Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Many of the models used in this project lack the ability to fix damage to DNA (the blueprint of life). When possible we will maintain animals so that they have one working copy of the DNA repair factor. This means that we will only use mice that lack the DNA repair factor when we do the experiment.

Some DNA repair factors are important for life. However, we are only interested in studying what happens in germ cells (the cells that give rise to eggs and sperm). Therefore instead of working with mice that lack the DNA repair factor everywhere (and show signs of suffering) we will make lack the repair factor just in the germ cells. This allows us to study the process we are interested causing as little distress to the animals as possible.

Exposure to agents which cause damage to the genome cause suffering. We minimise this by using the lowest possible dose that still allows us to obtain useful information. We are guided by published

results and attempt at all times to minimise the suffering to the animal. An example of this is exposure to irradiation which we split between two doses to improve the outcome for the animals undergoing the procedure.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The majority of the animals that we use for experimental reasons will be used during embryonic development. This means that only embryos that lack the DNA repair factor will be generated. This means that we can reduce the number of adults born that lack the repair factor which may cause distress.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Many of the mouse models used will employ inducible constructs when possible. These mice should not display a phenotype until candidate gene expression or deletion is induced. This will allow us to study the effect of deletion in the germline without causing harmful non-germline phenotypes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We refer to the NC3R website as a great resource for ensuring that we are using the most refined experiments. In the case of surgical and tumour models we follow the current guidance and check the NC3R website to ensure that this is up to date. We also think with the ARRIVE and prepare guidelines when planning and also experiments to ensure that our experience can be communicated to other researchers (PREPARE: guidelines for planning animal research and testing. Smith AJ et al). Surgery will be performed to best practice as laid out in the LASA guidelines (http://lasa.co.uk/PDF/LASA_Guiding_Principles_Aseptic_Surgery_2010.2.pdf). When substance are administer or blood samples taken best practice will be followed as set out in A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Diehl et al.. When planning experiments we will refer to Norecopa (https://norecopa.no/) to identify guidelines, search for alternatives and ensure that we are following best practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Over the course of this project we will keep up to date with the latest advances in the 3R. Firstly, our named information officer provides us with regular emails outlining both interesting findings but also potential training opportunities.

Secondly, we have a close relationship the with animal technicians that provide daily care of the mice. The technicians regularly undertake formal courses (IAT) and attend international conferences. They therefore act as an invaluable source of information. They frequently trial new ideas to improve the welfare of animals in their care.

Finally, I have given talks at the local IAT meeting. This provides a useful forum to discuss our scientific aims in the context of animal welfare. This really provides a great forum to discuss the latest 3R best practice.

Explain the choice ofspecies and the related life stages

The mouse offers a useful system to study the reproductive system. Mammalian germ cells have a distinct life cycle from other vertebrates. Furthermore, mice are a genetic tractability system in which many resources to both study DNA repair and germ cell biology and development exist.

As we are interested in the life cycle of germ cells we will use animals at various stages of the life cycle to capture cells at those different stages.

NON-TECHNICAL SUMMARY

110. Mechanisms controlling immune cell killing

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand the molecular mechanisms controlling killer cells of the immune system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Killer cells of the immune system play a critical role in defending the body against cancer and viral infections. Understanding the mechanisms that control killing by these cells will improve the design of new immunotherapies.

What outputs do you think you will see at the end of this project?

We will provide new information on pathways that are required by killer cells of the immune system. We will publish our findings in peer-reviewed, open-access journals. Findings will be presented to the scientific community at conferences and to the wider lay-audience via outreach activities including videos available on the internet.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term the scientific community will benefit from new information about pathways required for killer cells of the immune system. Given the important role that killer cells now play in new immunotherapies the knowledge gained in this study should also improve cancer treatment.

How will you maximise the outputs of your work?

We will disseminate our research output via collaboration with other scientists, scientific publications, presentations at conferences and via public engagement.

Species and numbers of animals expected to be used

- Mice: 3400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

They will be killed using a schedule 1 procedure. These mice may also be used to generate new genetically altered lines, to cryopreserve these lines and to rederive existing lines into high health animal units.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Genetically modified animals used are not expected to exhibit any adverse effects. Animals are monitored every day and will be immediately killed by a Schedule 1 method if they exhibit any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

No adverse effects are expected.

What will happen to the animals at the end of the study?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The parallels between mouse and human are well understood and mice are known to provide excellent models of human disease. This allows us to study mutations that cannot be studied in man and generate results that are directly relevant to humans.

What was your strategy for searching for non-animal alternatives?

Human cell lines can sometimes be used as an alternative.

Why were they not suitable?

Very few human cell lines are available to study the function of the immune system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In the last year we have used just under 600 mice; thus we estimate we will use 3000 mice over the next 5 years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The use of mice expressing a single T cell receptor (T cell receptor defined mice) to activate killer cells permits the generation of 20 fold more cells per mouse. In this way the overall number of mice required is greatly reduced.

We also include a protocol for embryo derivation so that we can cross gene deleted mice to T cell receptor defined mice. This process means that fewer generations of mice have to be bred to achieve this cross, and hence reduces the number of mice required.

What other measures apart from good experimental design will you use to minimise numbers?

We have optimised culture conditions to generate and maintain killer cells in culture. We have also optimised gene deletion in cells in culture that should reduce the number of gene deletion mice required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use genetically modified mouse strains that do not develop any adverse effects.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice provide the best defined model of a vertebrate immune system. The parallels between mouse and human are well understood and mice provide excellent models for human disease. In this project we

only use animals to produce the cells required for experiments that we conduct in dishes in the laboratory. No animals are used in experiments, just their cells and tissues.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We continue to advance the use of improved in vitro cell culture, genetic manipulation and human cell lines as viable alternatives.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The department provides continually updated guidance on experimental refinements. Use of the website from the NC3Rs (https://www.nc3rs.org.uk) and LASA (Laboratory Animal Science Association) will also be made.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We constantly review methods for replacement, reduction and refinement provided by the scientific literature and our support team within the facility, attending workshops to stay up to date.

Explain the choice ofspecies and the related life stages

Adult mice are required to generate and preserve new genetically altered lines. Adult mice enable us to generate the greatest number of mature killer cells per mouse, and use fewer mice.

Home Office

NON-TECHNICAL SUMMARY

111. Mechanisms of gene and cell regulation by small RNAs in infection and inflammation

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand the way that cells in our body communicate to control infection and inflammation and to determine the molecules that they use to do this. We study one specific type of molecule, ribonucleic acid (RNA), which controls gene expression inside of cells and has recently been shown to be transmitted between cells. Our first aim is to identify the genes required for RNA transmission between cells and determine the role of RNA communication in terms of the ability of the immune system to mount a response to, and control, infection. We have also discovered that viruses and parasites produce their own RNAs during infection that can alter host gene expression and can be transmitted between cells. Our second aim is to determine how pathogens transmit their RNA to host cells and the importance of RNA transmission on pathogen survival in order to develop strategies to block this virulence mechanism.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This work fills in key gaps in our understanding of the molecules that pathogens use to establish chronic infections in animal hosts. This information is needed to advance new drug strategies to treat infection, in the face of mounting resistance of existing therapies. Our research will also build new understanding on how immune cells communicate with one another using RNA. Immune cell function and signaling are central to inflammatory and infectious diseases as well as cancer and our basic research could inform new disease therapy strategies.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Our studies use mice as a model organism and we expect to use up to approx 15,000 mice over the course of 5 years. These animals have specific gene modifications and the majority will be used in the breeding program to supply postmortem tissues for analysis. Approx 30% of the mice will be used for maintaining the Heligmosomoides polygyrus hookworm parasite model which can not be maintained in culture or for studying the immune responses during pathogen infection with maximum moderate severity. Approx 300 rats will be used over the course of 5 years: 200 for maintaining the hookworm model Nippostrongylus brasiliensis and 100 for antibody production.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The majority of animals are used in the breeding program or as donors of organs that are manipulated

ex vivo in the lab and have a “subthreshold” severity rating. A proportion of animals will be subject to procedures that are “mild” or “moderate” severity rating and experience only very mild, if any, forms of discomfort.

However we are trying to understand how the immune system controls infection and it is important to understand this with a diverse range of pathogens, some of which induce a degree of pathology. In the case of some bacterial and viral infections there may be moderate severity however we expect all mice to make a full recovery and less than 1% death. It is expected there will be moderate severity due to irradiation of mice in bone marrow chimera experiments however damage is mainly restricted to the hematopoietic and intestinal mucosa and mice are expected to make a full recovery. A small fraction of the immunisation experiments will use CFA which could lead to granuloma formation and ulceration however the incidence is expected to be low (1%) for the duration of the project. The mice will be humanely killed at the end of the experiment.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Our studies require us to examine the ability of the immune system to respond to pathogens and the ability of pathogens to survive in an animal host. The immune response is a highly complex process involving multiple cell types that work together and pathogens have evolved to utilize and control very specific niches inside their hosts. We can not study these all of these processes without an intact physiological immune system. Where ever possible we use cell culture systems to address specific research questions.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Our experiments are designed carefully to enable us to interpret results and draw conclusions with the minimal number of mice. We build on our previous work and consult statisticians to ensure this is the case. We continuously look for ways to reduce the number of animals used including new tissue culture models that simulate the cell composition and structure of body organs.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to

The mouse is the most appropriate animal species based on the extensive understanding of the immune system, the tools available to study immune signalling and the similarity of pathogenesis in infection models to those observed in humans. Mouse is the smallest laboratory animal species that can be used to model the interaction between a mammalian host and intestinal parasitic nematode. While the majority of our studies involve mice, a small number requires rats (for parasite infections and generation of antibodies, with minimal harm) as the most appropriate, or only, species for these studies.

NON-TECHNICAL SUMMARY

112. Mechanisms of heart regeneration in fish and mouse

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile
Oryzias latipes (Medaka)	adult, embryo, neonate, juvenile
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To better understand the role of metabolism, inflammation, scarring and the light/dark cycle during heart regeneration.

A retrospective assessment of these aims will be due by 08 October 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Coronary artery disease is the single most common cause of death in Europe, accounting for 1.8 million deaths in Europe each year. There are around 7.4 million people living with cardiovascular disease in the UK, more than twice as many people than with cancer and Alzheimer’s disease combined and causing more than a quarter (28 per cent) of all deaths in the UK. Blockage of one of the arteries supplying blood to the heart results in a lack of oxygen in the downstream heart muscle and subsequent death of the starved cells (heart attack). The dead heart muscle is replaced by fibrous scar tissue in those fortunate enough to survive the heart attack, providing a necessary solution in replacing necrotic muscle to close the ventricular wall. However, the non-contractile fibrous tissue will never be replaced by new heart muscle, and may cause severe contractile dysfunction, resulting in heart failure and even recurring myocardial infarction. The combination of improved treatments for cardiovascular disease, increased public awareness of the risk factors, and government strategies aimed at helping people live a healthy lifestyle, has reduced mortality rates, meaning that the number of people who survive a heart attack is steadily increasing. This impressive improvement in survival rate as well as the increasingly elderly population, however, also mean more people living with the long term effects of

reduced heart function and heart failure, costing the UK economy £9 billion per year, with this number steadily increasing every year.

Complete regeneration of the adult heart after injury is a feature exclusive to a limited number of species, including lower vertebrates such as the zebrafish and salamander. Injury to a zebrafish heart results in a spectacular scar-free regeneration process, with the wound tissue completely being replaced with new, functional cardiac muscle. If we can discover what fundamental mechanisms drive natural heart regeneration in fish, we can directly apply this knowledge to heal the human heart after injury. Differences in metabolism, inflammation, scarring and the light/dark cycle are thought to be important differences between animals that can regenerate their hearts and animals that cannot, but not much is known about how these processes regulate heart regeneration. If we can understand what is so unique about the fish heart that it can regenerate, we can apply this knowledge to find therapies to heal the mouse and human heart after a heart attack and during heart failure.

What outputs do you think you will see at the end of this project?

We will know more about the mechanisms underlying heart regeneration in fish and how we can use this knowledge to repair the mammalian heart after injury. We will have improved our understanding of what the difference is between heart muscle cells that can regenerate and ones that cannot, and how the immune response influences this process. Within the time frame of this licence, we aim to have identified >20 new genes that play an important role during heart regeneration and found drugs that target these genes. We will publish these results in scientific journals to help advance the field as a whole. For the most promising targets we will establish collaborations with spin out/farmaceutical companies soon after the licence as well as in the longer term.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The aim of this project is to better understand natural heart regeneration and to take our knowledge forward to induce heart repair in adult mouse hearts. During the time of this licence, this knowledge will be shared with the wider academic community, to be able to find collaborations that further drive the results forward. Our results will be shared at conferences and in papers, and discovery of new drug targets will be shared with spin out/farmaceutical companies as soon as possible, within the time frame of this licence or soon after wards, In the long term, the aim is to find therapies to help patients with heart attacks and heart failure.

How will you maximise the outputs of your work?

We will continue to collaborate locally, nationally and internationally to advance the project and to make the best use of expertise and animals. Initially with other research groups, followed by spin out/farmaceutical companies as soon as we have identified drug targets. We will present our work at national and international conferences to disseminate the new knowledge. We will publish both successful and unsuccesful approaches to help the research community and avoid duplication of work.

Genes identified from our fish experiments will be taken forward to the mammalian mouse model within the timeframe of this licence to be able to identify drug targets that work across species. Identified targets will be shared with the wider community, academic and industry, to, in the longer term, take these further to human patients.

Species and numbers of animals expected to be used

- Zebra fish: 10000
- Other fish: No answer provided
- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The typical experience for animals on this protocol, both fish and mice, is either breeding to produce offspring that can be used for surgery, or cardiac surgery followed by isolation of the heart for further analysis.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We are breeding GA animals, with GA that affect genes that have a cardiovascular function and could result in clinical symptoms. Most GA animals are expected to have no abnormal clinical signs due to the genetic modification, but the phenotypes of new GA animals are difficult to predict. We also perform cardiac surgery that has the risk of sudden death. The majority of sudden cardiac death will be during or immediately following surgery while the fish/mice are being monitored for recovery, with a small proportion suffering sudden death due to cardiac insufficiency which can't be predicted by clinical signs as with human patients, though increased monitoring used to mitigate. These animals will be closely monitored for signs of discomfort or distress, relating to cardiac insufficiency such as abnormal swimming activity, increased rate of respiration, and/or lack of reaction to the presence of food for fish and increased heart rate, breathlessness, inactivity and decreased feeding for mice. Any animal showing these signs will be humanely killed by schedule 1 method if these symptoms do not approve within the time frame carefully set for each species.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

- Sub-threshold: fish > 30%, mouse > 30%
- Mild: fish <10%, mouse <10%
- Moderate: fish <10%, mouse <10%
- Severe: fish <50%, mouse <50%

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 08 October 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The heart is a complex organ containing many cell types of which arguably the most important are the muscle
cells, responsible for the pumping function of the heart and the endothelial and smooth muscle cells, which
make up the blood vessels of the heart. Many of the experiments we propose will be carried out on isolated
pieces of cardiac tissue or cell cultures of heart muscle, blood vessel, and other heart cells studied in the
laboratory. However cells in a test tube or in a tissue culture dish cannot be used to study the complex changes occurring in the complete heart, nor how it functions in a living animal. Especially effect of the body immune response is important for heart regeneration, for both scarring and healing. This cannot be replicated in vitro. Equally, isolated cell
populations in tissue culture transform to adopt different functional characteristics, compared to the

equivalent
cells as they reside in the heart proper, which confounds any experiments to determine the effect of externally added
factors on heart injury and repair. Despite these caveats, we perform
experiments on cells, tissues or whole hearts (excised under anaesthesia) in vitro as an integral component of
the project to enable the testing the role of the targets during heart regeneration and find factors that potentially play a role in protecting the heart against periods of ischaemia and in repair/regeneration of the
heart after myocardial injury. While researchers have tried to regenerate hearts in vitro, heart regeneration is a unique process that only occurs within the body. Therefore, the only way to understand how heart regeneration occurs, is to study animals that can and cannot regenerate.

What was your strategy for searching for non-animal alternatives?

Whilst we do not understand the process well enough yet to use computer modelling of heart regeneration, we have created a large database of bioinformatics data on our models to be able to carefully select targets before any in vivo experiment. We collaborate with bioinformaticians to further combine our datasets with already published datsets to find the most promising candidates for further study. We use cell culture approaches to determine the effect of over expression/gene loss-of-function on
pathways to help establish mechanisms of action, before going to the in vivo models, but also alongside these experiments to help us understand the in vivo models better. We have considered culturing fish hearts in vitro to be able to study heart regeneration in more detail, but the hearts only regenerate within the body. We are setting up in vitro cell culture lines from fish cells, that will allow us to further test substances in vitro before taking the most promising candidates in vivo. This will also allow us to perform in vitro drug screens and replace animal work.

Why were they not suitable?

Our bioinformatics data sets help us to replace a large number of animals, and only test the most promising targets in vivo, but heart regeneration can not be modelled in vitro. Also the fish heart cannot regenerate in vitro. Cell culture approaches have been useful in determining cellular consequences and probing mechanisms of action and exploring therapeutic potential. However, in vitro cell-based assays cannot address the effect of our in vitro manipulations on disease initiation and progression or even regression following treatment with therapeutics.

A retrospective assessment of replacement will be due by 08 October 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animals numbers have been established based on power calculations and our experience with these experiments. We have made a prediction based on these calculations and the expected funding over the 5 years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To reduce the number of animals, we use the NC3Rs' Experimental Design Assistant during the experimental design as well as carefully select the targets of interest using our bioinformatics database. Besides using power calculations to use the correct number of animals, we also regularly discuss our experiments with a local statistician. For our sham and control experiments, wherever possible we use historic controls.

What other measures apart from good experimental design will you use to minimise numbers?

We have meetings with the group as well as with collaborating groups to discuss optimal experimental design. We sit down to plan the most effective breeding strategy, especially for inducible lines that require multiple crosses. For all new targets of interest, we will first do a pilot experiment to determine if it has a function during heart regeneration before further characterisation. To reduce numbers of animals, we analyse the hearts using sections, allowing us to test about 30 different genes per heart. When available, we obtain transgenic/mutant fish from stock centres around the world. As these are established lines we only obtain minimal numbers. To generate the lines ourselves would require much larger numbers. Over the years, we have performed sham and control experiments when needed, allowing us to build up a database with control samples. Therefore, wherever possible in our experiments we will use these historic controls.

A retrospective assessment of reduction will be due by 08 October 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use fish model because of their unique ability to regenerate their hearts. We use different fish species that have their specific value due to their ability to regenerate or scar. Only when we have found targets, pathways and cellular mechanisms that regulate heart regeneration in fish and are possible candidates to take further to test for therapeutic options, we will use the neonatal and adult mouse models for cardiac injury. The neonatal mouse is comparable to fish in that their hearts regenerate and will be used to test if the targets/mechanisms we have found to regulate heart regeneration in fish also regulate heart regeneration in mammals. The adult mouse is comparable to humans and will be used with the aim to try to change their response to a more neonatal mouse or fish-like response and improve their ability for heart regeneration. For the cardiac injury method, we and other groups have carefully optimised the method to cause the least pain and distress.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We will select targets after careful literature, database and in vitro selection and will the test the candidates of interest in the least sentient animal possible for this research, the fish, before going to the mouse model for the most promising candidates. While we can use fish to identify targets that are crucial for heart regeneration, we need to know if these targets also play a role in the mammalian (mouse) heart to know if we have found targets that could possibly used to design therapies to treat cardiovascular disease in patients.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The disease models in this licence are established in our laboratory and that of our collaborators. We have refined protocols in collaboration with other groups in REDACTED with whom we collaborate and who themselves use these techniques. For instance, it is now standard practice that recovery surgery is performed earlier in the day to allow sufficiently frequent monitoring within normal working hours. After

procedures, we will provide pain management and increase monitoring to be able to identify and treat welfare issues as soon as the appear.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the Code of Practice for the Housing and
Care ofAnimals Bred, Supplied
or Used for Scientific Purposes as well as keep up to date with literature on these techniques, which will allow us to immediately implement
any further refinements in our experimental protocols. For all procedures, the LASA guiding principles for preparing for and undertaking aseptic surgery will be
used.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We regularly check relevant websites, including NC3Rs, FRAME and Altweb, and NC3Rs newsletter for alternatives for the use of animals in research. We always attend the departmental animal welfare meeting for further updates on alternatives from within the community. Any alternative that we identify that is relevant for our work is discussed in our group and implemented if possible.

Explain the choice ofspecies and the related life stages

We will use the adult zebrafish and Astyanax mexicanus surface fish because of their unique ability to regenerate their hearts. Medaka and Astyanax mexicanus cavefish cannot regenerate theirs hearts. Directly comparing heart regeneration versus scarring between fish, especially within the same species, allows to focus on the mechanisms underlying these processes. Using different species that can or cannot regenerate will allow us to find the overarching mechanisms that is similar between the different species. We also use neonatal mice because of their unique ability to regenerate their hearts. What we learn from these models will then be tested in adult mice, that are chosen for their inability to regenerate.

