesthetic with recovery, animals will be subjected to a variety of techniques to simulate heart failure. They will be allowed to recover and then compared to 'athletic' animals that have been trained to run or swim predetermined distances or times. In this way we can compare disease-induced heart growth with exercise-induced heart growth. While the exercise is not severe, the induction of heart failure is and these animals will show all the signs and symptoms of human patients with heart failure – e.g. breathlessness, fatigue, listlessness etc. During the study, animals may be imaged using techniques such as echocardiography or MRI (similar to those used in people). At the end of the experiment all animals will be humanely killed and their tissue taken for further study.

A retrospective assessment of these predicted harms will be due by 10 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Heart failure is a complex disease involving the whole body. Hormones, the central nervous system, the kidneys, etc all actively influence the disease progression. Athletic training also alters the whole-body – it changes our circulation, metabolism, fat, blood composition, insulin secretion, nervous system controls, hormones etc. It is impossible to simulate these complex scenarios in cells in culture or in computer models.

A retrospective assessment of replacement will be due by 10 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use sophisticated monitoring and serial non-invasive imaging systems to maximise the data that is generated from a single animal. Studies that 25 years ago would have taken tens of animals can now be done in a single animal. All experiments are designed in advanced using statistical power analysis to ensure that the minimum number of animals will be used that is compatible with proving our scientific hypotheses. We will also, by combining tissue from one animal, be able to study the consequences of 3 distinct pathologies affecting the heart, skeletal and vascular muscle. This reduces the number of animals required by 2/3rds.

A retrospective assessment of reduction will be due by 10 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Many years ago such experiments used larger animals (often dogs). Recently, however, miniaturisation has allowed us to use smaller animals in particular mice and rats. The mouse has become the preferred animal of choice for many studies as it is cost effective to house in large numbers, it has a short gestation period and, in captivity, breeds readily and repeatedly just as it does in the wild. This makes it the species of choice for manipulating its genome (that is adding, deleting or mutating its genes) to test the role of specific genes or proteins. Mice also love to run! So they are a good species in which to study exercise physiology. Given a running wheel, a mouse will voluntarily run for 4-8 km/night – our record is 17 km in one night – the equivalent of a human running to Australia and back! Running wheels and environmental enrichment enhance the environment for the animals. We are refining the swimming protocols so that the animals acclimatise to the procedure and stress is kept to a minimum. All surgical experiments are done using anaesthesia and analgesia (pain killers) as would be provided to humans and post-operative care will be designed to minimise stress and suffering. Any animal found to be suffering outside the expected limits of this application will be humanely killed.

A retrospective assessment of refinement will be due by 10 December 2025

The PPL holder will be required to disclose:

With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand the blood cells that enter and populate various tissues (e.g. lung, pancreas, kidney, etc.). We seek to understand the pathways that control how many there are and the signalling that is necessary to get there and reside long term. Additionally, we seek to understand the function that tissue-resident cells may have in both homeostatic conditions that may be involved in development, maturation and ageing of various tissues and the involvement of these cells in disease onset, progression and resolution.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Intensive research over decades has given us a comprehensive understanding of the components of the immune system and their function in health and disease. However almost all of this research has taken place on circulatory cells or cells in secondary lymphoid tissues: blood cells or accessible tissues such as tonsils in humans, and blood, spleen or lymph nodes in mice. Arguably, however, the most important immune reactions are those that occur in the tissues: asthma, allergy, most autoimmune disorders, many autoinflammatory disorders, most infections and most cancers are diseases of the tissues. It is therefore critical that we start to understand what is different about the immunology of the tissues compared to the immunology of circulation: what controls homeostasis, what controls development, what are the kinetics, what are shared and distinct functions.

What outputs do you think you will see at the end of this project?

Key output of new information: a comprehensive understanding of the cellular and molecular basis of tissue lymphocyte biology, with regards to homeostasis (the number of cells in the population), development, migration and function.

Key output of new genetic tools: the generation of genetically modified mouse strains is to enable proliferation and apoptosis (cell death) quantification, tracing and modification of tissue-resident migratory populations, and tissue-selective expansion/deletion of lymphocyte subsets.