A retrospective assessment of refinement will be due by 08 October 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

113. Mechanisms of Myelination and Ion Channel Distribution

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To gain an understanding of the development and function of our nervous system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The communication between our sense organs, such as our eyes or skin, and our brain and spinal cord occurs through electrical signals that are carried by our nerves. Nerves are composed of bundles of neuronal extensions called axons. Axons conduct these signals through the regulated flux of sodium and potassium ions over the axonal membrane through specific channels. Many of the axons in our nerves are insulated by a fatty layer called myelin, which is made and maintained by support cells called Schwann cells and oligodendrocytes. The myelin layer speeds up nerve signalling enormously, allowing us to respond rapidly and with great accuracy to any physical challenge coming our way. The way myelin speeds up signal conduction is by clustering different sodium and potassium ion channels to high density at regularly spaced regions along the axon.

The importance of this arrangement and density of ion channels becomes apparent when the integrity of the myelin layer is damaged as in multiple sclerosis, Charcot Marie Tooth disease or in diabetes, which alters or even block conductance. But how these ion channels are arranged and kept in specific regions is largely unknown.
Understanding how these channels are distributed will aid the development of strategies to harness the nervous systems capacity for repair in demyelinating neurological diseases.

What outputs do you think you will see at the end of this project?

In the coming years we hope to gain a deeper understanding of how the insulating myelin sheath around axons in our brain and nerves is made and maintained and how this sheath contributes to the electric properties of the axon. This understanding is important as it opens new avenues for clinical treatment of the many devastating neurological diseases in which the function of the myelin sheath is compromised or even destroyed. We will publish our findings in peer reviewed scientific journals. The project will provide training for graduate students and results will be incorporated into the teaching to students at different levels.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

short/intermediate term:

Development of *in vivo* biotinylation technology will be benefit other scientists interested in identifying protein interactions that underpin functional outcomes.

Our GA modified animals are of interest to other scientists and we have distributed our animals to many laboratories, either directly or through the Jackson lab.

Training for postgraduate students.

Longer term
:

Generation of new knowledge of Kv1 biology and function. This will benefit researchers and clinicians working on immune mediated encephalopathies involving Kv1 channels.

This research project is of strategic importance and close interactions with other research groups with an interest in myelin and myelin-related diseases ensures that our work contributes directly to the capacity and capability of this larger research community.

Our studies will have a wider resonance as it will impact our understanding of myelin and axonal function in, for example, the hippocampus and cerebellum of the adult and aging nervous system. As such this work is of direct relevance to scientists working on other aspects of neuronal biology.

How will you maximise the outputs of your work?

Dissemination of new knowledge through publication in peer-reviewed open access journals, seminars, conference attendance and poster presentations.

Species and numbers of animals expected to be used

- Mice: 5200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The genetic alteration in these mice allow us to study the function of these genes in the development and function of mice by taken out nerve tissue and analyse alterations in its shape and composition. For this the animal will first be culled by an approved method. Additionally, we can study the effect of gene alterations on the behaviour of the animal such as the way it moves, grabs objects and explores it environment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We don't expect an adverse impact on the general health and behaviour of the animal apart from a number of situations where we model a human clinical disease such altered motor behaviour or seizures. In these cases the animals will be culled well before the impact on the animal becomes severe.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of animals used in this study will not experience any adverse effects during their lifetime. Around 10% of animals will experience mild discomfort as they receive drugs, administered orally or through inection. A small number of animals that model human disease will experience some adverse clinical effects. This is a small number (<5%) and we are actively working to replace these animals with animals that have genes deleted only in a subset of neurons and glia cells.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The development, function and response to trauma of the nervous system of vertebrates including mice and man cannot be fully studied in a petri-dish or with computer models. Mice have a sufficiently evolved nervous system to readily compare to humans. Thus general principle we learn from our animal work will guide work on humans. To learn how the genes we study here affect the function of the nervous system and how it affect posture and movement we will have to this in mice. Cell culture models are intimately integrated in the current programme but still require the breeding of genetically altered mice and the isolation of neurons and Schwann cells from mice and rats (Schwann cells).

What was your strategy for searching for non-animal alternatives?

The development of Schwann cells and neurons from cultured cells is in its infancy and promising results have been achieved, However, in its current state this approach does not provide a viable alternative for animal based research.

Why were they not suitable?

The method is limited in that it is unreliable, takes very long, is very expensive and can only address interactions between glia and neurons. When this method further matures it will contribute to the further refinement and reduction of the use of animals. These alternative methods would not allow us to address the physiological and behavioural role of these genes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on historic use and power calculations. These studies require a large number of different genetic mutants and most of the mice will be used for breeding to maintain stock

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experiments are carefully planned and controlled so that only the minimum numbers of genetically altered animals are maintained in the breeding colony. Colony size for each mouse line is routinely discusses and kept at a minimum. When we know the strength of the effect of a genetic alteration we can quatify this and perform calculations to estimate the minimum numbers of animals we need to use in an experiment to obtain reliable results

What other measures apart from good experimental design will you use to minimise numbers?

REDACTED that will not be used within a 12 month period will be terminated. All REDACTED will be preserved by freezing sperm samples so that lines can be revived through in vitro fertilisation at a later date.

We will use male germ line specific Cre recombination to generate null alleles for Adam22, Adam23 and Lgi4 sperm. Homozygous embryos and postnatal animals can be obtained with a higer frequency (50% versus 25%) from crosses with a heterozygous female, reducing the number of animals significantly

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice have a well-developed nervous system that resembles that of humans in all key aspects studied. The ability to modify the genome of the mouse at will and the availability of functional assays make the mouse the species of choice to model human disease states relevant to the objectives of this programme. We are using, where possible, genetic methods that will only affect a limited group of cells in the nerves and brains so that we limit or even completely eliminate distress in our animals.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We are using embryonic tissues and neonatal animals to address some of our questions but posture and movement of the animal can only be studied in adult animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We use specific genetic techniques to minimise welfare costs for the individual animal and have defined clear endpoints to ensure that no animal will experience adverse effects beyond moderate. Animals subjected to experimental procedures will be closely monitored and humane endpoints applied. We will follow good practice suggestions by the nc3Rs, such as the single use of syringes

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

ARRIVE and the Nc3Rs website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will be notified of advances in the 3Rs through regular email updates from the National Centre for the replacement, reduction and refinement of animals in research and through the Crack It website. Further information is obtained through the scientific literature.

Explain the choice ofspecies and the related life stages

The development and function of the nervous system of vertebrates including mice and man cannot be fully studied in a petri-dish or with computer models. Mice have a sufficiently evolved nervous system to readily compare to humans. Thus, the mouse is ideal to study developmental and functional aspects of the nervous system that is of direct relevance to our understanding of human nervous system development and function in health and disease. We are particularly interested in how the genes under study affect our peripheral nerves and general motor behaviour.

NON-TECHNICAL SUMMARY

114. Mechanisms regulating local and distal immune responses in barrier site health and inflammation

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

immunology, infection, gut, mouth, lung, mucosal, inflammation

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project is to define critical pathways that control local and long-distance immune responses when we are healthy and when we have inflammation of the places where our bodies meet the outside world (termed barrier surfaces). We will particularly focus on the gut and mouth barrier surfaces.

Currently, the mechanisms by which immune responses are controlled in health and inflammation at the barrier surfaces of the gut and mouth are incompletely understood. We also aim to understand how inflammation of one organ, such as the mouth can lead to inflammation in another organ such as a joint. Better understanding could lead to improved treatment of patients with inflammatory diseases such as inflammatory bowel diseases (IBD), rheumatoid arthritis (RA) and gum disease.

The overall aims of this project, therefore, are to understand the factors that control establishment of immune cell populations at barrier sites, such as the gut and the mouth, in health and, subsequently, how following infection or inflammation they provide protection and eventually healing.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Using our new-found knowledge of barrier immunity, we hope to inform development of novel therapies to: (i) prevent, or improve outcome in, infectious diseases that target barrier sites such as worm infection; and (ii) treat the plethora of inflammatory diseases that affect barrier sites such as inflammatory bowel diseases (IBD) or periodontitis. These findings are also likely to be relevant to animal health as the mechanisms we define are likely to be ubiquitous between many species.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice are the only species to be studied, 7000 will be used in total over a five-year period. We anticipate using approximately 5350 mice for experiments, 800 untreated but genetically altered mice for investigating immune cells isolated from these mice and an additional 500 mice as breeders to generate the mice used on this license.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Over half of the experimental animals will undergo infections, or treatments, that will lead to mild generalised discomfort. A typical example of a mild severity experiment would be general discomfort following infection with natural parasites of mice, followed by transient irritation during an injection or immunisation aimed at treating the parasite infection. In some models of human disease used on this license, including colitis, periodontitis and arthritis, the animals may experience discomfort at the site of inflammation. For example, in colitis this would be the large intestine or in periodontitis the gums. Animals in which these types of inflammation will be induced will account for about 30% of mice used on the license. Every effort will be made to limit this discomfort to the shortest time possible and to administer painkillers to alleviate discomfort. In a very small number of animals (<1%), discomfort may become more pronounced in which case the animal will be immediately and humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The body's immune system operates as a co-ordinated response involving multiple cells and molecules at a variety of body sites that at present cannot be accurately modelled solely by using cell culture systems or computational approaches. In particular, the relationships between inflammation in one organ (e.g. the gums) and its effects on another (e.g. the arthritic joint), currently, cannot be reliably established outside of animal models. Where possible we already utilise tissue culture systems to inform our animal experiments. Over the course of the experiments, knowledge from the animal models will be utilised to better refine new tissue culture approached to complement and replace animal studies wherever possible.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use appropriate statistical expertise to ensure that we design experiments using the minimum numbers of animals required to generate meaningful results. All experiments will be designed to the highest possible standards to ensure reproducibility and limit unappreciated experimental bias. For example, blinding of researchers to treatment groups. We maximise the information gained from each individual animal through the use of the most advanced technologies enabling extensive analysis of small numbers of immune cells.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

In order to understand the mammalian immune system, we use the mouse as a model system as it is the best understood animal in terms of how the immune systems works and has remarkable similarity to

other mammals, including humans. The mouse system also provides us with many tools to precisely define immune responses, thus ensuring that the precise mechanisms that underlie inflammation can be well-established. The specific infection and inflammation models used have been carefully selected to ensure that relevant features of human disease processes are recapitulated and that maximal information can be obtained with the minimal harm to the animal. Key general measures of limiting harm to the animal include: (i) daily monitoring of experimental animals using carefully designed criteria to ensure animals are not experiencing unexpected discomfort; (ii) use of painkillers, where possible, to alleviate discomfort; (iii) utilisation of experimental approaches that result in mild generalised discomfort in preference to local inflammation, where information gained is not impacted (e.g. infection with parasites rather than utilising the colitis model); (iv) limiting discomfort to the minimum time necessary to obtain relevant and usable information; and (v) immediate and humane killing of animals experiencing pronounced discomfort.

NON-TECHNICAL SUMMARY

116. Mechanisms underlying atherosclerosis

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Atherosclerosis is the process by which arteries become progressively narrowed by fatty deposits in their walls. It is the principal cause of coronary heart disease and stroke. Recent evidence suggests that

inflammation of the arterial wall is an important contributor to atherosclerosis, but the specific mechanisms underlying this remain unknown. This project will identify the specific inflammatory pathways contributing to atherosclerosis, as well as novel treatments targeting this which may subsequently be tested in the clinic in patients with atherosclerosis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project will increase our understanding by which atherosclerosis develops; and will also provide novel therapeutic targets which may in the future be exploited to decrease the burden of cardiovascular disease in humans.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will be using 9,000 mice, of which 4,000 will be used for breeding and the remaining 5,000 will be used in experimental studies, over a 5 year period.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Animals will be fed a high-fat diet, which will cause the development of atherosclerosis in their arteries. This is necessary, since the project is aimed at elucidating the mechanisms that underlie atherosclerosis and how these mechanisms may be modified to prevent the progression of this condition. It is expected that no animal will suffer harm or welfare issues as a result of high fat feeding.

Some animals will receive drugs in order to assess their effects on atherosclerosis progression. Such drugs may cause adverse effects: for example, anti-platelet drugs such as aspirin will be used, which may predispose to increased bleeding; or antibodies may be used, which can rarely cause allergic reactions. In most cases we expect animals to not feel unwell as a result of receiving such drugs; but in all cases, the animals will be closely monitored for expected side effects of the drugs used, as well as for any more general welfare issues or for any signs of suffering. At the end of an experimental procedure or if it becomes necessary to alleviate suffering at any time then animals will be humanely killed.

Some animals may undergo surgery to remove their sex organs (ovaries or testicles), to examine the effects of sex hormones on atherosclerosis progression. Some animals may undergo surgery to insert slow release pellets of certain drugs or pumps placed under the skin that will slowly release drugs over time. None of these procedures is expected to result in any welfare issues or suffering in themselves. However, with all surgery, animals will experience a little discomfort similar to that experienced by patients postoperatively, but this will be controlled by use of pain relief before, during and after surgery. Again, at the end of an experimental procedure or if it becomes necessary to alleviate suffering at any time then animals will be humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We are interested in understanding the mechanisms that give rise to the physiological changes in the arterial wall during inflammation. Whilst we can study individual cell types in culture, there is currently no lab technique not involving animals that can replicate the physiological changes in the way that atherosclerosis develops in living animals and humans. Where possible we do undertake experiments using human cells in culture.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We are committed to maximising the amount of experimental information we obtain from each individual experimental animal, enabling us to hopefully minimise usage yet at the same time without subjecting any animal to increased associated harms. In some cases, we will perform imaging of animals on a number of occasions during their lifetime, which will enable multiple data sets to be collected in the same animal, and the data thus collected over their lifetime will then be linked to post mortem tissue findings within the individual animal at the end of the study. Such data collected from each animal is more robust scientifically as it comes from the same animal at different time points, and gives a better overall picture from the data perspective than data sets from different animals. Collecting data at multiple time points in the same animal reduces animal use, as the alternative would be to cull a number of different animals at individual time points to collect that data.

We will use good experimental design practice, where the number of animals can be calculated for each experiment (using appropriate statistical techniques and power calculation) . We will use single strains of mouse in our research and use multiple organs from the same mouse in order to keep animal usage down. We will also try to minimise the amount mice we breed in our research.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare

costs (harms) to the animals.

We are using mice as they have an immune system comparable in complexity to humans and are the most frequently used model for the human immune system. The apo E knockout mouse in particular is a widely used genetically altered animal model, that is a well validated and accepted model of atherosclerosis. We are mindful at all times to minimise welfare costs to the animals we use. All of our protocols are designed to minimise any welfare costs, and in the event that adverse welfare is unavoidable animals are monitored closely and welfare endpoints are rigorously applied, so that animal suffering is kept to a minimum. For example, it is well established that apo E knockout mice can develop a skin condition known as ulcerative dermatitis, which can result in the animal feeling itchy and damaging their skin through scratching, and we will monitor our mice closely for this and treat promptly and vigorously; but if there is any sign of deterioration or suffering despite such treatment, those animals will be humanely killed without delay.

NON-TECHNICAL SUMMARY

117. Mechanistic insight into, and assessment of novel therapies for, preeclampsia and fetal growth restriction

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, neonate, juvenile, embryo
Rats	adult, pregnant, embryo, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

In rodent models ofpregnancy complications to:

- improve understanding of the mechanisms underpinning preeclampsia, a maternal syndrome characterised by maternal high blood pressure and worsening kidney function, and fetal growth restriction, the poor growth of a baby, with a specific focus upon the placenta and maternal/fetal blood vessel function.

- assess the effectiveness of a number of candidate therapeutics at improving short and long-term outcomes for both the dam and offspring.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Poor function of the placenta can result in a number of complications for mum and baby. These include preeclampsia (PE), a maternal syndrome characterised by high blood pressure and poor kidney function, and fetal growth restriction (FGR), a baby that does not grow as well as it should do. Together, PE and FGR affect around 10% of all pregnancies and increase the risk of stillbirth. Additionally, both PE and FGR place mum and baby respectively at increased risk of heart disease and other adulthood diseases such as diabetes as they get older. Despite the importance of PE and FGR, there are no current therapies to treat them. The major reasons for this are (i) we do not fully understand the reasons why poor placental development and function occurs in some pregnancies and (ii) drug companies are reluctant to invest significant money into designing drugs for use in pregnancy given the additional risks of treating both mum and baby and especially the risks of harming the baby. As such, studies that identify the reasons why some placentas function poorly in pregnancy are key to improving understanding of PE/FGR and to identify new drug targets. There is also a need to test both new and existing drugs/therapies, especially those that we know are safe in pregnancy, in appropriate animal models of PE/FGR to see if they have the potential to be used in women.

What outputs do you think you will see at the end of this project?

There will be several expected key outputs following the end of this project. New information on placental and blood vessel function in preeclampsia and fetal growth restriction will be disseminated via research publications and research conferences, both within our immediate field and to more general physiology/scientific audiences. These studies will also generate important preclinical data and identify new candidate treatments for testing in clinical trials. If successful, these approaches may improve the future health of mothers and their babies after a pregnancy complicated by PE or FGR. Our group, together with our obstetric colleagues with whom we work closely alongside, has a proven track-record of taking data obtained in animal models and advancing this knowledge to clinical trials.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short-term, data from this project will likely benefit a number of groups. Scientists and clinicians in the reproductive and physiological fields will benefit directly from knowledge gained in these studies that help to shed light on mechanisms underpinning poor pregnancy outcomes in high-risk groups, such as women with advanced maternal age or women with obesity. Obstetricians caring for these women will also benefit from this knowledge as it will help to inform future clinical care in these groups of patients. Importantly, pregnant women are also likely to benefit from this work, both in terms of improved management of higher-risk pregnancies and in cases where preeclampsia and/or fetal growth restriction has been detected. In the longer-term, towards the end or after the completion of the work outlined in this project, patients and obstetricians are likely to directly benefit from new treatment options for preeclampsia and/or fetal growth restriction.

How will you maximise the outputs of your work?

We will report findings in reputable scientific journals, both within the field of reproduction and in more generalised scientific journals, ensuring maximum scope. We will also communicate findings at scientific meetings attended by scientists, obstetricians and midwives. We will continually build upon and seek out new collaborators who are able to help us to better understand the reasons why placental function is poor in some pregnancies and not in others, and use this knowledge to identify new treatment options for preeclampsia and fetal growth restriction. When studies do not work as planned or treatments do not improve pregnancy outcomes, we will also report this data as this is also key information for scientists, obstetricians and patients to know. We regularly engage with our patient information panel who help to shape the direction of our research and we will continue to seek their advice and communicate findings to them and also the general public via regular community education and outreach events.

Species and numbers of animals expected to be used

- Mice: 6300
- Rats: 1700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, animals in this project will either be used to inform us about maternal cardiovascular health (e.g. blood pressure, cardiac function, blood vessel function) and placental function in health and disease (preeclampsia and fetal growth restriction) or to assess the effectiveness of candidate treatments at improving short and long-term outcomes for mum and baby. Animal models used will demonstrate aspects of preeclampsia and/or fetal growth restriction; examples include mice of advanced maternal age, obese mice, mice exposed to a low oxygen environment (to mimic what happens in some cases of fetal growth restriction) and rats infused with substances to simulate what is observed in preeclamptic human pregnancies.

For our obese model, mice will be fed a high fat diet for several weeks before, and during, pregnancy. To study the effects of advanced maternal age, female mice will be aged to approximately 9 months of age before mating. For mice in a low oxygen environment, mice will be housed in their normal cages but also within a chamber which allows us to reduce oxygen levels (for the majority of the duration of pregnancy) similar to what is experienced when living at high altitude. For our rat model of preeclampsia, rats will undergo a short surgical procedure in mid-pregnancy to implant a device under the skin to administer a substance over several days, resulting in increased maternal blood pressure.

In these models, we will assess cardiovascular health (of dams and their offspring) and placental function (e.g. transfer of nutrients from mum to fetus). This may include measuring blood pressure up to three times during the pregnancy, which requires restraint of mice. Additionally, a small subset of animals will undergo anaesthesia to allow us to perform assessments of blood flow to/from the placenta using ultrasound (non-invasive) and a further sub-set of animals will be required to have blood pressure assessed under terminal anaesthesia near the end of pregnancy.

In sub-sets of animals, we will administer treatments we feel have the potential to improve outcomes for mum and infants (e.g. reducing maternal blood pressure, improving fetal growth). The majority of these treatments can be given via drinking water or the diet but in some instances, animals may undergo injections under the skin or into a vein for several consecutive days or undergo a short surgical procedure to implant a device under the skin to administer the drug over several days. As above, we will measure blood pressure up to three times during the pregnancy which requires restraint of the animal and a small subset of animals will undergo anaesthesia to allow us to perform assessments of blood flow to/from the placenta using ultrasound (non-invasive) and a further sub-set of animals will be required to have blood pressure assessed under terminal anaesthesia near the end of pregnancy. In the rat model of preeclampsia, we also wish to monitor long-term health of the previously pregnant animal, including those that will be treated with blood-pressure lowering drugs immediately after the end of pregnancy (via drinking water). This will involve drug treatment via drinking water and assessments of heart and blood vessel function by ultrasound under general anaesthesia. For some animals who are treated during their pregnancy, we will allow the pregnant female to litter down as normal and then perform assessment of blood pressure and early indicators of diabetes (by measuring how well the animal handles a glucose (sugar) challenge) in offspring on up to 2 occasions, a few weeks apart. This

will involve restraint of mice in order to measure blood pressure and a single injection into the abdomen (for glucose studies) followed by blood sampling of the tail vein (a single needlestick).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The animal models chosen in this project will demonstrate aspects of preeclampsia and/or fetal growth restriction. Aside from these clinical signs, we do not expect any of these models to demonstrate serious adverse effects or abnormal behaviour. The majority of treatments will be via drinking water and/or diet and we do not expect any adverse effects of this dosing strategy. When we need to perform injections, these will result in momentary discomfort/pain but no lasting effects. Our surgical procedures are limited to insertion of a device under the skin to delivery substances (e.g. drugs) which will be performed under general anaesthesia. We expect animals to demonstrate normal behaviour within a day of this procedure but may demonstrate mild pain/discomfort which will be controlled via painkillers. When we measure blood pressure in mice, this will involve restraint of the animal. This will provide a brief discomfort but is unlikely to cause long-lasting harm/stress. Assessment of glucose tolerance involves a single injection and needlestick into the tail vein, again providing a brief discomfort but is unlikely to cause long-lasting harm/stress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals in this project will reach a threshold of no more than mild severity, as determined by interventions/procedures that cause only a transient, mild discomfort and no long-lasting harm. Where there is a need for repeat procedures e.g. measurement of blood pressure under restraint and an assessment of glucose tolerance, blood flow via ultrasound, this may move to a moderate severity. For animals undergoing general anaesthesia (including more than once), the duration/nature of the recovery may be such that it reaches a moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

One of the reasons why so little progress has been made in developing drugs for pregnancy diseases is that clinical trials testing treatments in pregnant women are very difficult and ethically challenging. Thus, in order to assess the effectiveness of potential therapeutics for use in pregnancy, the use of animals is a necessary step in the translational pipeline.

What was your strategy for searching for non-animal alternatives?

We always run experiments using human placental tissues and maternal tissue biopsies (e.g. omental tissues derived from caesarean section deliveries) in the laboratory alongside animal experiments as a first step in determining effectiveness of candidate therapies in women. Additionally, by performing studies on placentas/blood vessels from cases of FGR/PE, we can gain insight into vascular and placental function. Computer modelling, particularly for nutrient transport processes, is currently inadequate for our needs.

Why were they not suitable?

Experiments using human placenta cannot inform us of any general beneficial or harmful effects to mother and fetus or their function when a blood supply is intact. Additionally, performing measures of placental function at different points of gestation are highly informative; this is currently not possible in women when studies on placenta are only possible after delivery of the baby/placenta at the end of pregnancy. Computer modelling of the pregnant woman remains some distance from realisation with our present state of knowledge.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For the studies described in this project, we have performed power calculations to inform us of the minimum number of animals required to produce an effect that is biologically/clinically relevant. Experiments are designed to compare disease effects i.e. normal versus complicated (e.g. FGR/PE) pregnancies and/or to assess the effects of treatment (treatment versus a control group). These calculations are largely based upon data from our own research group (from studies similar to those described herein). Where no previous data is available, we will carry out pilot studies to base future power calculations upon.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

During planning for this project, we have had regular meetings with local statisticians and the experimental plan/power calculations have been performed in agreement with both parties. We have

also consulted the NC3R's experimental design assistant to aid with planning and to inform our discussions with statisticians.

What other measures apart from good experimental design will you use to minimise numbers?

We have several years experience of these types of experiments and will utilise this experience to enable efficient breeding regimes. We will keep the number of animals to a minimum by making as many observations/measurements as possible on individual animals (also aided by the fact that each litter comprises multiple pups) and by removing as many tissues as appropriate for later analyses. This ensures that from one pregnant animal, we can obtain multiple datasets. In addition, we will allow other researchers to share tissue from animals used in this study where possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The models described in this licence represent well characterised models of PE and/or FGR without significant adverse effects i.e. that do not cause significant pain/suffering or a change in behaviour of the animal but do show the clinical signs we require. When treatments are administered, we will prioritise the diet or drinking water as preferred routes which represent the least invasive methods. Only if this is not possible, will injections or insertion of minipumps underneath the skin be employed.

For invasive procedures (e.g. insertion of minipumps under the skin), anaesthesia will be used alongside careful monitoring of the animals to ensure they are not in discomfort, using painkillers as necessary during and after procedures to minimise pain.

Whilst we do not expect any adverse reactions from our candidate therapeutics, the use of treatments directly targeted to the placenta will potentially further limit any off-target effects.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

As we require knowledge on placental function a mammalian species is essential for our work. Mice and rats have a uterus and placenta similar to that in women and also allow us to study genetically modified strains, as well as those with dietary/environmental modifications, that have aetiologies or disease symptoms similar to those found in human PE/FGR. Such accurate disease models are not available in less sentient species. The models of PE and FGR described within this licence largely

represent established animal models in which to assess placental/vascular function and in which to test candidate therapeutics. In order to assess candidate therapies, we require animals to be treated for several days, generally via the diet/drinking water, that does not cause lasting harm or serious adverse effects. Terminal anaesthesia is not appropriate for the majority of studies described in this licence, but is used when the most information can be gained from an invasive procedure (e.g. placental nutrient transport).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

When animals are on treatment protocols, we will ensure they are assessed daily by researchers and that all staff involved in husbandry are fully aware of the need for additional monitoring of these animals. For new treatments, we will monitor animals more regularly to ensure there are no unexpected adverse effects. When general anaesthesia and surgery is required (e.g. insertion of minipumps underneath the skin) we will ensure that anaesthesia is at an appropriate depth for the animal to feel no pain and administer painkillers during/after the procedure to ensure any potential harm is minimised. These animals will be closely monitored until they are fully recovered from anaesthesia and thereafter. When restraint is required (e.g. measurement of blood pressure in conscious animals) we will ensure animals are appropriately trained beforehand to become used to the restraint device and thus reduce stress during procedures; this will also lead to less variable data meaning we can use less animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will continually remain updated with the latest findings of the NC3R's including the continued use of the experimental design assistant (EDA) and ensure statistical advice is provided throughout the course of the project. When published alternative models or approaches are available which represent an improvement upon current practices, we will perform studies (including pilot studies) to confirm their effectiveness and ensure that all users are fully trained and adopt these approaches if they are deemed an improvement on previous practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will regularly consult the NC3R's website and engage fully with the regional programme manager of the NC3R's to ensure we are kept informed of latest developments and opportunities to implement new alternatives/refinements; an example of this is our commitment to the recent drive by the NC3R's to avoid picking the mice up by the base of the tail, even for brief periods, which has been shown to increase levels of anxiety/stress. In addition, we will keep up to date with relevant literature within the field including attendance at research conferences in order to make continued assessments about whether there are further ways to refine our experiments and/or reduce/replace the animals we use. When alternative models or approaches are available which represent an improvement upon current practices, we will perform studies (including pilot studies) to confirm their effectiveness and ensure that all users are fully trained and adopt these approaches.

Explain the choice ofspecies and the related life stages

Our work focuses upon complications of pregnancy such as preeclampsia, characterised by maternal high blood pressure and deterioration in kidney function, and fetal growth restriction, a baby that does not grow as well as it should. These outcomes increase the risk of poor short and long-term health for both mum and baby. Poor function of the placenta is key to the onset of these complications and so we require models of pregnancy that demonstrate similar placental structure and function to women, in both health and disease, hence the choice of mice and rats. Mice will be primarily used but for some protocols, there will be a necessity to use rats. Justification for the use of rats includes that for some candidate therapies, e.g. kynurenine, the signalling pathways in rat are comparable to human, which is not the case in mice. Additionally, in order to assess postnatal interventions to improve maternal health following a preeclamptic pregnancy, we will use a well characterised and published rat model of preeclampsia which is clinically-relevant and enables us to focus upon a single pathway known to be important in the onset of PE.

NON-TECHNICAL SUMMARY

118. Mechanistic strategies for tackling chronic liver disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The over-arching aim of this project is to apply insights from human chronic liver disease to discover and develop effective treatments thatare tailored to patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Liver disease is a silent killer and is on the rise. It is now the biggest cause of death in the UK in those aged between 35-49 years old. If detected early, liver disease can often be reversed, but many people present with advanced liver scarring (fibrosis or cirrhosis) when the options for treatment are limited. There is an urgent unmet clinical need for effective treatments and preventative strategies for cirrhosis and its complications, to improve outcomes for patients. Increasingly, human liver samples and clinical data can be used to uncover promising targets for treatment, but carefully selected animal models are still required to investigate the effects of new or known medicines for different liver conditions.

What outputs do you think you will see at the end of this project?

There is a liver disease crisis in the UK. Since 1970, deaths due to liver disease have increased by 400%. Every day, over 40 people die from liver disease in the UK. Yet there are no medicines 'on the market' to treat liver scarring (fibrosis or cirrhosis) or non-alcoholic fatty liver disease (NAFLD) which is the commonest cause of liver disease affecting 25% of the global population. New treatments are urgently required, as are diagnostic tests to identify people at risk of developing advanced chronic liver disease.

The key outputs from this project will include new information about how liver disease develops, why it progresses in some individuals more than others, and how it could be reversed using novel treatment approaches - this information will be obtained primarily from human data initially (including genetics, analysis of liver biopsies and electronic health records) and used to discover promising new treatments and diagnostic tests that will then be studied in animal models before proceeding to future clinical studies. Given the importance of this work, it is anticipated that other outputs will include: scientific publications, new research collaborations with other academics or with Pharmaceutical and Biotech companies, increased public awareness of liver disease/NAFLD), and potentially patents and products if new medicines, tests or devices are developed.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

The main beneficiaries of these outputs will ultimately be patients - through access to new and effective treatments for chronic liver disease. Although it can take time for new medicines to reach patients in the clinic, we have previously shown that it is possible to move promising treatments (such as the molecule relaxin or macrophage cell therapy) from the laboratory into clinical trials in less than 5 years. Another potential benefit is education and public empowerment. Among patients with diseases most associated with NAFLD (type 2 diabetes, obesity, and hypertension) only 6% had heard of NAFLD (Continuum Clinical, 2019). Low public awareness is a barrier to preventative health strategies and to clinical trial enrolment. The work in this project will form part of our broader public engagement strategy.

In a shorter time-frame, the research community will benefit from the project through new insights into liver disease and potential approaches to develop better treatments and diagnostic tests. We will ensure that fellow researchers realise these benefits by making our protocols and data as accessible as possible.

How will you maximise the outputs of your work?

The results of this work will be used to establish new collaborations with other scientists and with Pharmaceutical and Biotech companies to generate further research funding and to speed up the development of new medicines or tests that could benefit patients.

The research findings will be published in high impact open access scientific journals and presented at national and international meetings. We will also engage with the British Liver Trust and liver support groups, where appropriate, to disseminate the research through their websites and networks. We will craft plain English summaries and visual representations for the public section of our institutional website, and for the annual International NASH Day to ensure our research has global reach. They will also identify opportunities and produce materials for participation in Science Festivals, public lectures and other events. We will use social media judiciously (e.g. Twitter, LinkedIn) and continue to interact with print and broadcast outlets to showcase our work.

Species and numbers of animals expected to be used

Mice: 600
Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, liver disease will be studied in mice or rats using special diets or substances that cause chronic liver damage over 4-12 weeks. Animals may receive treatment with a new therapeutic agent during or after the development of liver disease. Blood samples or imaging tests that are relevant to human health may also be performed to better understand the effects of treatment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

To replicate the advanced stages of human chronic liver disease and its complications requires models where animals may display clinical signs of liver disease such as jaundice, ascites (fluid in the abdomen) or weight loss. However, we have used these models for many years and have learned how to minimize the chances of unnecessary suffering or harm. Animals are very closely monitored for signs of distress and killed in a humane manner if necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The mouse and rat models of fatty liver and liver fibrosis that we will use in this project are classified as moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are necessary to study complex biological processes such as liver scarring (fibrosis) and non-alcoholic fatty liver disease (NAFLD) where multiple cell types in a body organ are constantly interacting with each other, and also to capture the circulatory changes associated with chronic liver disease in a manner that reflects the human situation as closely as possible. As yet, laboratory culture dish (‘in vitro’) experiments simply cannot model this complexity. For this, we require animals - even

lower organisms, such as flies, do not have the same level of tissue complexity that we find in mice and human.

Additionally, animal models are critical to demonstrate proof that new drugs have a good chance of working in humans and to obtain information about the likely dose required and any potential safety issues.

Wherever possible, we are planning to incorporate non-animal methods to achieve our project aims.

What was your strategy for searching for non-animal alternatives?

We are using a range of non-animal methods and only using animal models for specific experiments, such as studying the effects of a new treatment or the utility of a new diagnostic test in the liver and other body organs.

We will use computers to undertake initial screening for new drugs ('in silico' studies), in vitro experiments that mimic simple processes that occur in a living animal (such as fat accumulation in liver cells), and human liver samples that we have already collected. During the course of the project, we also aim to establish a new technique using small slices of human liver which are kept alive in an incubator for several days - this might prove very useful in studying the effects of new drugs.

Why were they not suitable?

Non-animal techniques are suitable for many aspects of the work in the project, but cannot yet be used reliably to fully understand and measure the effects of a new treatment or a new diagnostic method (such as MRI).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our group has many years of experience in the design and conduct of rodent liver disease models. We have used data from our previous published studies to estimate the minimum number of animals needed to show a true effect from a treatment whilst at the same time maintaining sufficient numbers for the experiment to be meaningful. We use biomedical statisticians to advise on our study designs and analysis methods when required.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We used the NC3R's Experimental Design Assistant to map out experimental studies. In certain circumstances non-invasive techniques (such as magnetic resonance imaging) can enable us to track disease in an individual animal over time and will help to reduce the numbers of animals required.

What other measures apart from good experimental design will you use to minimise numbers?

We use the very best models available that mean each animal gives us essential information, with little wastage. Tissues from the animals we use in research are stored and kept for future analysis, meaning that we do not need to repeat the experiments to generate further tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use models of liver fibrosis and non-alcoholic fatty liver disease (NAFLD) in mice and rats - they are very well-established and provide a reliable system to understand how liver disease is caused and to determine the effectiveness of new treatments. It is important to use models that reflect specific types of liver disease in humans (e.g. the carbon tetrachloride model most closely mimics human liver injury due to alcohol or toxins, whereas dietary models exhibit key features of human fatty liver disease). Therefore, the observations we make in these species can be directly translated to the human condition. The clinical complications of cirrhosis only occur at the more advanced end of the disease spectrum. Therefore, in certain studies where we are interested in investigating or treating cirrhosis, models of at least moderate severity are often required. We will minimize any potential suffering by using the least amount of liver injury required for each model, the earliest possible study endpoints, and judicious administration of anaesthesia and analgesia.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rodent models are extremely well-characterized and validated for studying the progression and regression of liver fibrosis and for evaluating the efficacy of new therapeutics. Lower organisms, such as flies, do not have the same level of tissue complexity that we find in mice and human and are not suitable for this type of research.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

A major component of our research programme is the development of non-invasive techniques (imaging, blood tests) which may refine our approach – for example, by allowing experimental models to be stopped sooner if these tests give an earlier indication of response to a drug.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will adhere to the ARRIVE guidelines and regularly consult the NC3Rs website to ensure best practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I follow the NC3Rs on LinkedIn and Twitter. My group will also regularly consult the NC3Rs website and attend our local annual 3Rs symposium.

Explain the choice ofspecies and the related life stages

Once potential new treatments for chronic liver disease are identified we need assess their effects in animal models of liver disease that mimic, as close as possible, the human condition before they can be evaluated in clinical trials. Models of liver disease in adult mice and rats are most commonly used for this purpose and several drugs are now in advanced clinical development based upon supportive data accrued from rodent studies such as those proposed in this project.

Animal models are necessary to study complex biological processes such as liver fibrosis and its complications in a clinically meaningful fashion. As yet, laboratory culture dish (‘in vitro’) experiments simply cannot model this complexity. Furthermore, animal models are critical to demonstrate proof that new drugs have a good chance of working in humans and to obtain information about the likely dose required and any safety issues.

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To identify any aversive taste in new medicines during their development or once they are marketed.

To develop an internal library of the various ingredients of medicines including the active ingredient, the medicine itself, to understand how they affect the taste of a medicine or predict how a new medicine may taste.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Palatability of medicines is important. If medicines are not palatable this can stop people taking them and the medicine may not be effective. This is the case for medicines taken orally, inhaled and intranasally, and is a particular issue for children.

Work performed under a previous project licence provided an invaluable way to identify and help mitigate taste aversion before administration to humans. Prior to this, aversive taste associated with potential new medicines was a risk and could not be measured until early clinical trials. An aversive taste at this stage can be sufficient to stop a medicine going on the market (a rare event) or require modifications to the formulation of the medicine. To address these issues, the medicines palatability test was introduced to REDACTED to predict any taste issues and minimise changes to medicine formulations as they are developed and tested.

There is evidence of genetic and cultural components to taste, and REDACTED takes due account of the likely ethnicity of their target patient population, especially children. The close correlation between the rat brief access taste aversion (BATA) test and human data is evidence of the translatability of the BATA to humans.

With REDACTED's focus on reducing the failure rate of medicines to successfully treat patients for unmet clinical need, the BATA is used across therapeutic areas as a key and unique tool in medicine development.

This test is predominantly used in the early stages of discovering a new medicine or in the first stages of clinical trials.

What outputs do you think you will see at the end of this project?

A reduction in the number of substances that fail or experience delays late on in development due to taste related issues.

Inclusion of palatability data in documents provided to the regulatory authorities during the approval process for new medicines.

External presentation/ publication of refinements to the BATA test.

Publication of academic/ industrial collaborations.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Output from the BATA will contribute to key medicines reaching the patient population in a timelier manner and reduced taste issues should ensure more people take their medicine, particularly children.

Early identification of palatability issues (particularly for inhaled medicines) could prevent more animals being used to test toxicity and humans going through clinical studies to develop medicines with little hope of the medicine getting to market by deselecting these compounds at an earlier stage in development.

Inclusion of pre-clinical palatability data in regulatory documents enables REDACTED to inform formulation development plans, particularly for medicines intended for children. Improved formulations with optimal taste qualities will help ensure patients take their medicine and reduce the issues caregivers typically experience when administering aversive tasting medicines to patients.

Increasing information in our database will provide REDACTED information on the effect of ingredients of a medicine as well as the active ingredient, the medicine itself.

Information that is not intellectual property of REDACTED will be shared, including further validation and refinements to the BATA test. This will help towards a standardised research approach, improving reproducibility and reducing repetition of animal studies.

How will you maximise the outputs of your work?

Collaboration with academic, industrial and non-government organisation partners, and agreeing development strategies will maximise alignment and minimise unnecessary repetition. Outputs will be disseminated via presentation at conferences, external meetings and scientific publications.

Species and numbers of animals expected to be used

- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Rats will be water restricted for a typical 21 hours (up to 22 hours) per day for a maximum of 4 days. Rats will be placed into a chamber (attached to the lickometer) with restricted space and exposed to a series of test formulations for up to 30 minutes per day and for up to 4 consecutive days. The rats choose whether or not to drink each of these test formulations. Following each 30 minute session, rats are returned to their home cage and provided with drinking water for typically 2.5 hours (minimum of 1.5 hours) prior to the next water restriction period.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Transient body weight loss due to the water restriction period of up to 8%. Under the previous project licence, no animals experienced 10% weight loss at any time during studies and all animals showed weight gain with a maximum weight loss of 4% within the rehydration period.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild (100%)

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Without the use of animals, accurate prediction of palatability can only be determined during clinical development of medicines. To get to this point several safety assessment studies, usually in rats and dogs, must be conducted for regulatory authorities.

There are 25 bitter receptors currently identified in humans and there is a complex interrelationship between these receptors, and between receptors which detect bitterness and those involved in the other taste senses which is difficult to model in non-animal alternatives. No fully validated non-animal alternative for the assessment of palatability currently exists.