Key output of resources: we will create online resources for the major datasets generated through this study

Key output of publications: we will seek to publish all results from this study

Key output of patents: where recommended by our knowledge exchange and commercialisation team we will patent findings.

Key output of products: this project will develop immunomodulatory reagents that modify the immune context of specific organs. These products may have potential for clinical application.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Other Researchers:

Our work will create a unique resource of systematic transcriptomics and functional biology of tissue-resident lymphocytes. This resource, through both publication and the provision of online interactive datasets, will directly inform the research of other researchers. The work will identify candidate pathways for investigation in biomedical research, and in silico data mining resources to substitute for animal research. Moreover, researchers will be able to use the genetically altered mice that we generate and characterise.

Industry:

Tissue-specific immune modulation remains the key objective of many drug development programs. Targeting systemic pathways not only reduces efficacy when treating organ-specific disease, but it increases the chance of unwanted side-effects, from systemic immunosuppression to off-target inflammation. Tissue-specific targeting, by contrast, increases efficacy and reduces unwanted side-effects. By providing a functionally validated list of genetic and epigenetic pathways that can modulate immunity in a tissue-specific manner, and potentially pre-clinical drugs that work in this manner, we will e development of tissue-specific immune modulation in industry.

Patients and Clinicians:

We will continue to ensure that our research findings in mouse models are translated to the human immunology context. >50% of our research publications in the past 5 years have included data derived from human samples, ensuring, wherever possible, that our results are relevant cross-species and result in translational advances. REDACTED allowing us to directly work towards translating this pre-clinical research tool into clinical practice.

How will you maximise the outputs of your work?

We will publish all data and also create online data resources of the complete dataset. This will enable other researchers to access and mine our data for incidental findings that we did not identify. We will share our research tools, methods developed and datasets freely. We will patent findings when advised that this approach will increase uptake by industrial partners.

Species and numbers of animals expected to be used

- Mice: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In protocols 1-4, we will perform the injections and surgeries required to generate new mouse models. These surgeries are similar in nature to those involved in IVF, and while the surgery does result in discomfort, pathologies are generally avoided.

In protocols 5-8, we will breed and maintain mouse strains for experimentation. Protocols 5-6 will cover maintenance until one year of age, covering most mice used in this study. A small subset of mice will be aged out past 1 year, as some immunological processes change with age and this needs to be accounted for. Protocols 5 and 7 cover the maintenance of mouse strains where no or mild adverse effects are predicted. Protocols 6 and 8 cover the maintenance of mouse strains where a fraction of mice are expected to have adverse effects that are moderate.

In protocol 9, we will inject mice with substances to modify their immune system, using ex vivo analysis.

In protocol 10, we will create bone-marrow chimeras. This is a procedure very similar to bone-marrow transplantation in humans, and while it results in discomfort and some adverse effects, pathologies are generally avoided.

In protocols 11-13, pathologies will be induced. Protocol 11 involves giving mice an attenuated flu virus or a dead vaccine / synthetic immunogen. This results in some inflammation, similar in duration and severity to that of a patient receiving a vaccination. This procedure was selected due to the physiological relevance of flu vaccination to humans, as well as the highly-refined low-pathology nature of the protocol in comparison to other respiratory infection models. Protocol 12 will induce colitis, which is a pathology of the gastrointestinal tract. This will result in moderately severe discomfort for the mice, with diarrhoea and weight loss similar to a patient with Crohn's disease or ulcerative colitis, generally for a period of around a week. This procedure was selected as it is highly validated as a read-out for immune function, allowing us to reduce total mouse use. Protocol 13 will induce allergic asthma. This will result in moderately severe discomfort for the mice, with breathing difficulties similar to an asthmatic patient for several weeks. The model was selected as a non-infectious counterpart to the flu model (to determine whether there are differences in gene functions in infectious vs non-infectious inflammation) due to the highly-refined low-pathology nature of the protocol in comparison to other respiratory inflammation models.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The majority of mice in this project will experience no or minor adverse effects, similar to the transient pain and inflammation caused by an injection.