Rats possess taste receptors similar to humans and the BATA has shown excellent ranking of test compounds when they are compared. Because of the tests sensitivity (slight changes in palatability affect the rate of licking) we are able to obtain high quality data, improving the accuracy of clinical prediction. The complex interrelationship between receptors in man also exists in the rat and the BATA can be used to assess the taste masking effect of medicine formulations. Thus, at present, the rat BATA is the best model of the clinical situation.

What was your strategy for searching for non-animal alternatives?

We have previously worked with an academic group to develop an electronic sensor array system (e-Tongue) which can mimic biological taste.

We have worked with another academic group to determine the potential utility of the amoeba *Dictyostelium discoideum*, a unicellular organism sometimes referred to as 'slime mould', as a model of measuring bitterness.

We are currently working with an academic group using machine learning to develop a computer algorithm to predict bitterness based on a substances chemical structure.

We are aware of work that has been conducted using cells transfected with bitter taste receptors and human taste cells that can now be cultured *invitro*. These technologies were (and continue to be) reviewed as part of a cross-industry UK working group of which our Company is part of.

Why were they not suitable?

Data from the e-Tongue has not been sufficiently reliable in 'blinded' assessments for us currently to use it with confidence it will provide accurate data.

Limited data generated in the *Dictyostelium discoideum* model suggests reasonable correlation with human data and might be considered as a triage model (prior to the rat BATA) in due course. However, further validation is required before a decision can be made regarding its utility. In addition, *D. discoideum* do not respond to non-bitter taste sensations (sweet, sour, salt, umami) and do not have the complex interrelationship between receptors seen in rats and human, so it could not be considered as a full replacement for animals.

Machine learning computer algorithms are currently not capable of determining the intensity of bitterness to an acceptable level of accuracy. However, this technology is developing rapidly and may be a potential triage model (prior to the rat BATA) in due course.

The use of taste cells *in vitro* to assess the taste properties of substances is complex and requires more research. At present, these types of cell-culture assay are not capable of modelling the complex interrelationship between receptors and do not provide an accurate picture of overall taste liability of substances.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We anticipate running one study every two weeks (excluding holiday periods) for the five year duration of this licence. This equates to 24 studies per year for five years, using 12 rats per study. Assuming each rat is used an average of five times (4 re-uses) and accounting for variation in demand, we estimate a potential use of 300 rats.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Statistical advice will be sought to optimise study design and minimise animal usage.

Information collated in a database on medicines and their ingredients, and their effect on palatability will be used to advise on medicine development, reducing the need to assess these in the rat BATA and ideally avoiding further animal use in the first place. In addition, fewer substances with such liabilities will be used in other animal studies under the authority of other project licences.

Prior to committing to animal studies, potential test substances will be assessed for solubility and chemical stability. Substances with very low solubility and hence only limited interaction with taste receptors will be deemed to be of 'low taste risk' by default and rat studies will not typically be performed. Substances which cannot remain chemically stable for the duration of a study session (approximately three hours) will not typically be assessed under this licence. Under exceptional circumstances (for example assessment of a formulation for children prior to inclusion in regulatory documents), substances with limited chemical stability (between one and three hours) which are stable enough for use on individual lickometer sessions may be assessed under this licence.

Batches of animals which have undergone one BATA study (of one week with suitable periods to access water in between individual tests) have been shown to be suitable for re-use in subsequent sessions (where there are sufficient substances needing to be tested or validation studies needing to be performed). The advantage of re-use is that one fewer water restriction, and one fewer habituation session in the lickometer would be needed per study compared with using a naïve batch of animals. Welfare assessments indicate limited impact to the animals of 23h (reduced to 21h in most cases) water restriction with periods to access water once testing is complete.

What other measures apart from good experimental design will you use to minimise numbers?

Use of prior knowledge captured in our database will enable more informed study design and avoid the unnecessary use of substances which themselves might cause taste aversion.

Noise levels will be kept to a minimum during studies to ensure rats remain focused on the task at hand and are not distracted, for instance by radios, unnecessary talking or other sudden noises. This will

reduce variability of the data generated and thus the number of animals needed by avoiding having to repeat studies or use more animals to minimise variability.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

There is a large amount of literature supporting the use of rodents in assessments of palatability, indicating the physiology, molecular biology, and behavioural aspects of taste in rodents are similar to human.

Evidence generated during the course of previous BATA studies following single and multiple uses suggests rats experience no signs of acute or chronic stress, normal behaviours, growth rates, blood chemistry and haematology, with no abnormal post mortem findings. Body weight loss (typically below 10%) does occur during the water restriction phases, but this is transient and recovered once animals have access to water again.

Rats will be maintained in 'tower' style caging with various in cage levels/ platforms and an enriched environment that improves the rate of learning and habituation to novel tasks and thus reduce the variability of the data generated. Rats are housed in standard caging where a specific scientific or welfare reason has been identified.

Welfare assessments will be conducted that include body weight monitoring; skin ‘tenting’ as evidence of sufficient water intake, body condition and general observational assessments.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Most non-mammalian species (e.g. zebra fish) are not considered to be suitable alternatives due to their different mechanisms for detecting taste to mammals.

Although taste cells develop during the embryonic stage of mammalian development, the complex interrelationship between receptor types cannot be modelled in non-mammals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

During the course of previous licences, various refinements have been assessed and we will continue to explore opportunities for further refinement. Previous assessments have included:

- Reduction of the typical water restriction phase to 21 hours (from 23 hours)
- Reduction of the number of times rats are offered substances to taste (from 3 to 2) per session, reducing the typical lickometer session to 30 mins (from 45 mins)
- Use of the home cage for post session access to water (replacing use of a separate chamber)
- Use of enriched 'tower' caging to improve the rate of learning to novel tasks

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The published principles and philosophies behind the PREPARE (2018) and original ARRIVE (2010) guidelines have been incorporated into the sponsoring company's internal project planning standards of care and standard operating procedures. All work carried out under authority of this licence will undergo assessment of the study design during planning stages as part of a peer review process that is based on those guidelines and will include statistical consultation. Facilities and processes are audited by independent bodies such as AAALAC International which has published guidelines and procedures to ensure work is carried out to high ethical and humane standards. The following published documents will advise on experimental design, animal welfare and husbandry during the life cycle of this licence:

● Kilkenny C et al (2010). Improving Bioscience Research Reporting: The ARRIVE Guidelines for Reporting Animal Research. PLoS Biol 8(6).

● Smith A et al (2018). PREPARE: guidelines for planning animal research and testing. Lab Anim; 52(2):135-141.

● Percie du Sert N et al. The ARRIVE guidelines 2019: updated guidelines for reporting animal research. BioRxiv. 2019: 703181.

● NC3R's - Responsibility in the use of animals in bioscience research: expectations of the major research council and charitable funding bodies (2019).

● Guidance on the operation of the Animals (Scientific Procedures) Act 1986. (Home Office 2014).

● LASA - Guiding principles on good practice for animal welfare and ethical review bodies. (2015)

● Prescott MJ, Lidster K. Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156, (2017).

● Review of harm-benefit analysis in the use of animals in research. Report of the Animals in Science Committee Harm-Benefit Analysis Sub-Group chaired by Professor Gail Davies (Nov 2017).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The role of REDACTED's Named Information Officer (NIO) includes the sharing of animal welfare, best practice and 3R's related information. The NIO also liaises directly with REDACTED project licence holder network through their meetings, and also raises this type of information and discussion points at the Animal Welfare and Ethical Review Body (AWERB). The licence holder for this work regularly attends both these groups and is also aware of the 3R's related work of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). Experience to date has shown that 3R's issues and advances are highlighted, discussed and actions are implemented within REDACTED centrally and effectively via these forums. In addition, the licence holder regularly liaises with scientists specialising in laboratory animal behaviour and with a special interest in rodent taste models, and attends/ presents at relevant scientific symposia.

Explain the choice of species and the related life stages

Data from the rat is more predictive of human responses than non-mammalian or non-animal alternatives. Rats and humans possess similar taste receptors and respond to the majority or substances (particularly bitter) in a way that is highly translatable between the rat and man. Use of the rat as a model for predicting taste aversion in humans has been validated in rats between 8 weeks and approximately 1 year of age within which the rat response has shown to be acceptably consistent. Published studies suggest rats outside of this age range give a more varied and less translatable response to bitter tastes.

Home Office

NON-TECHNICAL SUMMARY

120. Melanoma formation, immune responses and evaluating novel therapeutic approaches and agents

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To learn more about how melanoma (an aggressive form of skin cancer) arises, how it interacts with the immune system and to exploit this knowledge to develop new therapeutics

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are approximately 16,000 new diagnoses each year in the UK of melanoma, resulting in approximately 2,300 deaths per year. For most patients diagnosed with advanced melanoma (melanoma that has spread to other anatomical sites) there is little prospect of a cure and survival time can be a few years or even only months from diagnosis. However, through acquiring knowledge of the molecular, cellular and metabolic processes that go wrong during the formation of melanoma it has been possible to develop drugs and cellular therapeutics that significantly delay disease progression in many, or occasionally even cure patients. The number of these therapeutics are limited, however, and treatment resistance is still a major hurdle. More research is needed in order to expand the pipeline and understand and deal with the issue of resistance.

What outputs do you think you will see at the end of this project?

By the end of the project we hope to have validated several novel potential therapeutic targets for treating advanced melanoma (which may be of relevance to other malignancies). We also aim to generate understanding of how melanoma cells develop resistance to immune checkpoint inhibitors, drugs that boost T cell responses [T cells being part of the immune system]. Potentially, resistance mechanisms may be reversed using other drugs. Further, we aim to generate and evaluate the safety and efficacy of a novel chimeric antigen receptor (CAR). CARs are assembled from multiple proteins and introduced into T cells (ultimately from a cancer patient). They guide T cells to a cancer surface protein and then activate the T cell so it can destroy the cancer cell. Our findings will be disseminated at scientific meetings and in publications and our reagents licensed where appropriate for commercial development.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our research is guided by our desire to benefit melanoma patients. Within the next five years, we anticipate that other scientists in academia and pharma may build on the knowledge we generate and disseminate to develop novel treatments and diagnostic tools. However, new therapies resulting from our discoveries may take several years before they reach patients, as drugs need to be identified and rigorously tested before they can be prescribed.

How will you maximise the outputs of your work?

We will maximise the output of our work by collaborating and by publishing at the earliest opportunity through pre-print servers and then Open Access journals. Further, we will disseminate our findings at international meetings attended by academics, clinicians and industry representatives. Currently we collaborate with a Biotech company and are thereby able to transfer our knowledge directly to an organisation capable of developing cellular therapeutics and testing them clinically.

Species and numbers of animals expected to be used

- Mice: 3100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Some animals will only be used for breeding. However, in the majority of animals, we will establish melanoma tumours at superficial sites. We will track how the tumours are developing over several weeks to months, sometimes using medical imaging approaches. Certain animals will be dosed with therapies, including drugs and cells. We will then monitor closely
over days to weeks how well the therapy is working and whether it is causing any side effects.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Cancer growth within an animal, as in a human, can cause detrimental effects. We monitor weight and specific behaviours in the animals that would indicate pain or distress and have well designed endpoints to minimise any suffering. There is a risk that we may observe toxicity with treatments. To limit this, we use therapies
at doses that have previously been shown to be well tolerated using the route of least severity and the minimum number of doses to produce an anticipated anti-tumour effect. If the monitoring described
above indicates toxicity, we reduce therapy dose and/or stop treatment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Minimal if any side-effects are anticipated in animals used for breeding. All procedures used for animals with tumours are moderate.

We will not allow tumours to grow bigger than 1.5 cm^3, nor to interfere with vital functions. At the end of experiments animals will then
be humanely killed and tissues may be taken for further laboratory tests.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The multiple cell types implicated in the process of cancer formation and progression and treatment response are all present only in an animal host. Additionally, in the case of drugs or cell therapies, we are intending to address whether the therapeutic will be absorbed, metabolised and distributed effectively to have its effect without causing significant toxicity. Ultimately this requires an intact, living organism (notwithstanding the caveat that mouse and humans have important pharmacological differences).

What was your strategy for searching for non-animal alternatives?

Human tumours and tissue culture were considered as non-animal alternatives and will be used extensively before animal experiments.

Why were they not suitable?

Non-animal alternatives can not be used to test all our hypotheses due either to our inability to manipulate the system (as with human tumours, outside the context of a clinical trial with its own attendant ethical issues) or as with tissue culture because we cannot yet replicate all the important features of the in vivo environment and certainly not holistically. Co-culture systems can begin to address interactions between different cell types a couple at a time but not the entire spectrum of interactions. In particular, immune responses require the orchestrated activities of multiple cell types located at distinct anatomical sites, with various cells needing to migrate from one anatomical site to another.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For individual experiments, pilot and historical data are used in power analysis to predict optimal group sizes. Numbers are then scaled to encompass the anticipated/desired number of experimental scenarios, incorporating controls, different doses and independent replication.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experiments will be appropriately controlled and mice of the same age, genetic background and source used to reduce the variability of results and to produce highly consistent data. An on-site statistician has advised us on design and power analysis, alongside use of the NC3Rs Experimental Design Assistant. Bias will be avoided by random allocation of animals to treatment groups. Where possible and practicable, endpoints will be assessed by a technician who is unaware of the treatment the animal has received. Experiments will be designed carefully to avoid other sources of bias such as week-to-week or operator-to-operator.

What other measures apart from good experimental design will you use to minimise numbers?

The use of real-time data monitoring of cells (e.g. luciferase mediated imaging of tumour cell development) has considerably reduced the group sizes required for significant experimental results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse is the lowest vertebrate that offers an in vivo situation (anatomy, physiology, metabolism) relevant to human cancer and that can be manipulated in a manner that will generate data relevant for the treatment of human cancer. As such, the mouse is the most appropriate in vivo model to achieve the stated objectives.

Sampling blood, the injections (subcutaneous or tail vein) to introduce tumour cells or drugging by gavage, intraperitoneal or intravenous injection are routine procedures and will be performed by highly trained staff, which ensures brevity of the procedure and the lowest level of discomfort. Needles will only be used once when sampling or administrating substances to mice. By responsibly considering

the adverse effects associated with the regulated procedures, mechanisms are in place to minimise these (e.g. appropriate analgesic regimes for pain relief).

To reduce any suffering of tumour bearing animals, animals will be humanely killed as soon as tumour formation is sufficient to yield satisfactory data and always before animals become moribund, manifest severe pain or lose significant weight (which is closely followed).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Cancers develop in vertebrates. We model melanoma both in zebrafish and mouse. Mouse is more similar to humans than zebrafish and this is critical both for using reagents like drugs developed for human targets and for translating findings back to the clinic. Cancers develop over many weeks to months, so use of terminally anaesthetised animals or immature animals is not practicable. Also immature mice lack a functional immune system which is important for our research.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Immune-based therapies may be associated with toxicity related to the underlying mechanism of anti-tumour activity. Local experience reveals that this has most frequently been associated with weight loss in less than 20% of all experimental animals and has been managed through close observation and the provision of mashed food and nutritional gels rather than hard pellet. Wherever possible, animals will be provided with analgesia as detailed in the relevant Protocol to control adverse symptoms associated with the treatment. In all cases, judgement will be used to assess whether the duration of such symptoms is excessive or whether the animals appear stable and / or show an improvement in symptoms over time suggesting that these effects were transient.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All tumour studies will be conducted in accordance with the guidelines for working in rodent models of cancer as described by Workman et al (2010). (Guidelines for the welfare and use of animals in cancer research. Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA. Br J Cancer. 2010 May 25;102(11):1555-77).

LASA guidelines will be followed regarding volume of blood samples, and drug dose volume limits.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with my NACWO, NVS and HO inspectors.

Explain the choice ofspecies and the related life stages

Adult mice will be used as

- The mouse immune system has been intensively investigated and is the most advanced in terms of understanding.
- The necessary reagents are available and usually well tested which is not the case for most other species.
- The mouse represents the lowest level of sentience that most accurately reflects the human system for immunotherapeutic studies
  .
- Correlative studies between mouse and man indicate the potential for results to translate between the species.
- The immune system is mature in adult mice and only they are big enough to host tumours, are more practical to treat, and more able to tolerate any side-effects compared to younger mice.

NON-TECHNICAL SUMMARY

121. Metabolism and Residues of Agrochemicals in Food Producing Animals

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Cattle	juvenile, adult, pregnant
Goats	juvenile, adult, pregnant
Pigs	juvenile, adult
Chicken	adult, juvenile

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The intention of work covered by this licence is to determine how agrochemical materials are absorbed by the body of food-producing animals, how they may be changed by the animals (metabolised), how they are broken down and excreted, and what residues remain. The work is designed to meet the requirements of government regulators in Europe and elsewhere, who must agree to the sale and use of these materials in society.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Agrochemicals; primarily insecticides, herbicides, fungicides and other materials designed to kill crop pests, are essential for the prevention and treatment of diseases that commonly occur in our food crops. However after use, a residue of the material may remain in the food stuff, and be eaten by animals. It is therefore important to determine that these materials are not toxic to the animals, and that any parts or products of the animal (eggs, milk and meat) are then safe for humans to eat. Without these studies, it is currently not legally possible to manufacture and sell these materials in the UK, in Europe, or into other markets in the world. Development and use of safer and better materials requires conduct of these studies.

What outputs do you think you will see at the end of this project?

Data collected will be information on the absorption of various agrochemical materials by food-producing animals, how the body changes and excretes these materials, and what resides may remain in products which contribute to human food (milk, eggs, meat). The data will be collected to the standards required by government regulators in the UK, Europe and elsewhere, who will make decisions on whether these materials can be safely marketed and used in society.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

Our clients, typically commercial agrochemical companies, will benefit from the provision of high quality data. This will to help them in their work to produce safer and more effective materials which can be safely made and used without increasing health risks for those who could potentially be exposed to them through the eating ofanimal-based food.

Enabling development of successful agrochemical materials will benefit society, for example by enabling improved crop yields in multiple regions of the world, which are exposed to a range of biological challenges.

How will you maximise the outputs of your work?

By conducting the work to the expected quality standard (Good Laboratory Practice), the outputs of the work should be readily accepted in all markets of the world.

Collaborations and information exchange with others within the organisation and with our clients, helps to identify and spread information on successful and unsuccessful approaches, and on product development.

Species and numbers of animals expected to be used

- Cattle: 30
- Goats: 60
- Pigs: 10
- Sheep: 0
- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be given a chemical material by methods which reflect the expected route that they would be exposed to them. Samples are collected, including milk from goats and cattle (standard farming practices are used) or eggs from hens. Sampling may also include blood samples. Urine and faeces, and the excreta of birds are commonly collected, which requires housing the animals singly, although next to each other, in a small cage which allows the urine and faeces to fall through a grid, typically for

about up to two weeks. To ensure that urine is not lost confinement of goats and cattle is typically in a type of stall which prevents them from turning round.

Animals will be humanely killed after the collection period, and tissues may be taken from the animals post mortem, and analysed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The process of dosing animals or taking blood samples may cause minimal discomfort during conduct; no lasting effects expected.

The materials are not normally expected to cause any significant harm for the animals.

Confinement for collection of excretions may cause a degree of discomfort; a degree of reduced food consumption and/or weight loss may be noted, but this is not expected to be significant based on experience of studies conducted over many years.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Although no significant harms are normally identified clinically, the single housed confinement of animals for more than a week, particularly if it includes restricted movement, results in a consideration that this is of moderate severity. This is likely to be the case for the majority of animals used in the project, because of the need to collect the excretions of individuals for a sufficient time to complete the scientific aims.

What will happen to the animals at the end of the study?

- Killed
- Kept alive
- Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are used in some aspects of the programme of safety assessment of new materials, they are currently not able to predict effects on whole body systems or to provide information on how much of a material is absorbed, or how animals change and excrete materials. Crucially, animal products which contribute to food (meat, milk, eggs) need to be assessed for presence of chemical residues which could cause harm to people.

The protocols described in this project are conducted according to internationally-agreed guidelines, and are expected to be performed before government authorities will authorise the marketing of new agrochemical materials.

What was your strategy for searching for non-animal alternatives?

The organisation conducts non-animal tests as part of the programme of safety assessment of new agrochemical materials, but as noted, above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes.

Studies of absorption, change or excretion after dosing by mouth still can not currently be achieved adequately without using animals.

Why were they not suitable?

These studies of absorption, change, excretion and residues in materials which may be in human food, still can not currently be achieved adequately without using animals; and so the materials can not be approved for use in society.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The animal numbers for studies required by government regulators typically follow those identified in internationally-accepted guidelines, as expected to provide sufficiently significant outcomes.

Some studies use only one animal per study, where the scientific aim can be achieved with this design. In studies requiring multiple animals, previous experience can be used to agree a study design

including fewer animals than is advised in the relevant guideline.

What other measures apart from good experimental design will you use to minimise numbers?