A minority of mice in this project will experience adverse effects that are rated as moderate. In most cases these are transient effects, with pain, weight-loss, discomfort or minor diarrhoea, similar to recovery from a standard surgical procedure and lasting several days. Other mice will have moderate adverse effects from disease induction, with exposure to attenuated influenza (similar to a human cold in severity), induction of colitis (similar to the human disease of colitis, with intermittent gastrointestinal discomfort over the course of around a week), and induction of allergic asthma (similar to human asthma, with intermittent restriction in lung function over the course of several weeks).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Total animals (mice) used: 59109

Total animals used (mild phenotype): 53438 (majority >80 will be due to tissue biopsy for identification purposes)

Total animals used (moderate phenotype): 4250

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immune responses are complex processes involving multiple cell types and interaction with the tissue microenvironment. When tissue-resident immunity is involved, further complexity is generated, with modifications to the system in primary lymphoid tissues, secondary lymphoid tissues, circulation and the tissues. To date, an in vitro model of such a complex system is not available, and it will not be possible to develop such a model until we have a full understanding of the in vivo context we seek to model. The complex interactions between different cells of the immune system cannot be modelled adequately in tissue culture or by computational methods. This is because immune cells are highly sensitive to the environment, responding to cellular, extra-cellular matrix and soluble mediator cues, which differ in minute but important ways between tissues, between locations within tissues and even temporally within the same tissue location. Furthermore, even the successful modelling of a single anatomical location (a scientific feat not yet possible) would negate the highly migratory nature of lymphocytes, which differentiation and activate in multiple tissues, linked by complex blood and lymphatic migratory

patterns. Ultimately, while we can model simple distinct processes in vitro, complex immune reactions need to be modelled in vivo.

What was your strategy for searching for non-animal alternatives?

We have considered the use of in silico modelling, cell line work, in vitro cultures, organoid systems and non-vertebrate animals.

Why were they not suitable?

For in silico modelling, there are no datasets currently available that cover the experimental designs needed. A key output of this project will be the generation of these datasets and in silico models. For cell line and in vitro culture work, the systems do not adequately recapitulate the complexities of immune regulation. Certain validation experiments can and will be performed in cell lines and in vitro, however the in vivo experiments described here cannot be performed with the same degree of scientific accuracy without an in vivo system. Organoid systems are showing increasingly interesting results at modelling single anatomical sites, however the study of immune responses in organoids is limited by the need for primary MHC-matched donor cells and the lack of normal vascularisation. Added to this is the multi-organ nature of the questions here being assessed. Non-vertebrate animals do not have adaptive immune responses and therefore cannot be used in this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice required for the generation of modified mouse strains are based on the standard operating procedures extensive experience and literature review. The numbers of mice required for the breeding and maintenance protocols is based on estimations of mouse strain numbers, experience at sustainable colony management practice and the frequency of required genotype combinations. The numbers of mice required for individual experiments are based on power calculations and statistical modelling. We input the known statistical properties (phenotype average and variation), decide upon the minimal effect size acceptable from the experiment from a biological perspective and hence calculate the appropriate group size. The number of experiments required within each protocol is based on the assumption of all go-no go decisions being positive and successful grant funding achieved.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The key steps taken to reduce the number of animals being used are: 1) use of controlled animal facilities to reduce biological and environmental variation, 2) use of optimised internal standard operating procedures to reduce technical variation, 3) consultation with a full-time mathematician embedded in our research group, 4) design of experiments to allow large-scale measurements from each individual mice (e.g., parallel assessment of lymphocytes inside every tissue per mouse, rather than running one experiment for the lung, one of the gut, etc), 5) design of multiplexing screening experiments, such as CrispR screening, where many candidate genes can be functionally tested in the same mouse.

What other measures apart from good experimental design will you use to minimise numbers?

Where possible we will share mouse strains rather than generate new strains. This bidirectional exchange will reduce net mouse use during mouse generation. Breeding strategies are designed to minimise the number of mice experiencing mild or moderate severity, e.g., by only bringing together harmful combinations of genetic modifications when required for experiments, rather than constantly maintaining the combination. We have a dedicated mathematician embedded in the group to generate mathematical models from the data that can guide future experiments with greater levels of precision. We will stock frozen stores of biological samples (bone-marrow, serum, tissue sections) so that certain experiments can be performed on previous samples rather than using new mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice are proposed as their immunological responses bear a high degree of similarity to that of humans. The genetic background and immunoreactivity of mice is very well characterised and there are a wealth of reagents and research tools available that are compatible with mice.

Suffering will be minimised by provision of analgesia where appropriate, provision of diet-gel food on cage floors should animals have difficulty accessing water due to mobility impairment, sub-cutaneous hydration if dehydration is apparent, housing in heat room/on heat pad if temperature drops significantly (e.g. following anaesthesia).

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The choice of species is limited by the fact that invertebrate species do not have an adaptive immune system that is comparable to humans. Mammals share key aspects of immune biology with humans, and have formed the basis of the modern immunological synthesis. Immune responses change markedly with age, and thus studying adult mice is the appropriate life stage. Terminal anaesthesia is used when experiments are of sufficiently short-term (minutes to hours) to allow for it, however when the immune processes to be study are in the range of days to weeks terminal anaesthesia is not feasible.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Given the impact on the well-being of the animals, this project has carefully selected protocols that are only mild or moderate, avoiding any studies classified as severe. Experimental pipelines work first through the protocols that are considered mild, with only high priority experiments being performed in the moderate models. For the moderate severity models, our work focuses on identifying the onset of pathology and key pathological stages, or delaying the onset of pathology or key pathological changes. As we are not studying the effects of chronic pathology or trying to treat chronic pathology we can avoid any prolonged (> weeks) adverse effects to mice. Additionally, input will be encouraged from animal technicians and NACWOs (Named Animal Care & Welfare Officer, responsible for overseeing the day-to-day husbandry, care and welfare of the protected animals held at their establishment) following studies to identify possible areas for refinement. Clinical score sheets linked to humane end points and cumulative severity limits will be developed in collaboration with REDACTED staff and put in place for all diseases models.

Administration of compounds is performed according to the route and dose that minimises toxic effects. All recovery and long-term non-recovery surgery will be done aseptically to HO Minimum Standards of Aseptic Surgery. Peri-operative and post-operative analgesia will be given when necessary using advice from the NACWO and NVS (Named Veterinary Surgeon, responsible for, monitors and provides advice on the health, welfare and treatment of animals). Choice of analgesic, duration and dose will be adjusted to the clinical signs observed taking into account possible impacts on the experimental plan.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All experiments which will integrate refinements from the NC3Rs (e.g., the ARRIVE guidelines), the LASA aseptic guidelines, LASA Diehl guidelines on volumes and frequency limits and the most up-to-date veterinary knowledge.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will actively stay updated with our field of research through collaboration, conference attendance and reading the literature. We will take particular note of any technical advances that enable reduction, refinement or replacement in our experimental design. The local mouse facility is also a key source of knowledge, transmitting the latest information on the 3Rs to researchers. Internal protocols are shared across the institute, enabling rapid uptake of any improvements to the method across groups.

Explain the choice of species and the related life stages

We are using mice because they are currently the best non-primate model for human immunology. The immune system comparison of mouse and humans shows strong parallels between cell types and functions, in both health and disease, although some details vary across the species. For any other mammalian species, the level of basic immunology knowledge is much lower, and an enormous amount of validation work would need to be run before the project could be initiated. Furthermore, many tools are already developed for mouse work, including optimised immunomodulatory drugs and processes for genetic modification.

NON-TECHNICAL SUMMARY

109. Maintenance of Genome Stability in Development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand the mechanisms which detect and repair damage to the DNA (that contains the instructions to make an organism) between generations. To understand how mutations are avoided or transmitted from one individual to its offspring and to understand the DNA repair mechanism that are specific to the cells responsible for heredity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Failure to repair DNA damage can either lead to cell death or to errors in the genetic instructions (known as mutations) that built cells and organisms. In this project we aim to gain insight into how DNA damage is detected and repaired accurately. In order to understand how damage and repair are affected by general processes such as metabolism or development we will use animals since none of these functions of the body can be recapitulated by cell cultures or in vitro methods. Ultimately we aim to understand how the genetic information is passed from one generation to the next with sufficient accuracy to sustain normal development, avoiding genetically transmitted disease and many childhood cancers.

What outputs do you think you will see at the end of this project?