A careful process is followed, to understand the specific needs for any particular material for which testing is requested, to understand the purpose of the testing, where in the world a material might be made, transported or used, and what tests may have been already performed/submitted to government regulators.

All studies are performed according to the principles of Good Laboratory Practice (GLP), which is an international standard for the quality of experimental study conduct with animals, and is overseen by an independent agency of the government. Following this practice should ensure the quality of studies and acceptance of results by government regulators worldwide, and also reduce the potential for error.

By fully understanding the needs for testing in each case, and by following internationally-agreed guidelines and GLP, the same study should be acceptable to government regulators in all parts of the world where it is needed, removing any need to do the similar work more than once, and use more animals, to meet the needs of all markets where agrochemical materials may be used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Materials are given to the animals by the same way in which they would be exposed in the environment,typically by mouth, through the eating of animal feeds).

The dosing methods used are all very well established and common for the animals to be used, and known to cause minimal discomfort based on extensive experience at the site. Similarly, sampling methods follow published guidance where relevant, and animals are kept confined for the minimum time to meet the scientific needs.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species used are selected based on known standards of outcome which will answer the scientific questions. They are species proposed as appropriate for the work by internationally-agreed guidelines, for the studies which are expected to be performed before government authorities will authorise the marketing of new agrochemicals.

The outcomes are assessed over a time period which makes continued anaesthesia impractical, and would interfere with the outcome in most circumstances.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinement of procedures is an on-going consideration at the site, and new opportunities are particularly assessed if any concerns are identified during or after studies; for example new methods or additional assessments may be included in future study designs as a result of a review. Single housing and confinement in a reduced space are commonly needed in these studies, and ways to improve (enrich) the stall or cage used discussed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Where required, blood volume limits are within those proposed in the 2001 publication of Diehl et al: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Both our clients and our colleagues working in the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which propose refined approaches to conduct of work.

Explain the choice ofspecies and the related life stages

The animals and life stages used in the project are examples of species which contribute to human food. They are also species included in relevant guidance accepted by government regulators in the UK, Europe and elsewhere.

NON-TECHNICAL SUMMARY

122. Metabolism of Chemicals

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To evaluate how various types of chemical materials are absorbed by the body of animals, how they may be changed by the animals (metabolised), and how they are broken down and excreted. The work is designed to meet the requirements of government regulators in Europe and elsewhere, who must agree to the sale and use of chemical materials in society.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work is required to help protect the safety of people who are involved with the manufacture and transport of various types of materials, as well as those who may be exposed to them during deliberate use or accidental exposure. Without these studies, it is currently not legally possible to manufacture and sell these materials in the UK, in Europe, or into other markets in the world. Development and use of safer and better materials requires conduct of these studies.

What outputs do you think you will see at the end of this project?

Data collected will be information on the absorption of various chemicals materials, as well as how the body changes and excretes these materials. The data will be collected to the standards required by government regulators in the UK, Europe and elsewhere, who will make decisions on whether these materials can be safely marketed and used in society.

Improved methods of conduct of specific data collection processes may be developed during the course of the project.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our clients, typically commercial chemical companies, will benefit from the provision of high quality data. This will to help them in their work to produce safer and more effective materials which can be safely made and used without increasing health risks for those who make, use or transport them.

Enabling development of successful chemical materials will benefit society, for example by enabling improved crop yields, reduced danger to workers
, or provision of chemicals as ingredients in safer or better medicines.

The wider scientific community may benefit from publication of refined approaches to animal use.

How will you maximise the outputs of your work?

Our organisation has colleagues who also have experience of such work in different parts of the world. Collaborations and information exchange with others within the organisation, helps to identify and spread information on successful and unsuccessful approaches.

Collaboration with clients (knowledge gained on products).

On-going collaborations with NC3Rs on various aspects of regulatory safety studies, over many years.

Presenting outputs at scientific conferences and contributing to publications in the scientific literature where relevant.

Species and numbers of animals expected to be used

- Mice: 1200
- Rats: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will normally be given a chemical material by mouth or by intravenous injection, and most commonly on a single occasion only. Samples such as blood samples will be taken to assess how much of the material is absorbed after swallowing, and/or samples of urine and faces to see how much of the material is excreted in various ways. Collecting urine and faeces requires keeping the animals, normally singly, in a small cage which allows the urine and faeces to fall through a grid, typically for about a week, but for a maximum of 14 days.

Some animals will have surgery conducted under anaesthesia, and with use of pain relief, to allow collection of bile from animals after they have been dosed and single housed as described above.

Animals will be humanely killed after the collection period, and tissues may be taken from the animals post mortem (after death), and analysed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The process of dosing animals, taking samples and confining for collection of urine/faeces can cause a degree of discomfort during conduct. The materials are not normally expected to cause any significant harm for the animals. Surgery can cause some discomfort, but this is prevented or minimised by use of appropriate anaesthetics drugs and pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The harms described above are expected to fall about half within the mild category and about half within moderate. Where surgery is performed, as described, this would be noted as moderate severity, and may involve about a tenth to a quarter of the total number of animals. If animals are single housed for a period of days for collection of urine/faeces, that is also considered as a moderate harm. Severe outcomes are not anticipated; if seen in individual animals, these would be reported to Home Office.

What will happen to the animals at the end of the study?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are used in some aspects of the programme of safety assessment of new materials, they are currently not able to predict effects on whole body systems or to provide information on how much of a material is absorbed. It is not currently possible to acquire all of the information on how the body absorbs, changes and excretes materials, without using animals. This information is essential, to protect people involved in the manufacture, transport or use of chemical materials. The protocols described in this project are conducted according to internationally-agreed guidelines, and are expected to be performed before government authorities will authorise the marketing of new chemical materials.

What was your strategy for searching for non-animal alternatives?

The organisation conducts non-animal tests as part of the programme of safety assessment of new chemical materials, eg in vitro metabolism studies are used within programs to aid with translation to human safety and also to confirm suitability of the rodent species with respect to metabolite profiles.

However as noted, above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes.

Studies of absorption, change or excretion after dosing by mouth still can not currently be achieved adequately without using animals. Studies of absorption through the skin can be conducted either in animals or by non-animal methods. Generally the non-animal method is suitable in this area of work, using isolated human or animal skin samples.

Why were they not suitable?

There are limits to non-animal skin absorption studies; the skin samples are only usable for up to about 24 hours, so where absorption has to be followed over a longer time period, an animal study will then normally be required.

In some cases, the results of the non-animal method then require use of an animal method to confirm

Also, where skin penetration is shown to be high in the non-animal method, the relatively increased risk for humans will then normally require that an animal study is also conducted, to provide additional information regarding safety for people who may be exposed to the material.

In rare cases, enough is known about the properties of a test item to judge that a non-animal study alone will not meet the scientific need to fully assess human safety. In such cases, an animal study and a non-animal study may be planned to be conducted together. However such a plan must be specifically approved by the Home Office.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The animal numbers for studies required by government regulators typically follow those identified in internationally-accepted guidelines, as expected to provide sufficiently significant outcomes.

What other measures apart from good experimental design will you use to minimise numbers?

A careful process is followed, to understand the specific needs for any particular material for which testing is requested, to understand the purpose of the testing, where in the world a material might be made, transported or used, and what tests may have been already performed/submitted to government regulators.

All studies are performed according to the principles of Good Laboratory Practice (GLP), which is an international standard for the quality of experimental study conduct with animals, and is overseen by an independent agency of the government. Following this practice should ensure the quality of studies and acceptance of results by government regulators worldwide, and also reduce the potential for error.

By fully understanding the needs for testing in each case, and by following internationally-agreed guidelines and GLP, the same study should be acceptable to government regulators in all parts of the world where it is needed, removing any need to do the similar work more than once, and use more animals, to meet the needs of all markets where a chemical material may be made, transported or used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Materials are given to the animals by the same way in which people would be exposed during manufacture, transport or use of the materials, most commonly by mouth; occasionally by putting it on the skin, and then comparing how much is absorbed with dosing directly into the blood. In a small number of cases, surgery is performed, under anaesthesia and with pain relief, to allow samples to be taken from the animals.

The methods used are all very well established and common for the animals to be used. The amount of material given is in line with published guidance on minimising discomfort, and/or is known to cause minimal discomfort based on extensive experience at the site.
Similarly, blood sampling follows published guidance on suitable volumes which can be taken while minimising harms to animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species used are selected based on known standards of outcome which will answer the scientific questions. They are species proposed as appropriate for the work by internationally-agreed guidelines,

for the studies which are expected to be performed before government authorities will authorise the marketing of new chemical materials.

The outcomes are assessed over a time period which makes continued anaesthesia impractical, and would interfere with the outcome in most circumstances.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinement of procedures is an on-going consideration at the site, and new opportunities are particularly assessed if any concerns are identified during or after studies; for example new methods or additional assessments may be included in future study designs as a result of a review. Habituation of animals to restraint (if needed) is a routine process, and the schedule can be amended in response to outcomes for individual animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of Diehl et al: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

Welfare end-points are developed in general line with publications on the topic, including the NC3Rs document from 2010 on dose level selection for regulatory toxicology studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Both our clients and our colleagues working in the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which propose refined approaches to conduct of work.

Explain the choice ofspecies and the related life stages

The animals used in the project have been shown to provide important information for assessing safety of chemical materials, and this is reflected by the recommendation of the particular animal species in internationally-agreed guidelines for how to best produce the information required.

Home Office

NON-TECHNICAL SUMMARY

123. MITIGATING IMPACTS OF RIVER ENGINEERING ON FISH

Project duration

5 years 0 months

Project purpose

None selected

Key words

Dams, hydropower, acoustics, telemetry, electricity

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims to: (1) quantify the impact of river infrastructure (e.g. hydroelectric turbine intakes and pumping stations) on fish; and 2) develop environmental impact mitigation technology, such as behavioural deterrents (e.g. using acoustic/electric fields), to protect fish.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Information obtained will provide evidence of negative impact of man-made river structures on fish distribution, movement, and survival to help develop and prioritise conservation actions. This will help regulators ascertain whether current methods to protect fish (e.g. fish ladders and screens) are effective for the species of conservation concern, and highlight areas where improvements can be made. Identification and quantification of secondary impacts associated with river structures and their operation, such as the sounds created, will be achieved so that alternative protective measures can be developed.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Fish.

The total number depends on the number of sites selected by the Environment Agency for monitoring. Total maximum number = 22,100 over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The adverse effect of this study will related to the marking of fish (e.g. use of elastomer tags, fin clips, and PIT tags) which will require minor procedures involving a hypodermic syringe, tagging of fish which will involve surgery and suturing, and stress associated with exposing fish to sound and electric fields. These will include minor discomfort and elevated stress during the use of anaesthetic and marking /tagging procedure, associated with insertion of hypodermic needles (e.g. to implant visual markers) and surgery associated with implanting a transmitter into the body cavity of the fish. When encountering electric fields likely adverse effects are likely to be minor and relate to those common for sedation and anaesthesia, primarily that motion and breathing is reduced accompanied by a partial loss of equilibrium, but remaining reactive to touch stimuli. The likely/expected levels of severity will range from mild (all protocols except tagging studies involving surgery) to moderate (use of surgery to tag

fish). Risk of mortality will be low (less than 1:1000) and any fish exhibiting stress or suffering as indicated by abnormal behaviours and increased rates of gill ventilation as a result of the procedure will be humanely killed with a lethal dose of anaesthetic. In most cases fish will be returned to the wild after completing the procedures.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

It is currently impossible to model movement behaviour of many species of fish in response to conditions encountered at river structures. Live animals must be used to obtain the information necessary to facilitate greater understanding of this so that models may eventually be developed. This project will provide information needed to develop deeper understanding of fish behaviour on which conservation efforts can be based. The approach proposed will use the minimal amount of animals to obtain the information necessary.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Statistical tests will be used to estimate the numbers of fish that should be used to obtain valid results. Through a process of continuous re-evaluation and adaptation of the research methodology, the numbers of fish required will be constantly refined by updating the estimates the number of fish needed while still achieving scientifically valid results. Statistical tests will be used on data collected to inform estimates of numbers used in subsequent phases of the research. This way the number of fish required to ensure meaningful conclusions will be minimized.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

It is essential that the animals used are the same species for which this research is intended to benefit by developing the most appropriate management strategies based on real world observations. The species selected represent those that of high conservation and/ or economic value as defined by national and international legislation, yet maintain populations that are relatively stable and healthy in the study rivers selected. The selected species also provide representatives of fish with a range of different body morphologies, swimming capabilities, behaviours, and life history traits. All surgical techniques will use well developed and widely used protocols to minimize handling and associated stress. Effects of the techniques will be monitored to reduce probability of causing pain and suffering during future phases. Behavioural traits will be monitored to indicate humane endpoints i.e. the earliest indicator in an animal experiment of severe pain, distress, suffering, or impeding death. Post-surgery

behaviour will be closely monitored over the period of recovery to assess deviation from the pre-surgery condition. The data will be regularly reviewed to assess whether behavioural measures can be refined to enhance the efficiency of identification of humane endpoints based on a relationship between exhibition of aberrant behaviour and resulting deterioration in condition.

Home Office

NON-TECHNICAL SUMMARY

124. Modeling liver disease in rats

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

When the liver is damaged by fat or alcohol or viruses' scars can form: if the injury is stopped then the scars are slowly degraded and the damage is repaired. However, when the liver is exposed to repeated injury then the scars persist, a process known as fibrosis. In the diseased and fibrotic liver there is an increased risk for cancer to form and grow.

Currently there are no medications which prevent or limit fibrosis and for cancer, the only drug treatment, Sorafenib, only extends life expectancy by ~3 months and often has side effects.

This project has 3 aims;

The first is to understand how scars form in the liver when it is damaged and then to identify new targets for drug development. We then want to test medicines, which have the potential to prevent or reverse scar formation in animal models of liver disease.

The second is to understand how cancer develops in the diseased liver and then test drugs that might prevent or limit cancer development.

The third is to determine how protection from developing fibrosis when the liver is damaged can be passed on from either grandfathers or fathers to their offspring.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The primary outcomes of our work are;

1. Identify new drugs, which limit scar formation and prevent fibrosis or liver cancer.

2. Identify biomarkers of disease (e.g. develop a test that will allow us to measure proteins or DNA in the blood that are released from the damaged liver) or use imaging (a simple scan) to help assess how advanced the fibrosis or cancer. Our aim is that the biomarkers and imaging methods will be developed to assess disease in both rodents (to minimise animal use and procedures) but also to be developed as a test that can ultimately be used in patients with liver disease or cancer. For example, biomarkers may include molecules or proteins released into the blood that can be detected by a simple blood test, or an imaging method could be develop as a scan that measure the amount of fibrosis in the liver or the size of a tumour. By performing repeated scans this will tell us if a drug is working and reduces the amount of scar tissue or size of a tumour in the liver.

Clinical Importance:

The number of people with liver is continuing to increase year on year in the UK, primarily due to the increase in obesity, viral infection and alcohol.

Currently, in the UK, more than 16,000 people die in from liver disease, ranking as the fifth most common cause of death. Whilst in the US it is the second leading cause of mortality amongst all digestive diseases. At present, there are no effective drugs to treat liver fibrosis. The only treatment option for patients with advanced liver disease/liver failure is a liver transplant. However, donor organs are extremely limited and in 2009 only 58% of patients on the waiting list received a transplant.

Liver cancer, typically develops on the background of chronic liver disease, effects over half a million people each year, and has a poor 5 year survival of only 10%. The number of people diagnosed with liver cancer is rising at an alarming rate and is now reported to be the 5th most common cancer in men and the 7th most common cancer in women. The poor survival rates are primarily due to late diagnosis and a lack of effective drugs.

There is an urgent need to identify new drug targets and test potential new therapies to treat chronic liver disease (CLD) and liver cancer. Our program of work will help understand how CLD and liver cancer develop and allow us to identify and test new medicines to treat CLD.

This program of work will also hope to develop imaging methods to help assess liver disease/cancer in living animals and also aid the development of blood tests which can predict the stage of disease.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Rats, we have estimated using up to 3500 rats over a 5 year project.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

All procedures with the exception of protocol 1, which are non-recovery are classified as moderate.

We isolate different cells from the liver and grow them in a petri dish to perform early drug testing and understand how these cells behave under different conditions to help identify new drug targets. Under protocol 1, rats are placed under anaesthesia (into a deep sleep) and the liver is exposed and perfused with solutions that aid cell isolation. This method is a non-recovery procedure.

To cause liver injury in rats we will use either liver damaging chemicals (carbon tetrachloride), surgical models (blocking of the bile duct) or by feeding of western lifestyle diets which are high fat and sugar diets.

The rat will develop liver disease and very rarely show signs of sickness e.g. hunched posture. Very occasionally jaundice (skin becomes a yellow colour) or swelling of the belly may develop in the bile duct surgical model.

For our studies investigating how protection from scar formation in the liver is passed from generation to generation we will also ask if other organs are affected. We will promote disease in other solid organs including; 1. The kidney by surgically tying the ureter, to prevent urine flowing from the kidney to bladder. 2, The lung by putting chemicals into the lung to cause damage. 3. The skin of rats by punching two holes in the skin and watching the wounds heal. In these models, scars will form in the effected organ.

We will administer chemicals to rats to injure the liver and induce liver cancer. The rat will develop liver disease and cancer slowly. The animals may lose weight but tumours will not be allowed to develop to a point where significant clinical symptoms occur.

We do not expect therapies to cause adverse effects, typically the therapies are drugs, which have been used in animals to treat other diseases, but are likely to have value to treat liver disease or cancer. If a compound had not been used in animals before, we would perform small pilot studies to determine drug bioavailability and tolerance. Starting doses would be informed by literature regarding the compound solubility and activity in a test tube and from experiments performed in cells or tissue slices.

We will use imaging machines (e.g. x-ray, MRI or a machine that measures light) to scan the rats with CLD to help assess the level of the disease in living animals. To see the scar tissue we will give special “tracers” which bind the scar or scar cells. The tracers light up or glow, vibrate or release when stimulated and can been seen by the special imaging machines. From our current experience we do not anticipate any adverse effects of imaging.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Liver disease and cancer are complex processes; they develop over many weeks and require lots of different cells both within the organ and within the blood to talk to each other

In our “inheritance” study we are asking how protection from developing fibrosis can be passed from father to son. To achieve this we need to promote fibrosis in the dad, then breed him with a female rat and then injure their offspring and then compare the amount of scarring to rats bred from injured or un-injured parents.

For these reasons these programs of work can only be conducted in animals and not alternative systems such as growing cells or thin slices of an organ in a petri dish.

Wherever possible, we use human tissue to isolate cells or make slices or stable cell line cultures generated from human cells, which we can culture in a petri dish to replace animal models of liver disease.

We also use stored frozen and wax embedded liver tissue collected from previous studies to help answer our research questions and minimize further use of animals.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Studies are always planned very carefully and use statistical analysis to calculate the minimum numbers of animals needed to achieve meaningful results and achieve our research aims.

Primary cells, cell lines and slices of liver tissue are also used to help reduce numbers of animals used. Before testing drugs in rat models of liver disease we first show that they have a “therapeutic effect” in cultured cells and tissue slices, this way we only test drug that we expect/predict to have a positive response.

Using non-invasive imaging is another strategy we employ to reduce group sizes or numbers of time points.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

All of the liver disease models chosen are the lowest severity model that can be used to answer our research questions.
Whilst, the majority of work is performed in mice under a separate project licence, some procedures are necessary to perform in rats because of the nature of the drug or imaging agent being tested or help advance our understanding ofthe disease biology.

For example, the chemical model (carbon tetrachloride) is very predictable therefore we can predict the disease stage at any given time point. We have lots of experience running drug studies in this chemical model, therefore we know exactly what time to give drugs and for the length of time to treat the animals. In this model rats receive bi-weekly injections of the chemical into their belly, however before we start the model the rats under a period of handling to minimise the stress of restraint and an injection.

We have good surgical techniques and operating theatres/equipment to minimise the risk of infection. The bile duct ligation model is a surgical model. In this model rats receive pain relief and a high level of post-operative care including soaked diet, a warm environment and fluids as required to minimize stress and suffering. We work with the vets and animal behaviour/welfare scientists to develop clinical scoring system to help assess the animal's well-being and level of disease.

Animals are checked regularly and supportive care is readily provided to minimise suffering and improve the rat's welfare.

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Individual variation and susceptibility to developing addiction-like behaviour, as well as the success of treatment strategies, will be compared in (1) animals that vary in motivation, (2) animals exposed to certain or gambling-like uncertain rewards, and (3) animals that experience early-life stress.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Studying the neurobiology of motivation and attention in animals may help us to understand disorders such as addiction people. The proposed research stems from our finding that certain rats, due to both biology and experience, are highly-attracted to reward-related stimuli may also display addiction-like behaviours. The brain's dopamine system also functions differently in these animals, and this may result from differential expression of specific dopamine-related proteins. Genetic differences in these proteins have been proposed to relate not only to addiction in people, but also ADHD and autism. Our goal is to investigate how variation in dopamine-related neurobiology in animals impacts addiction-like behaviour. Accordingly, we aim to develop strategies for decreasing potential development of addiction in susceptible individuals. Psychiatrists and clinical psychologists treating patients for mental health disorders will also benefit from our results. For example, patients with substance use disorder may be attracted to environmental cues that are predictive of a drug, and these cues may, therefore, promote drug-seeking. Our findings may suggest that it is possible to reduce the motivational power of these cues, either through cognitive-behavioural or pharmaceutical approaches. Beyond these initial goals, the research has relevance to increasing our understanding of the neurobiology of the brain's dopamine system. Thus, individuals who study a variety of disorders will benefit from the results. Following publication, results will be shared in an online data depository. We will encourage secondary analysis of the data.

What outputs do you think you will see at the end of this project?

This research will produce novel data which will be published in high-impact peer-reviewed journals, shared at conferences, and presented during invited seminars. Following publication, results (in the form of easily-accessible spreadsheets) will be shared in an online data depository. We will encourage secondary and meta analyses of the data.

Increasing understanding of (within 1-3 years):

- the neurobiological and behavioural-cognitive processes underlying individual variation in cue-evoked behaviour and addiction.
- how presynaptic regulation of dopamine transmission impacts postsynaptic signalling in dendritic spines and resulting cell body activation.
- brain systems that encode habitual versus motivated behaviours, and how these brain systems may become dysregulated in addiction.
- the shared neurobiology between drug and behavioural addictions, and the interaction with social experience during adolescence and adulthood.
- the influence of drug-taking environment on drug choice

Developing personalised pharmacotherapeutic and psychosocial methods for decreasing (within 2-5 years):

- acute and long-lasting motivational states evoked by exposure to reward-associated cues that drive aberrant reward-pursuit.
- habitual or goal-directed behaviours involved in reward-seeking or reward-taking.
- continued search for reward that occurs even when it is not available.
- motivation to pursue reward even when costs of doing so are high.
- choice of drug or pursuit of gambling by giving access to social reward.

This research will encourage the continued development of highly translational animal models of human behaviour, thereby refining research techniques (within 1-5 years).

A long-term consequence of researching individual variation in behaviour may be to reduce the total number of animals used, as neurobehavioural differences across rats will be acknowledged and studied with appropriate statistical methods (within 5 years).

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This research will interest academics who study (within 3+ years):

- how neurobiology influences patterns of behaviour evoked by environmental stimuli.

- how neurobiology regulates individual variation in motivated and conditioned behaviour.
- how neurobiology regulates individual variation in attention and impulsivity.
- neurological disorders involving the dopamine system. Such disorders include, but are not limited to, substance use disorders, eating disorders, ADHD, autism, schizophrenia, and Parkinson's disease.

This research will interest psychiatrists, clinical psychologists, and pharmaceutical industries who wish to treat patients for mental health disorders, including those who combine such methods as (5+ years):

- cognitive therapies designed to reduce the 'motivational magnet' properties of reward-predictive stimuli (especially those that influence addictive behaviours).
- contingency management therapies thatoffer social rewards
- pharmaceutical treatments for decreasing acute states of desire evoked by reward-predictive stimuli.
- individualised treatment methodologies for those identified as displaying high degrees of 'sign-tracking' or 'goal-tracking' behaviour.

How will you maximise the outputs of your work?

This research will produce novel data which will be published in high-impact peer-reviewed journals, shared at conferences, and presented during invited seminars. Following publication, results (in the form of easily-accessible spreadsheets) will be shared in an online data depository. We will encourage secondary and meta analyses of the data.

Species and numbers of animals expected to be used

- Mice: 3000
  Rats: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Some animals will perform tasks in chambers and consume food rewards (up to 6 hours per day, for several weeks). At certain points, animals may receive injections of drugs or control substances to alter their reward-related memories or motivational states (the number of injections an animal might receive will be limited). At the end of this experiment, rats will be humanely killed under anaesthesia. Their brains will be removed, and the tissues will be processed to investigate individual variability in neuronal structure and biochemistry.

Some animals will also undergo behavioural testing and receive, or self-administer, infusions of a drug (up to 6 hours per day, for several weeks). Surgery will be required for animals that self-administer a drug. In addition, some animals may also receive surgeries that enable (a) the injection of pharmaceutical compounds or viral vectors, or (b) the insertion of electrodes, directly into specific brain regions.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some animals may undergo surgery that will enable the measurement/modulation of brain activity and/or allow them to self-administer drugs directly into the blood supply. Following recovery from surgery, animals will not show clinical signs of distress during behavioural testing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

A significant portion of animals (approximately 1000 rats and 1000 mice) will experience only behavioural testing and will likely not encounter forms of distress. It is possible animals may be fed a specific amount of food at a certain time of day; this will help to motivate animals to pursue a food reward during behavioural tests. The weight of animals will be carefully monitored for abnormal gains or losses. We don’t anticipate any adverse effects of these studies.

Some animals will require surgery; example surgeries include (a) the insertion of a jugular vein catheter to support self-administration of drug (approximately 1000 rats), (b) the implantation of cannula into the brain to enable measurement or modulation of neuronal processes (approximately 2000 rats and 2000 mice), or (c) both of these types of surgery during a single session of anaesthesia (approximately 2000 rats). Surgical procedures are considered moderate in severity. Operations will be performed in anaesthetised animals using standard aseptic techniques, with the use of pain-relief medications. Animals will be carefully monitored for signs of distress multiple times per day for at least one week following surgery. We do not anticipate any long-term adverse effects of these procedures. At the end of this experiment, animals will be humanely killed.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To analyse the relationship between brain activity and behaviour, intact behaving animals are required. These experiments cannot ethically (or practically) be performed in people (e.g. implanting intracerebral cannulae).

The proposed experiments will enhance our understanding of the neurobiology of addiction and why some individuals develop addiction, while others do not. Accordingly, we will begin to develop personalised treatments for addiction.

What was your strategy for searching for non-animal alternatives?

Several *ex vivo* techniques will be used, including analysing the striatal neuroanatomy and biochemistry ofrats previously monitored for behaviour.

Why were they not suitable?

Since the studies link brain function and behaviour, it is necessary to sample brain regions taken from whole organisms and not from cultured cells. Because the relationship between brain neuroplasticity and behaviour is largely unknown, it is not currently possible to model *in silico*.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Appropriate statistics have been used to minimise the number of animals used. The number of animals used (and experimental design) are also based on evidence from previous studies of individual variation in behaviour.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Procedures have been optimised in our previous research. Where possible, a within-subject experimental design will be used, reducing animal numbers. Based on previous research screening 1000s of rats for Pavlovian conditioned approach, we expect a roughly equal distribution of behavioural phenotypes. Neuroanatomy or neurochemistry can be assessed in each rat by making separate observations in each hemisphere, thereby reducing the number of animals needed. Rats will be assigned to groups according to a randomised Latin Square Design and maximum effort will be made to ensure thatthe experimenter will be blinded.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies using small numbers of animals will be performed to optimise testing procedures before more extensive experiments take place.

We will record all factors that may impact individual variation in behaviour. For example, in the past, we have found that some rats that are ordered from specific facilities belonging to certain commercial suppliers are more likely to display particular behavioural traits (e.g., sign-tracking vs goal-tracking). Therefore, it is critical to consider what commercial supplier should be used when ordering animals for a given experiment; this will help reduce the number of animals used.

Other researchers at the establishment may perform similar behavioural experiments to those included in this project license (e.g., Pavlovian Conditioning). It is possible, therefore, that brain tissues taken from animals tested under other project licenses at the establishment can also be tested for neurochemical process related to learning, memory, and motivation. Some brain samples from animals used on our other licensed work can be used for addressing the research objectives of the present application (as well as serve as samples for pilot studies). Such samples have been taken into account and have reduced the number of animals required for use in this project license.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In the proposed experiments, studies in which animals do not undergo surgery (approximately 1000 rats and 1000 mice) are mild in severity and will not result in substantial pain, suffering, distress or lasting harm (PSDLH).

Studies that require animals to undergo surgery (approximately 5000 rats and 2000 mice) are considered moderate in severity. Animals recover quickly from surgery and will not have long-lasting PSDLH. From an experimental perspective, animals mustn't be tested if they exhibit signs of PSDLH; the presence of PSDLH would influence behaviour and thus confound the experimental results.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The use of rats and mice enable the investigation of individual variation in complex behaviours and the easy/replicable analysis of brain-region-specific neuronal processes. Less sentient animals (than rats or mice) would not be able to perform the behaviours we are studying, and thus such animals cannot be used.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Every effort will be made to refine procedures and minimise potential sources of distress. Animals will be given suitable bedding, shelter, chew-blocks, and nesting-material in appropriately-sized cages. Health will be monitored at least daily. For injections, safe volume sizes and needle gauges will be used. Experiments will have well-defined endpoints (after specific behavioural observations). Animals will be humanely killed.

All surgeries will be performed aseptically using combined general and local anaesthesia, according to well-established protocols. Following surgery, animals will be closely monitored for at least one week, given post-operative analgesic and anti-inflammatory agents based on Home Office practices and veterinary advice, and provided with palatable food to minimise distress. Individuals performing surgeries will be trained and supervised.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

When designing experiments and sharing our results, we will follow the recommendations of the ARRIVE Guidelines (Animal Research: Reporting of In Vivo Experiments) and the Experimental Design Assistant (EDA) provided by the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs).

We will follow the Animals (Scientific Procedures) Act 1986 (ASPA) and the Home Office's Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will regularly undergo reviews of our experimental and surgical procedures with our NACWO and NVS. We will also attend seminars on best practices in animal research that are held at the establishment and conferences we attend. We will follow events, updated documents, and blog/news posts that are highlighted on the website (and in email newsletters) published by the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs).

Explain the choice of species and the related life stages

To analyse the relationship between brain activity and behaviour, intact behaving animals are required. These experiments cannot ethically (or practically) be performed in people (e.g. implanting intracerebral cannulae). Therefore, the use of rats and mice enable the investigation of individual variation in complex behaviours and the easy/replicable analysis of brain-region-specific neuronal processes. The proposed experiments build upon our previous research.

Only rats will be used for studies in which animals are trained to self-administer drugs. There are several reasons for using rats, rather than mice, for self-administration, including (but not limited to) more straightforward surgery due to larger body size and better comparison to previous research (e.g., PubMed scientific literature search: "rat cocaine self-administration", ~2,750 articles; "mouse cocaine self-administration", ~430 articles). Also, rats have larger brains than mice; this allows for greater precision in the study of certain sub-regions of the brain (e.g., the core and shell subdivisions of the nucleus accumbens).

Genetically modified mice may be used for the study of specific cell types in the brain. These mice, which are engineered to express certain identifiable markers in specific neurons, are available both commercially and from our collaborators. Equivalent genetically modified rats are not readily available and may be more challenging to engineer.

The majority of animals used will be considered adults. A subset of experiments may use juvenile rats; these experiments will model how, in people, social experiences early in life can influence both the development and persistence of addiction.

NON-TECHNICAL SUMMARY

126. Models of haematopoiesis, therapy and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims firstly to improve our current understanding of cause and effect relative to each molecular lesion in Primary Immunodeficiency Diseases and metabolic disorders / Lysosomal Storage Diseases with the aim of improving existing treatment and developing new therapies.

Secondly we wish to demonstrate pre-clinical efficacy and safety of cellular and gene therapy protocols and conditioning regimens for treatment of PIDs, LSDs and malignancies, with an aim to improve upon the current vectors and protocols used in existing clinical trials.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Primary immunodeficiency diseases are genetic disorders classically characterised by impaired host defence and an increased susceptibility to infection. PIDs are associated with congenital defects in haematopoiesis and a dysregulated immune function. Due to rapid progress in diagnostic techniques, especially genome sequencing, more than 350 distinct disorders of In-born errors of immunity have been identified, with several new disorders identified every year. Most of the PID patients suffer from recurrent infections, have a poor quality of life, and will die if left untreated. The current treatments for PIDs are 1) expensive e.g. PEG-ADA (a current enzyme based therapy) costs between £200,000 and £400,000 per year compared to a one off treatment with gene therapy. and 2) cause adverse effects such as long-term toxicity.

The expected benefits of this project are firstly improved understanding of primary immuno deficiency diseases and metabolic diseases. Human samples are rare and often in small quantities due to the affected individuals mainly being children. The use of animal models allows an ethical and practical solution to this. Secondly we aim to improve the treatments available for Primary immuno deficiency diseases through the continued development of both cellular and gene therapies. We have shown a clear benefit from previous work where we have moved gene therapy treatment from the bench to the bedside, with the use of murine models crucial to this. We have also increased our understanding of haematopoietic stem cells and our ability to manipulate them. We are continually developing novel vector elements to improve the expression levels and location thus increasing the efficacy and safety. We expect further clinical trials to be started within the lifetime of this licence. Advances in vector development have shown clinical efficacy without the side effects previously seen. The next 5-10 years will see the treatment of these diseases using gene editing approaches, and also based upon vector improvements and increased understanding of the molecular basis of the disease.

What outputs do you think you will see at the end of this project?

Outputs are pre-clinical data that will be used to translate novel cell and gene therapy protocols into the clinic and publications in peer reviewed journals of new information for the benefit of the wider scientific community.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The main beneficiaries of this research are paediatric patients affected by monogenic disorders or cancer and their families.

The knowledge accumulated with these studies will also shed light on the properties of different sub-populations of cells involved in haematopoietic system and immune system, such as haematopoietic stem cells or T cells which will be beneficial to the entire scientific community.

How will you maximise the outputs of your work?

The outputs of this work will be used to secure further funding needed for translation of the pre-clinical data into the clinic.

The data generated will be shared with the scientific community through peer reviewed publications and presentations at relevant scientific meetings, including unsuccessful approaches, in line with the principles of 3Rs.

Species and numbers of animals expected to be used

- Mice: 15,600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be bred, tagged, marked and genotyped as appropriate. They may be used only for harvest of organs to study a particular disease phenotype at a particular stage of their life or may be used in other experiments.

Animals may be used in transplantation studies after conditioning by Chemotherapy, irradiation or antibody based reagents. Transplantation may be carried out by intravenous, subcutaneous, intraperitoneal, intrafemoral routes in adults, or intrahepatic or supra-facial veins in neonates, or in-utero laparotomy for transplantation of embryos. The engraftment of the transplanted donor cells will be tested by peripheral blood sampling or bone marrow biopsies of the recipient mice. The effectiveness of the immune reconstitution may be tested by challenging with immunomodulators. Animals may be then sacrificed by a schedule 1 method or by terminal anaesthesia for organ harvest.

Animals transplanted with cell and gene therapy products may be functionally assessed using motor function tests, cognitive tests and scans to confirm the restoration of their normal function. These tests are especially relevant to lysosomal storage disease models which exhibit musculo-skeletal, brain, cardiac and respiratory abnormalities.

Induced pluripotent cells may be assessed for their safety and efficacy by transplanting into immunodeficient mice. Occasionally certain induced pluripotent cells may induce tumours, and those animals will be sacrificed humanely before it exceeds the protocol severity.

Gene and cell therapy products which are specifically developed for treating tumours will be tested for their anti-tumour efficacy, after transplantation of the minimum number of tumour cells required to form a tumour. The time taken for the development of tumour may range between couple of weeks to a few months depending on the type of tumour studied.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Immunodeficient mice may develop pathogenic infections. Animals are therefore maintained in individually ventilated cages with sterilised bedding, water and food. Lysosomal storage disease mouse models may occasionally develop signs of Joint/muscular disease, respiratory, central nervous system or liver disease.

Animals that are conditioned using total body irradiation are expected to experience some weight loss and loss of condition during the first few days after irradiation. Pregnant dams that have had laparotomy for in-utero transplantation of embryos are expected to suffer moderate post-operative pain for a few days. Transplanted mice that undergo bone marrow biopsy are expected to experience moderate pain and transient difficulty in ambulation for a few hours. Superficial blood vessel sampling can (very rarely) cause profuse bleeding.

induced Pluripotent stem cells, upon transplantation can induce malignant transformation, and therefore some animals may form tumours, which can cause moderate pain. These tumours develop at the site of sub-cutaneous injection in flank region and is not expected to cause significant disruption to their normal activity. Animals that develop tumours are usually culled within a few days from the initial diagnosis.

Animals that are subjected to motor and behavioural function tests may experience some discomfort for a few minutes during each time point of testing.

Animals that are transplanted with tumour cells are expected to show weight loss, loss of appetite and general wellbeing for a few days, which may cause moderate pain. These symptoms usually relate to the tumour volume, site of tumour formation, degree of metastasis etc. On very rare occasions, superficial tumour may bleed or ulcerate and can cause secondary infections.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals do not suffer from significant adverse effects from the procedures that are undertaken in this license. However around 10-20% of the animals may suffer some from some clinical signs for a short period of time, as a result of the underlying disease.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Primary immunodeficiency Diseases (PIDs) and Lysosomal Storage Diseases (LSDs) are very rare diseases, and patients are few (even at large centres like REDACTED). Affected individuals are often very young children from whom only small blood samples can be obtained. The use of animal models of these diseases also allows us to study the immune system in vivo which is often not ethical or practical in humans. No other non-animal models exist that mimic human immunodeficiency and lysosomal storage disorders diseases and allow xenotransplantation as well as the PID mouse models we want to use. The complex organisation of the haematopoietic system makes in vitro culture unsatisfactory. In vivo experiments are required to measure engraftment and longevity of haematopoietic stem cells and development of functional immunity because the complex multifactorial interactions cannot be assessed in vitro. The safety of vectors over long periods of time and the potential for insertional mutagenesis can only be adequately assessed in vivo. In fact the current guide lines state in vivo testing is mandatory for testing efficacy of treatment in disease models, and assessing safety for the whole organism. It is not ethically possible to study PID, LSD, haematopoiesis or conduct cellular and gene therapy protocols in humans and current in vitro techniques are not sufficient for research or clinical regulatory bodies. In vivo experiments are required to measure engraftment and longevity of haematopoietic stem cells and development of functional immunity because the complex multifactorial interactions cannot be assessed in vitro. In addition we want to

assess the impact on health and behaviour. The safety of vectors over long periods of time and the potential for malignancy can only be adequately assessed in vivo.

What was your strategy for searching for non-animal alternatives?

In vitro culture

Mathematical modelling

Why were they not suitable?

In vivo experiments are required to measure engraftment and longevity of haematopoietic stem cells and development of functional immunity because the complex multifactorial interactions cannot be assessed in vitro. In addition we want to assess the impact on health and behaviour. The safety of vectors over long periods of time and the potential for malignancy can only be adequately assessed in vivo.

In fact the current guide lines state in vivo testing is mandatory for testing efficacy of treatment in disease models, and assessing safety for the whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For each experiment involving mice we will use statistical software packages and power analysis in order to define the minimum number of mice to be used as well as using our knowledge from previous experimental group numbers. Number of animals in each group will be adjusted depending on the effect size expected. Typically we expect experimental groups to consist of six to twelve mice. Sharing control groups for comparable treatments groups will also reduce the number of mice to be used.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Careful considerations were given to the Arrive guidelines and information available through the NC3Rs website using features such as Experimental Design Assistant to ensure that the minimum

number of animals are used in this project keeping in mind the experiments are robust and reproducible as possible and providing the best welfare possible for the animals.

What other measures apart from good experimental design will you use to minimise numbers?

Where possible, each animal will be used for multiple analyses post mortem (for example histological and immunological). Where animals have to be genotyped this will be done as early as possible and wild-type littermates will be used as controls thus minimising the need to purchase control animals. For longitudinal studies such as behavioural studies, we will maximise the observation points during the period when clinical signs are expected to reduce the overall number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We have chosen mice as we are studying models of inherited disease and mice are the most appropriate and best characterised lowest vertebrate group animal model. Murine models are regarded as the most appropriate judged by peer reviewed publications. Immunodeficient models are the most appropriate models which will allow the engraftment of human cells that are subjected to gene therapy and gene editing protocols.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Where appropriate, we use neonatal mice for studying haematopoiesis, by engrafting gene therapy and gene edited cells via intra-hepatic or supra-facial route in neonates and by inutero approaches by directly transplanting into foetuses.

However, some of the disease phenotypes are exhibited at certain developmental stages of the animal and often only in mature animals, requiring investigation at different time points.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Where possible we propose to treat before the onset of disease with in-utero injections rather than treat once disease has been established to minimise suffering. We have experience with breeding

immunodeficient animals and with long established protocols that have well defined end points so are able to provide high level training and thus competence for experimental procedures. Where necessary we will seek out advice and expertise from other groups in the UK and abroad to minimise suffering.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The ARRIVE Guidelines

NC3Rs resources

Workman et al, British Journal of Cancer 102, 1555–1577 (2010) guidelines for tumour studies

How will you ensure you continue to use the most refined methods during the lifetime of this project?