- Results obtained from this work will be published in a timely manner
- We will define the DNA repair requirements necessary to make functional germ cells
- We provide new insight into when during germ cell development mutations arise
- We expect to identify new factors ensuring the quality control of germ cells
- We expect to elucidate which DNA repair pathways are responsible for tissue specific mutation

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

- Throughout project

  The results obtained will be communicated to other researchers at national and international conferences and in academic publications. The results of this project are likely to promote our understanding of how the genome of germ cells are maintained free from errors. This will include the identification of new components and new cellular targets.

- Long term

This project will increase our fundamental understanding of how genome evolution occurs. Mutations which arise in the genome adversely affect human health as this is the process by which genetic diseases arise. This is also important to improve our understanding of infertility as damage to the gametes is an important cause of infertility. In the long term understanding the sources and consequences of damage to the gametes may allow us to identify damaged gametes or devise interventions which may prevent damage to the gametes in the first place.

How will you maximise the outputs of your work?

Animal models generated in the licence will be made freely available to academic researchers.

Results will be published in a timely manner and made freely available following MRC guidance(Open Access).

Data sets generated from mutational analysis will be deposited in a public repository

Species and numbers of animals expected to be used

- Mice: 39875

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The vast majority of mice used in this licence (>90%) will not undergo any intervention. They will be used in breeding or killed and tissues obtained. This means that those animals will not suffer any harm due to the scientific procedure.

More, rarely mice will have interventions. Of those the majority will receive a single injection which in itself will cause transient pain. The mice are expected to make a full and uneventful recovery.

We may perform surgery on mice to allow us to put cells into the testis. These mice will have anaesthetic during the procedure and be give pain relief when then wake up. During the surgery an incision will be made in the scrotum and the needle placed into the testis. The wound will then either be glued or sown closed. Mice are expected to make a full recovery and not to experience any suffer when the wound is healed.

We may also use surgery to place a small pellet under the skin of the mice. This is to allow us to give the animal a drug. These mice will have anaesthetic during the procedure and be give pain relief when

then wake up. During the surgery an incision will be made in the skin. The wound will usually be glued closed. The mice will make a full recovery and will not suffer when the wound is healed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We will generate mice that lack the ability to repair damage to their DNA or cause damage to their DNA. These mice may have a predisposition to cancer. The best indicator of either of these diseases is weight loss – therefore mice with a genotype that predisposes to these diseases are identified early. We will carefully monitor those mice and cull them before they suffer any ill health when possible.

The new technology known as 'CRISPR-Cas9' provides us with a new way to generate mice that lack the ability to repair DNA damage. This means that we make alterations to the DNA of the mouse when it is one cell (straight after fertilization). We then use surgery to put that embryo into a female so that it can continue to develop and be born.

One of the methods we will use to generate mice will involve delivering foreign DNA into their liver cells. We will do this by injecting a solution (containing the foreign DNA) into their vein. In order for the DNA to get into the cells we must inject it in a large volume over a short period of time. This causes the mice to temporarily lose consciousness, however we anticipate that all mice that undergo this procedure will be under anaesthetic. The mice rapidly recover (5-30minutes) after which this procedure does not cause additional suffering of the mice.

We will perform bone marrow transplants and also transplantation of cells into the testes during this project. In order to achieve this we must prepare the recipients by conditioning – the same procedure is performed in humans before transplantation. As in the case of humans conditioning will involve giving mice chemotherapy (used in the treatment of human cancer) or exposing them to X-rays (used when treated certain cancers or autoimmune diseases). This may results in mice losing weight for up to 2-3 weeks before recovering. If mice do not recover then they will be culled before they suffer any additional ill health.

Finally, in order for us to really assess the repair of specific kinds of damage to the DNA of the germ cells it will be necessary to expose mice to known DNA damaging agents. Following this process we anticipate that approximately 70% of the mice may lose weight but they will be carefully monitored. Weight loss is a good indicator of the health of the animals. Animals that gradually lose weight will not be allowed to lose more than 20% of their body weight if other clinical signs are seen. If no other signs are seen animals may be monitored for a further 48hrs before they are killed only if their weight remains stable and no other signs develop.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of mice are not expected to suffer because of this project (>90%).