NC3Rs website - https://www.nc3rs.org.uk/

Attending external conferences and seminars on animal welfare.

Explain the choice ofspecies and the related life stages

We are interested in studying the disease mechanisms, and developing novel therapies for primary immunodeficiencies, metabolic diseases and malignancies in a paediatric setting. Therefore we have chosen to use immunodeficient models which are highly efficient in engrafting human haematopoietic and immune cells. Moreover, the mouse models we use faithfully reproduce most of the clinical signs and phenotypes observed in humans.

In general, we will use adult mice for most of the experiments. However, there may be a few instances where neonates and embryos may be studied, in order to specifically understand the pathogenesis around the onset of disease as seen in human neonates and the influence of a specific mutation in the perturbation of normal development of the haematopoietic and immune system.

NON-TECHNICAL SUMMARY

127. Modulation of identified neural circuits for memory

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim is to define the types of brain cells responsible for giving us the ability to create, store and recall memories. To investigate this, we will control the activity of select subpopulations of nerve cells while monitoring the activity from other nerve cells that are connected to them, focusing on brain regions that contribute to mnemonic functions, such as the hippocampal formation, and parts of the thalamus and basal forebrain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Creating, storing and recalling memories is fundamental for survival as it helps us anticipate novel experiences and make predictions on how to act. By studying these processes in rodents, which have very similar brain structures and nerve cell connections to humans, we can define how memories are distributed in the brain and gain insight into what happens when this process starts to break down in progressive neurological conditions such as dementia.

What outputs do you think you will see at the end of this project?

We are working on brain regions that are known to be affected in neurodegenerative diseases such as Alzheimer's disease, which include the hippocampus and entorhinal cortex. These are key areas of the cerebral cortex (the outer part of the brain) that are vital for memory, including how we find our way around and how we remember locations and events. Other brain regions below the cerebral cortex are also very important for memory. We will define the activity, kinds of nerve cells, and connectivity to these cortical regions to increase our understanding of how memories are stored.

We will compare data obtained from mice and rats (e.g. models of neurodegenerative diseases) to data obtained from dementia patients and healthy controls. These will include data on the distribution of proteins that mark different populations of nerve cells and the presence of pathological (dysfunctional) proteins that indicate the disease. Other data include new information on the activity patterns of the different kinds of nerve cells contributing to memory in connected brain regions.

Valuable scientific (neuroscientific and neurological) data will be collected, advancing our understanding of the mechanisms involved for creating, storing and recalling memories, discovering and defining new nerve cell types that are responsible for spatial/episodic memories that end up in brain regions such as the hippocampus, and also gaining much needed insight into how these processes break down in the stages leading to dementia.

Valuable data collected from animals will be published in open-access peer reviewed journals. The multidisciplinary approach we use to study the brains of both rodents and humans will benefit the neuroscience community as well as clinicians and patients through access to these data in published form but also via other outputs such as public talks and seminars, posters and social media.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The immediate benefits will be to the neuroscience and neurodegeneration fields. The outputs can be rapidly disseminated at conferences and in the form of preprints (e.g. BioRxiv) before peer review publication. Novel observations and new insights relating to the cell types critically involved in enabling mammals (including humans) to encode, store and recall memories will be used by other laboratories and scientists to advance their own research.

Our findings will benefit the public, e.g. through outreach events, explaining how and why we do research. If we discover how particular proteins implicated in neurodegenerative diseases directly affect nerve cell activity, this information will benefit patients, medical professionals and pharmaceutical companies. This may take a long time (3-5 years) due to the different avenues of investigation required to understand mechanisms underlying memories.

How will you maximise the outputs of your work?

- Research results will be disseminated by publishing them in reputable journals in open access format, so that they are available to all
- Results and knowledge will also be disseminated through public lectures and poster presentations in scientific meetings and in teaching
- Open days, outreach events, science festivals
- Collaborations with other groups will be used as a way to efficiently share knowledge and expertise
- International exchange programmes, whereby scholars and students from other countries visit our research group
- Social media and press releases, videos

Species and numbers of animals expected to be used

- Mice: 10,000
- Rats: 1,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Studying brain activity at the level of individual nerve cells, and in populations of nerve cells in different brain regions, requires surgery in order to implant miniature devices that can detect brain signals. These surgical procedures are similar to those done for human patients, in that rodents are given an anaesthetic to put them to sleep and block any pain, then the skull is exposed, and extremely fine wires are lowered into the brain and secured in place with special bone cement. Sometimes we will inject into specific regions of the brain a non-harmful virus that will express specific proteins in groups of nerve cells. Surgeries typically last 2 hours and the animal recovers in its home cage, often with its cagemates, within ~24 hours. Some more advanced surgeries will last longer (e.g. implanting more complicated recording/imaging devices) and have a slightly longer recovery.

For actual experiments, rodents have their memories tested by letting them do some behavioural tasks such as running in mazes for sugar rewards. For the animals that have undergone surgery, they will be connected to cables so that we can monitor brain activity on a computer while they do behavioural tasks, simply explore an environment, or sleep. In some experiments, we will shine light inside the brain using a fibre optic cable, and this light is able to activate the special proteins that are expressed by the virus that was injected during the surgery. This light activation causes the nerve cells to become activated and we can measure what happens to other nerve cells after light delivery. By implanting a mouse with a small plate attached to the skull, we can temporarily restrain them by the head while they are free to voluntarily move and rest on a treadmill. Mice adapt very well to this and it enables us to gain direct access to the brain using specialised probes (such as glass electrodes), in order to accurately record activity of nerve cells from small regions of brain that would be very difficult to target otherwise. In other experiments with mice, we can actually visualise brain activity through a microscope while the mouse is running and resting on the treadmill. This enables us to understand how brain activity of different populations of nerve cells relates to memory, such as spatial navigation and recalling events.

We will use genetically-altered animals that have been engineered to express human proteins that are implicated in neurodegenerative diseases such as Alzheimer's disease and frontotemporal dementia. The expression of these proteins in the brain affects memory, so that genetically-altered animals show deficits in memory that increases with age. We want to keep these animals for many months, including until they are 'aged' (greater than 15 months old), so that we can track how the brain circuits directly related to memory are gradually affected and understand the mechanisms involved in their degredation. For the vast majority of these genetically-altered animals, their daily life is unaffected and the memory impairments do not impact their welfare.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Although we give the animals appropriate anaesthetics for pain relief, after surgeries when the drugs wear off they may occasionally feel some pain where the implants have been attached on the skull. This is temporary and most animals return to normal within 1-2 days. However in rare cases where they exhibit clinical signs we would give appropriate drugs to reduce this.

To motivate the animals to do certain behavioural tasks like learning how to find a sugar reward in a maze (testing their memories), we may need to temporally restrict their diet. This means that they lose weight (typically up to 10% of starting body weight) while they are being trained and tested.

For aged animals (greater than 15 months) we expect some to develop age-related conditions, much like humans do. These conditions will be monitored closely and animals will be used for experiments at the earliest stage possible.

For a minority of genetically-altered animals that have been engineered to develop memory impairments, a particular line may show some minor impairments in motor coordination that increase with age (e.g. gradual loss of hindlimb movement). This is a consequence of the type of genetic alteration. REDACTED and wherever possible the scientific information will be obtained before significant motor impairments develop.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All animals that undergo surgery (~70% of animals) are expected to reach moderate severity, since the surgery involves exposing the skull and attaching implants. This experience typically lasts 2-5 hours over the lifetime of the animal (1-2 surgeries per animal). For the majority of its time under procedures, the severity will be mild or even sub-threshold (we find that the animals actually enjoy exploring mazes) and experiments where we record brain activity typically do not involve any anaesthesia.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The anatomy, neurochemistry and physiology of a particular region of the brain, or indeed individual neurons in a particular region of the brain, can only be established by the analysis of the brain itself and thus requires the use of animals.

It will be necessary to carry out the experiments on mammals rather than reptiles or fish because other groups of animals do not have a brain structure sufficiently similar to humans. Experiments will thus be carried out on rodents. With the increasing scientific interest and availability of genetically altered animals, particularly those that mimic some aspects of neurodegenerative disease, mice will be the preferred rodent species. Genetically altered mice will mainly be used to aid in the discovery and definition of particular populations of nerve cells, and to artificially change (increase or decrease) their activity, which can reveal how particular neurochemicals affect memory, and how this activity relates to disease mechanisms. We will endeavour to use the most appropriate model for neurodegenerative

diseases such as Alzheimer’s disease and frontotemporal dementia; these models may be replaced over the course of the licence so that we only use the 'best' currently available model(s).

What was your strategy for searching for non-animal alternatives?

In addition to studying nerve cells in human brain slices in a related non-animal project, care will be taken to monitor the progress of the use of in vitro methods, such as organotypic co-cultures, to determine whether they can substitute for at least some of the in vivo work. We are also keen to explore in silico methods (advanced computer models) by initiating collaborations with computer scientists.

It will be necessary to use invasive techniques to study the brain instead of non-invasive imaging techniques (e.g. fMRI, PET and other forms of imaging) because of the low spatial (millimetres or centimetres rather than nanometres) and temporal (seconds rather than milliseconds) resolution of these imaging techniques.

Why were they not suitable?

Although we will also study human brain tissue to compare to the rodent, this cannot replace the use of animals because the questions we ask require behaviourally-relevant activity patterns involving large populations of brain cells. These particular patterns can not be replicated in cultures either.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimated the number of genetically altered animals generated through breeding and how many would be genetically altered (heterozygotes) and how many offspring would be non-transgenic. For animal experiments involving surgery (which includes the genetically altered animals), we based the numbers on previous licences involving similar procedures, the success rates for obtaining scientifically-relevant results, the difficulty of experiments, and the time investment in each animal relative to the number of researchers and their capacity.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Following expert statistician advice and taking assistance from the NC3Rs' Experimental Design Assistant, we can confirm that we have designed experiments compliant with subsection 4.1.3 of the Medical Research Council guidance with optimal sample sizes and high precision allowing within-subject and unbiased between-subject comparisons in order to achieve maximal statistical power.

What other measures apart from good experimental design will you use to minimise numbers?

We will monitor closely and implement efficient breeding, test new conditions using pilot studies and will be reusing tissue from the same animals for histological and electron microscopic investigations.

We will test antibodies as far as possible on tissue sections taken from the human brain.

Much of our work involves ex vivo analyses in which we perform immunocytochemical studies on perfuse-fixed tissue. In these experiments the sections that are not used are stored for future studies. Our multidisciplinary approach by combining physiology/tract-tracing/histology in individual animals enables far more data to be obtained from single animals than would be obtained employing standard methods. These combined experiments will be planned carefully for maximum scientific output with the minimum of cumulative effects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The use of wild type and genetically-altered mice (and to a lesser extent, rats) will allow us to take advantage of the wealth of information already available, thus aiding the interpretation of our results. We will thus exploit the power of genetics (and, more specifically, of genetic alteration or transgenesis) to give us the specific or selective access to certain cell types that we need to carry out the proposed functional investigations. Because of the wide availability of genetically altered mice and the relative ease of modifying mice, over the duration of the proposed licence more mice and fewer rats are likely to be used.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The cerebral cortex and related structures in the brain are relatively conserved in mammals. Rats and mice are the species about which we know most and are thus considered the least sentient vertebrate group in which to carry out the experiments. Data from these species are directly relevant to human cortical function and dysfunction.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Good surgical practice and aseptic surgery will be carried out using appropriate drugs to minimise any adverse effects of the surgery. Animals will be frequently monitored during post-operative recovery until being able to engage in species-specific behaviour.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

REDACTED

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We subscribe to the NC3Rs newsletter, attend Institutional/Departmental Animal Welfare meetings, attend animal welfare events (e.g. NC3Rs Research Days), and maintain excellent communication with animal technicians and vetinary surgeons.

Explain the choice ofspecies and the related life stages

We are mostly using adult mice, and sometimes adult rats. They are excellent species to work with because we know a lot about their physiology and anatomy, which is very similar to human. They adapt very well to the experimenter (as with pets) and scientists have tools specifically designed to be able monitor brain activity that work very well with these animals. The vast majority of animal experiments in research institutions use mice (and rats), so the infrastructure (housing, husbandry, expertise of vets etc.) is optimised for their welfare. Furthermore, genetically-altered animals (mostly mice) have been bred that mimic some aspects of neurological diseases, such as Alzheimer's disease, so this makes these animals ideal as models for human diseases.

Home Office

NON-TECHNICAL SUMMARY

128. Modulators of Immunity and Inflammation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Research into parasite infections with two overarching objectives, (i) to promote protective immunity through vaccination and/or other interventions; and (ii) to exploit natural immunomodulating products of parasites in the therapy of inflammatory disorders.

A retrospective assessment of these aims will be due by 13 November 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

More than 2 billion humans worldwide are afflicted with parasitic helminth infections, which are also highly prevalent in livestock with substantial welfare and economic consequences in the UK. No vaccines are currently available for human use, and are very limited in the veterinary sphere. In addition, a high percentage of the human population, particularly in countries such as the UK, suffer from inflammatory disorders (such as asthma, diabetes, inflammatory bowel disease and multiple sclerosis) which are poorly treated. Helminth (worm) parasites have evolved natural pathways to suppress inflammation and their molecular products may offer novel therapies to treat inflammatory diseases in humans.

What outputs do you think you will see at the end of this project?

Our primary outputs will be publications so that knowledge will be in the public realm. In addition, there may be commercial products based on, or using, the scientific results for therapeutic immunomodulators and/or new vaccine targets.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The impact of helminth modulators is likely to be high, in the longer term; we cannot predict which precise products will prove to be the most effective in treatment of inflammatory disorders, but the project is mining a rich vein of previously unexplored molecules. The impact on future vaccine development is also likely to be high, in the longer term, both through conceptually identifying the best strategy, and in taking specific vaccine antigens forward for clinical testing. In terms of vaccines, it is

also important to factor in the impact on animal health, if we can prevent helminth infection in livestock across the UK and globally.

How will you maximise the outputs of your work?

We will maximise output not only through the conventional channels (formal publications, conference presentations etc), but also through new forms of communication (BioRxiv, the laboratory website and Twitter streams), plus new forums for recording robust but unsuccessful studies such as Wellcome Open Research.

Species and numbers of animals expected to be used

- Mice: 29750
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Two types of procedures will take place. In the simplest, we will infect mice and rats with parasites so that we can grow the parasites and collect molecular products from them. These animals will be injected, or given parasites by mouth, just once. In more complex work, we will also induce in mice diseases corresponding to human disorders of allergy, multiple sclerosis and inflammatory bowel disease, which involves administering allergens, self-proteins and noxious substances to the airways by inhalation, the peritoneal cavity by injection, and the intestinal tract by mouth or rectal administration. Then test substances will be given to the mice by injection, by mouth, or by implanting miniature pumps that continuously release the substance. Typical experiments will last 1-2 weeks and the total number of animal used over 5 years is likely to be 10,000.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most animals show no untoward effects of the parasite infection itself in the doses and time scales we use. However, to test the effects on inflammatory diseases, some animals will develop stressful signs including weight loss, respiratory or intestinal discomfort, diarrhoea or in very few cases, limb paralysis. These effects may last for up to 2 weeks, although in severe cases (such as limb paralysis) the animal would be culled humanely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Sub-threshold - 40% of mice, 80% of rats.

Mild - 40% of mice, 20% of rats.

Moderate - 15% of mice

Severe - 5% of mice

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 13 November 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The parasites we study, the helminth worms, can only complete their life cycle in living animals, in our case mice and rats. The diseases we study are the incurable inflammatory disease of humans (asthma, inflammatory bowel disease and multiple sclerosis) each of which is a complex combination of factors only found in the live mammalian animal.

What was your strategy for searching for non-animal alternatives?

Laboratory cultivation of parasites without need to infect live animals; laboratory production of antibody-like reagents from bacteriophage; use of cell lines and tissue explants.

Why were they not suitable?

Currently, it is not possible to cultivate the parasites to complete their life cycle entirely in the laboratory, although this may become possible in the future and we will continue to monitor progress in this area. In vitro techniques for antibody generation cannot reliably produce high affinity reagents due to the lack of mutated affinity matured sequences; cell lines and tissue explants do not incorporate the complex web of innate, adaptive and stromal cell populations which migrate and differentially expand in vivo.

A retrospective assessment of replacement will be due by 13 November 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I referred to the annual usage of my research group over the past 10 years maintained at a similar level of staff members, having considered where we could reduce the number of animals used.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

At every step of the Protocols we have considered whether overall numbers can be reduced, refining for example techniques to minimise variation (and therefore group sizes) and taking advantage of recent innovations (for example single cell RNA sequencing) which greatly expand the data that can be recovered from individual animals, again obviating large group sizes. A further very significant development has been the method for growing laboratory cultures of intestinal cells which form "mini-guts" of differentiated, functional tissues reproducing the architecture of the intestinal tract, that allow us to test the effects of parasites and parasite products on intestinal epithelium, avoiding the use of procedures on live animals.

What other measures apart from good experimental design will you use to minimise numbers?

Our laboratory strives to make most efficient use of the animals available, synchronising workplans so that, for example, from a single donor mouse, some tissues (eg the spleen) are harvested as a source of lymphocytes (white cells) of the immune system, while intestinal stem cells are also recovered to form the cultures of "mini-guts" that grow to reproduce the architecture of the intestinal tract in laboratory-based experiments. Work to produce infective parasites is also organised to maximise efficiency and minimise animal numbers, with each round of infection serving to provide parasites for multiple procedures within the Project.

A retrospective assessment of reduction will be due by 13 November 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The animal models we use for parasite infection cause minimal suffering or distress to the rodents as they are naturally well-adapted to their host. The models of inflammatory disease, however, do inescapably cause a degree of suffering as they are designed to replicate severe human conditions. Our approach is to select models (a) which are very well established and well characterised with respect to the course of disease; and (b) on this basis select a window of time for analysis which minimises any suffering the animals may experience.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The animal models have all been developed in laboratory mice, and no alternative species is known. The models take up to 6 weeks to develop and hence anaesthesia is not appropriate.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will continue to discuss within our regular laboratory meetings, and at every opportunity with our veterinary colleagues and NTCO. An early priority will be to test smaller gauge needles for subcutaneous injection of parasites, to establish the optimum for animal welfare that does not damage the parasite larvae through shear forces within the needle. More broadly, we will encourage our research staff to attend courses such as the FRAME training school in experimental design.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our principal guidance will be through the ARRIVE (Animal Research Reporting of In Vivo Experiments) guidelines available through the NC3Rs website. In addition, our Animal Welfare and Ethical Review Board (AWERB) also produces specific guidelines (eg most recently on single use of needles, also blood sampling procedures) that further refine and ensure best practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our REDACTED has a very active system for disseminating information about best practice and new approaches for the 3Rs, including organising an annual 3Rs Symposium, and we are in frequent dialogue with our veterinary colleagues and our Named Training and Competency Officer (NTCO), about specific steps in the procedures we employ.

Explain the choice ofspecies and the related life stages

Rodents provide natural hosts for parasites of the intestinal tract which are related to those infecting some 2 billion people in tropical countries; we will study the immune response of adult mice in order to develop new vaccines, and to understand how the parasites can switch off host immunity in a manner that would be useful for new anti-inflammatory therapies.

A retrospective assessment of refinement will be due by 13 November 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

129. Molecular and Genetic Regulation of Glial Development and Function

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Zebra fish	adult, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our work aims to understand what genes allow glia to develop properly and provide support to a healthy brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

As life expectancy increases, there are a growing number of brain diseases affecting people. Researchers need to continue figuring out how the brain develops and functions so that these diseases can be treated or cured. Our brains are made up of two types of cells — some of these produce electrical signals (neurons), and others provide support (glia). For centuries, research has focused on neurons being the cause of brain disease. In many conditions, including Parkinson's and Alzheimer's, the supportive glial cells are abnormal and lose their ability to function. This research shows us that glia are very important in normal brain function. In fact, we now know that glia are often the underlying cause of these diseases. However, we still don't know much about how glia develop, and we don't understand how they protect our brains. Our studies try to start breaking the ice on how glia develop and function at a very basic level. We hope this will help find new ways to treat or prevent brain disease.

What outputs do you think you will see at the end of this project?

The goal of this project is to learn more about the fundamental principles giving rise to an appropriately shaped and functioning cell. This work will provide a valuable foundation for other research aimed at understanding the support cells(glia) of the brain. Some of the genetically altered animals generated in this research will also serve as valuable methods for designing new drugs used in the treatment of brain disorders. Throughout the project, we will share our findings with other researchers (at conferences or in collaborations) and will publish our results in open access journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We currently collaborate with other laboratories in the UK and internationally, who will mutually benefit from our findings to improve their experimental designs and establish new research programs aimed at understanding neural diseases. In the future, our results will likely enhance the development of drugs and/or methods that prevent, diagnose or treat human disease.