A small proportion of mice will develop cancer and those mice will lose weight before being killed.

Mice that undergo surgery will suffer from minor and transient discomfort.

Mice that receive conditioning for either bone marrow or testis stem cell transplants or that are given DNA damaging agents will lose weight lasting less than 3 weeks before beginning to put weight back on.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is very difficult to study the production of sperm and eggs in any system other than a whole organism. This is because sperm and eggs cannot divide to produce more sperm and eggs (since they only hold half of the amount of genetic information as all other cells). Non-animal models, whilst of huge promise, remain of restricted value.

We also want to see how these cells begin life in an embryo and this is not possible to achieve without using animals.

Mammals are the most appropriate model because the way in which they make their germ cells is distinct from other vertebrates. We are particularly interested in the mammalian germ cells as they go through the same set of processes as human germ cells.

What was your strategy for searching for non-animal alternatives?

We will perform initial experiments by growing these cells in a test tube. However, this has limitations as the process of maturing germ cells in a test tube is distinctly different than what happens in an organism.

Why were they not suitable?

The test tube germ cells do not undergo some processes that happen in a live animal. These processes can produce DNA damage, therefore we cannot always use this system to study the process of repair.

We can provide a first hand example of why they are not suitable. We employed our non-animal system to study the role of Ercc1 (a DNA repair factor) in embryonic germ cell development. The phenotype we observed in the non-animal system was very different from the results obtained in mice (the mouse phenotype is similar to what is found in human patients). Therefore, whilst 25% of my lab ties to develop non-animal systems these are not yet at a stage to replace the use of animals. The reason for this that this problem remains complicated. However, the advent of systems to study human germ cell development show enormous promise. It is my sincere hope that over the next decade we will vastly reduce our reliance upon animal models to study embryonic germ cell development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The vast majority of mice used in this project are required to generate new GA mice or combine mice will multiple alleles. As we work on fertility the maintenance of these mice is complex as they often cannot have young. Our experience over that last 12 years plays a significant part in estimating the numbers of mice that will be used in this project.

For many other aspects of this project the aim is to generate mutagenised DNA. As such the emphasis is on production rather than an in vivo experiment. The minimal numbers of mice are used in order to obtain that material. We have sufficient experience to know the efficiency of transplantation or hydrodynamic delivery to be able to use the minimal numbers of mice to successful obtained sufficient amounts of mutated DNA.

For individual experiments we do use power calculations to determine the numbers of mice needed. This can be challenging as we use embryos and so litter size (which is variable) complicates our calculations. In these occasions we need to make an estimate of the effect size. We determine this using a surrogate marker or by performing pilot studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experiments designed in this project are relatively simple. We have sufficient in house statistical knowledge to be able to plan those experiments. Typically we want to ask how many pregnant females are required in order to determine the frequency of primordial germ cells at developmental day E9.5. We either rely upon data from our in vitro assay or a pilot experiment to estimate the magnitude of reduction and to estimate the Mendelian frequency. We then use historic data of litter size at E9.5.

Together these data allow us to calculate how many pregnant females are required. Animals are retrospectively genotyped.

What other measures apart from good experimental design will you use to minimise numbers?

For conventional breeding we have a number of tools to ensure efficiency. These range from frequent reports of breeding efficiency to the use of conditional alleles to circumvent the sterility of certain mice.

The use of CRISPR-Cas9 technology provides us with the potential opportunity to reduce the number of mice used when generating new genetically altered mouse strains. Firstly, we can reduce the numbers of mice that undergo the superovulation procedure. Secondly, there is a reduction in the subsequent breeding. Finally, we can generate mice that have multiple genetic changes at the same time. To do this by breeding would involve multiple generations and the use of large number of mice.

We also aim to use a technique known as ‘hydrodynamic gene delivery’. This allows us to generate an experimental animal that can be used without the need for extensive breeding. This will result in us using fewer mice in order to conduct this specific kind of experiment. We may use inactivated viruses to help us delivery the right amount of DNA to the liver cells.

Finally, we will cryopreserve our strains. This prevents us needing to keep all of our mouse strains alive just to perpetuate the strain.

Refinement