How will you maximise the outputs of your work?

We already have active collaborations with basic and translational research labs that mutually rely on our research findings. We actively publish all of our results and openly share our methods and resources with anyone who requests them. As is required by most funding bodies and within the REDACTED, we publish our findings in open source platforms. Peer-review publication is often time-consuming and is often missing many negative results or unsuccessful approaches. We do and will continue to share our findings on open source un-reviewed platforms such as Researchgate and Bio Archives, which includes details of adverse outcomes and strategies in a public forum.

Species and numbers of animals expected to be used

- Zebra fish: 12950

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, adult wild type, mutant or transgenic zebrafish males and females are placed in a tank together and fertilised eggs are passively collected. We will also generate new mutant and transgenic zebrafish lines by injecting genetic material into fertilised embryos and allowing them to grow to adulthood. These stocks will enable us to visualise the effects of mutations or collect physiological (i.e. normal living function) data in non-sentient embryos (i.e. embryos which are life stages that cannot feel pain). To preserve genetically modified zebrafish lines that are not being actively used, we will occasionally collect and store gametes (eggs and sperm) so that these lines can be re-established at a later date.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

In general, mutations with severe defects or malformations do not survive to sentient ages (i.e. in embryos up to 5 days after the eggs were fertilised). We do not expect that any of our mutation or transgenic modifications will adversely affect animals in any way. However, should any abnormal behaviour or clinical signs develop in growing or adult fish, they will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild in all cases

What will happen to the animals at the end of the study?

- Used in other projects
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Unfortunately, we know so little about how glia develop, there are currently no alternatives to animals for our research. We are always working to replace some of our animal methods with other techniques. For example, we recently developed a CRISPR-based (a gene editing) method that allows us to screen genetic changes in early stage fish embryos before they can feel pain. This new method allows us to edit genes more accurately. It replaces older methods where large numbers of genetically modified adult animals where used and gives us the same results. We also actively collaborate with insect and cell culture labs. By sharing our ideas with these groups, we continuously evaluate other methods, including organoid culture methods. These efforts will allow us to continue replacing our animal methods as our research into glia progresses.

What was your strategy for searching for non-animal alternatives?

Cell culture (individual cells growing in a dish) and organoid development (a three-dimensional laboratory based culture method that enables the growth and analysis of whole tissues).

Why were they not suitable?

Cell and organoid cultures are being developed to study glia. However, these techniques have failed to replicate the mature cell shapes and functional qualities needed for our research. As we build our understanding of how glia mature and use this knowledge to adapt organoid culturing techniques, we will likely enable such studies in the future.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals estimated for use in this project is predominately made up of breeding, maintaining, generating and storing genetically altered (GA) animals. We obtained these numbers by

drawing on our experience carrying out similar studies. These estimates allow us to produce at least the amount of embryos we need for statically valid results.

Breeding and maintenance of GA animals: Breeding results in significant energy loss for the adult fish breeders. We, therefore, must ensure enough tanks of fish and prevent repeated use of breeders over a week. Some GA lines will be used more depending on the experimental design. However, we estimate that we will need up to 10 2.8L tanks per line (depending on the number of staff using each line). Overall, we expect to maintain up to 18 GA fish lines, expressing fluorescent markers or gene mutations, at any given time. Thus, the total number bred will be 18 GA lines x 10 tanks x 12 fish per tank. Stocks of breeders will be renewed every year, so the total fish number amounts to 18 lines X 10 tanks x 12 fish x 5 years= 10500 GA fish.

Generation of F0 founders: For our research, we plan to generate 18 transgenic and mutant lines. From experience, we know that the generation of genetically altered (GA) lines has relatively low efficiency and the presence of genetic modifications are not always passed to F1 offspring. To ensure that we successfully capture the desired mutation or transgenes, we will generate 5 F0 lines (with 2 tanks of each line) for each GA line we have proposed to make. Therefore, our usage is estimated as follows: 18 lines X 10 F0 tanks x 12 fish per tank = 2160.

Obtaining zebrafish gametes: For, obtaining gametes (sperm and eggs) it will be necessary to maintain separate stocks of males with optimal breeding performance temporarily. We will perform this for lines that need to be archived which from previous experience amounts to on average 6 GA lines per year. For a target of 2 tanks of 6 male-only fish (a multiplying factor of 2 has to be considered assuming a 1:1 ratio of males and females per clutch), we estimate 360 fish over 5 years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

All of our experiments are carefully thought out and follow the appropriate steps of the PREPARE guidelines checklist (https://norecopa.no/media/7864/prepare_checklist_english.pdf). Consequently, our experimental design relies on distinct hypotheses or questions. We use carefully selected negative and positive controls to ensure the validity of our findings. For example, phenotypes that we find in genetically altered embryos are confirmed by direct comparisons to control (un-altered) animals following the same test conditions. In genetic sequencing experiments, we extract both types of cells from the eye (the neurons- as a positive control, and glia – experimental cells). Most of our methods are already established and commonly used in zebrafish labs all over the world. However, when we develop new techniques, we carefully consider the literature and seek expert advice before starting. There are instances where we use blinding and randomisation to achieve unbiased results. For example, in reverse genetic screens, we use a random number generator to keep track of each gene we are testing. This way, the person imaging and quantifying phenotypes is unaware of which gene it relates to until the analysis is complete. All of our experiments are designed to use only the number of animals needed to generate enough embryos for each test and reach a robust statistical power. If we are uncertain about the analytical approach or power calculations, we always seek the advice of an experienced bio-statistician.

What other measures apart from good experimental design will you use to minimise numbers?

We also reduce the number of adult animals we use by collaborating and sharing some of our fish with other users at the REDACTED. We also maximise the outcomes of our findings by making our genomic data available on public databases. In turn, these open-source platforms provide other researchers with data and prevent replication of our work in other labs. We reduce the breeding of transgenic lines by using wild type embryos wherever feasible. We collect gametes from genetically altered adults and store them for later use to reduce the number of animals we maintain at any given time.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will be using non-genetically altered and genetically altered zebrafish lines. The latter were either previously made or will be generated by the proposed work. The purpose of this licence is strictly to create, house, maintain and store the zebrafish lines. There are no methods proposed that are likely to cause pain suffering distress of lasting harm to these animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

All experiments that are outlined in this proposal will be conducted on non-sentient stages of development.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The maintenance and care of adult animals are carried out by highly trained bio-facility staff. Together with our animal facility staff and other zebrafish researchers at the REDACTED, we frequently discuss ways to improve animal welfare in the facility. This includes discussions about additional precautions for preventing diseases, enhancing the viability of embryos through diet and improving water quality by replacing old filtration equipment. REDACTED. We have shown that removing this very small amount of tissue causes no pain to our fish. This means our fish do not need to be held in a tank containing water to which an analgesic (pain killing drug) has been added and so enables us to return our fish to tanks where they can be fed and allowed to interact with others in normal water (see

https://www.liebertpub.com/doi/full/10.1089/zeb.2015.1165). We will continue to work closely with these staff to refine our methods for our research.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We ensure our publications conform to the ARRIVE guidelines: https://www.nc3rs.org.uk/arrive-guidelines. We also make use of 3Rs tools that are specific to fish and continuously updated by the REDACTED biomedical services team:
https://www.ubs.admin.cam.ac.uk/3rs/search/category/species- specific/topic/fish

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our animal facility officers and staff continuously inform us of advances in the 3Rs as it relates to our work. All project holders are also required to have a member of their group attend quarterly facility meeting where these advances are discussed in more depth. Any implementation of these advances is done under the strict guidance of a named veterinary surgeon.

Explain the choice ofspecies and the related life stages

Zebrafish are a classical developmental model that has been successfully used to understand many critical biological and disease-related questions in science. They are the best model organism for our research because they give us the ability to perform much of our experiments before they are sentient animals that can feel any pain. During these stages, zebrafish embryos are small and translucent which means that a microscope can be used to noninvasively observe normal and abnormal development.

Home Office

NON-TECHNICAL SUMMARY

130. Molecular architecture, function and dysfunction of the Blood Brain Barrier

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, juvenile, neonate, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to deepen the understanding of the mechanisms that link brain vascular malfunction and dementia with the hope that our results will be translated into the development of early diagnostic methods and treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A fine control of the brain environment is essential for the brain's function. Unlike other organs, the exchange of substances between the blood and the brain is tightly regulated by vascular and brain cells which together form the Blood Brain Barrier (BBB). The BBB provides cellular boundary that restricts the invasion of toxins and pathogens into the brain, and controls the uptake of molecules from the blood that are necessary for brain function. Failure in BBB stability leads to severe neurological disorders. In spite of the crucial function of the BBB and the strong efforts made to understand the mechanisms that underlie its disruption, there are important aspects of BBB function that remain largely unexplored. How is the BBB maintained? How do the BBB cellular components interact? What are the molecules leading to BBB malfunction?

These studies will advance our understanding of neurological conditions like dementia. They will enable the development of new scientific tools and disease treatments by both identifying unknown BBB malfunction mechanisms and providing targets to design treatments to ameliorate or prevent dementia.

What outputs do you think you will see at the end of this project?

We will generate new information about how the brain vasculature is maintained and altered in disease. In particular, we will focus on understanding how different BBB cell types interact during health and disease. We will obtain information about what are the specific molecules involved in this process and how altering their amount can affect brain function and mouse behaviour. Our results will be published in scientific journals. The information we collect could be used in the future to design new drugs.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The most immediate benefits will be for the scientific community. This project will contribute to the scientific community, not only by generating new scientific knowledge, but also by preparing new high level scientists.

In the longer term, the results obtained with this research will benefit the public, by increasing the knowledge about the brain. It will also benefit neurological disease patients by contributing to the understanding of disease that eventually will be applied to the generation of new treatments.

How will you maximise the outputs of your work?

Throughout our research, we will establish collaborations that will allow us to get the most information with the highest quality.

Results will be shared in scientific meetings and also in outreach events. They will also be published in scientific journals and shared through other type of media available to the general public. Our publications will contain the positive and unsuccessful results so the scientific community can be informed and not perform unnecessary duplication.

Results will be also summarized in short videos that will be made available to the public.

The lab will have a website where we will publish the latest updates.

Species and numbers of animals expected to be used

- Mice: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The animals used in this project will undergo surgical interventions, injections of certain substances, behavioural tests and/or in vivo imaging. The experiments will typically last one month, from the initial surgery to the end of the experiment. During most of the experiment time, the animals will stay in their home cage. A lot of the time is waiting time for some genes or phenotypes to express.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

No severe effects are expected. They may lose some weight after the surgery, but pain will be prevented treating animals with analgesia. They could present abnormal behaviour like decreased

activity. The effects are not expected to last more than 3 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The maximum severity for these experiments is moderate. It is estimated that about 80% of the animals may experience moderate effects like transitory sickness. The other 20% could be included under mild severity, since they won't undergo any major procedures.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The focus of the project is to study the interactions between the blood vessels and the brain cells in health and disease. Such interactions are dependent on the blood flow and the substances that are transported in these vessels thanks to the blood movement throughout the body. Currently there is no cellular model or computational tool that can resemble the complexity of such a system.

What was your strategy for searching for non-animal alternatives?

Cell lines of brain cells, induced pluripotent stem cells, organoids.

Why were they not suitable?

As stated above, none of the alternatives is able to resemble a completed circulatory system that irrigates brains cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice has been calculated based on previous experiments that I and other colleagues performed at REDACTED, using the same techniques. For new experiments, power analysis will be used to calculate the appropriate numbers of animals in each group and professional statistical advice will be sought when required. Based on our experience of most of the models we can determine the group sizes required. As examples, to perform proteomics, each sample is generated from collection and pulling of protein of 8-10 mice. Each proteomics experiment needs to be repeated at least four times per condition. For studies in ageing animals the studies have to be overpowered to allow for a loss of animals in studies due to age-dependant adverse effects e.g. tumours. Most of the procedures are established and the variability of the models is known. However, with new approaches, pilot experiments may be necessary in small numbers of animals.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The experiments have been designed such that the animal work is reduced to the minimum. We will first collect mouse proteomics data. The results of these experiments will be used to test changes of the expression of the interesting protein candidates in cell culture models. This will dramatically reduce the number of animals used for candidate testing and will allow to select one or two candidates that will be further corroborated in animal models.

Whenever possible, already published data will be used to avoid unnecessary duplication of experiments. A good example of this practice is the use of already published proteomics and RNA-seq datasets.

What other measures apart from good experimental design will you use to minimise numbers?

We will use both females and males.

We will share tissues and experimental data that can be reanalyzed with collaborators.

We will revise our protocols, and reduce the number of animals if possible. For example, if by using a more sensitive mass spectrometer we can reduce the amount of animals needed for each proteomics experiment, we will do so.

We will try to get as much information as possible from the same individual. For example, in some instances, animals that have been used for in vivo imaging could be used for immunohistochemistry once the animal is killed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Most of the experiments in this project will be performed in wild type mice. We will study molecular changes of the blood vessel - brain cell interactions in mice through ageing and in models in which neuroinflammation induced by administration of an exogenous compound. Occasionally we will include disease models in the studies, however, due to our interest in early disease alterations, we won't work with mice in severe stages of the diseases.

The surgeries will be performed under anesthesia and analgesia, and animals are expected to recover within few hours with no major complications. Nonetheless, mice will be monitored after every procedure to ensure there are no signs of distress like piloerection, abnormal locomotion or hunched posture. In addition, clear endpoints are defined for intervention either to correct weight loss and dehydration or for termination of the experiment if necessary.

Although the majority of our work will be conducted in vivo, there will be some phases of the programme in which multi-cellular culture models will be used to test specific molecular pathways that are identified with the animal work. We do not have the expertise to conduct these studies but we will collaborate with other groups that have proven expertise of combining in vivo and in vitro approaches to address specific research questions. In addition, the programme includes the use of ex vivo studies to probe cellular communication signalling in brain cells or slices. These approaches will reduce animal suffering given that the animal will be humanely killed before the in vitro experiment is performed.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The use of mice has many advantages over other models. Mouse is an ideal model to do translational research as there is a wealth of studies that compare mouse and human data. The understanding of astrocyte and endothelial cell biology is much deeper in mouse that in other species. This is an advantage towards reduction of the number of animals because already generated datasets can be reanalyzed. In addition, the AAV tools that we propose to use in this programme have been designed for mice and they do not exist for their use in any other species. Moreover, there is a wide variety of genetically modified models that we will use in future studies once we have defined the protein functions we want to explore.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to

the animals?

At the beginning, researchers will be exposed to the animals with frequency so they can learn the differences between normal and abnormal behaviour and appearance. Animals will be provided an enriched environment and they will be handled frequently to reduce their stress. When animals are required to perform a specific task, they will be familiarized with the new environment before the test. If surgical procedures are performed, we will do regular check outs, to assess recovery and pain. If there are signs of pain, analgesics will be provided.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Guidance on the Operations of ASPA, https://www.nc3rs.org.uk/

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Me and the rest of the people in the group will stay informed of the latest news by consulting resources as: ARRIVE and PREPARE guidelines, https://www.nc3rs.org.uk/, https://www.gov.uk/research-and-testing-using-animals, www.understandinganimalresearch.org.uk, www.frame.org.uk and http://www.procedureswithcare.org.uk.

Vets will also be contacted with frequency to keep improving our practice.

Explain the choice ofspecies and the related life stages

We decided to use mice for several reasons:

1- They have a complex mammalian brain which allow us to study the mechanisms we are interested in, and further translate our discoveries into human.

2- There is a wealth of published data from many different mouse models that we could use to understand our observations.

3- There is an enormous number of tools for mouse work and genetic models that we can use for our studies.

Most of the experiments will be performed in young adult mice. A subset of experiments will be performed in young and old mice, to better understand the effects that age has on the brain vasculature.

Home Office

NON-TECHNICAL SUMMARY

131. Molecular Basis of Development and Disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to understand how genes regulate developmental processes and the maintenance of stem cells and organ formation during embryonic development as well as in adult organisms. We also aim to understand how deregulation of these processes leads pathological conditions

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The findings from our research will provide information on how organ formation takes place during embryonic development and how stem cells are maintained in organs such as brain and intestine. This information will have applications in developing better methods of cell reprogramming, tissue engineering and repair as well as increase our understanding of cancers. In addition, deregulated developmental processes can give rise to pathological states such as neurodevelopmental disorders, neurodegenerative diseases and cancers. Mouse models for developmental and disease processes will help unravel disease mechanisms and have applications in evaluating therapeutic approaches.

What outputs do you think you will see at the end of this project?

Research conducted under this PPLwill

- provide new information on the mechanistic understanding of neuro-developmental and late onset neurodegenerative diseases which will be communicated for publication in high impact peer reviewed journals.
- be presented at International and national conferences and workshops

Expected benefits from : studies on how knockout of/or mutations/deletions in proteins that form the basal body of the primary cilia cause neuro-developmental disorders (ciliopathies) and motor neuron disease.

What we hope to find from our research:

1. The molecular changes associated with mutations in basal body proteins such as Talpid3 seen in the ciliopathy-Joubert syndrome (a neurodevelopmental disorder).

2. How mutations in basal body proteins such as Nek1 and C21orf2 lead to motor neuron disease (a neurodegenerative disorder)

3. The molecular mechanisms that links stem cells and neurodevelopmental/neurodegenerative disorders and find out if these diseases share some common mechanisms.

Expected benefits from :studies on how DNA binding proteins such as Caudal, Polycomb group and Trithorax group regulate stem cells in the brain and intestine.

What we hope to find from our research:

1. Studies such as the ones proposed for Cdx, PcG and Trx-G genes will provide new insights into the molecular basis of the regulation of stem cell identity and function in adult tissues such as the intestine and brain. The outcomes will have implications in our understanding of tissue regeneration with implication for tissue repair and tissue engineering.

2. Data from such *in vivo* experiments will enable us to design and perform *in vitro* experiments to dissect the molecular mechanisms of the function of these genes.

3. Experiments such as those on the skeletal patterning mutants will provide an understanding of the molecular basis of human birth defects which are developmental lesions.

Expected benefits
from: What is the molecular basis underlying the pleiotropic role of Angiogenin in neural development, neurodegeneration and stem cells.

1. Studies proposed under this objective will provide new insights into the molecular basis of the regulation of stem cell identity and function in adult tissues such as the intestine and brain. The outcomes will have implications in our understanding of tissue regeneration with implication for tissue repair and tissue engineering.

2. Data from such *in vivo* experiments will enable us to design and perform *in vitro* experiments to dissect the molecular mechanisms of the function of this gene and the mutations found in motor neurone disease patients.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The proposed research will lead to a better understanding of (1) stem cell regulation; (2) ciliopathies, a group of neurodevelopmental disorders classified as rare diseases which are ill understood and; (3) late onset neurodegenerative diseases.

Our research findings and mouse models will

- be of interest to the rare diseases patient interest group
- be of interest to patients with motor neuon disease
- have applications in therapeutic evaluation.
- have implications for regenerative medicine and directed differentiation with applications in tissue repair, regeneration and wound healing.
- will help develop better approaches to their treatment of neuro-developmental and neurodegenerative diseases

- The genetically modified animals will provide disease model systems which will be of interest to pharmaceutical companies for evaluation of therapeutics.
- Our research will also be of interest to clinicians and pharma.

How will you maximise the outputs of your work?

Based on our findings we will seek to collaborate with tissue engineers and clinicians for appropriate applications of our findings on stem cells, motor neuron disease and ciliopathies.

We will present our findings in scientific conferences and also highlight any unsuccessful approaches.

Successful application of the 3Rs will be disseminated through NC3Rs.

We will publish our finding in peer reviewed journals.

Species and numbers of animals expected to be used

- Mice: Estimated number for mice annually on an average is 3110 mice which will include the wild type mice generated through breeding protcols

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most of the strains we propose to use have already been generated by us or others. We will be generating a few lines with human disease specific changes. For this we will inject hormones, obtain very early embryos or eggs and inject these eggs/embryos with genetic material, transfer them to foster mice and allow the embryos to come to term. These mice will be checked to see if they carry the altered gene and bred for experimental purposes as described below.

Pre-implantation stage embryos obtained by superovulation or sperm will be used for cryopreservation.

Embryonic stem cells will be derived from pre-implantation embryos isolated after superovulation.

More typically we will mate genetically altered mice and obtain embryos or tissues after humane killing of the mice. We may for some strains induce gene expression by either administering Tamoxifen or tetracycline and then isolate tissues or embryos after Schedule 1 killing.

The cells, tissues or embryos will be analysed for cellular, molecular and biochemical changes using histology, immunohistochemistry, fluorescence activated cell sorting for cell cycle analysis, proteomics and transcriptomics.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some of the DNA binding protein knockout mice are smaller than their normal litter mates, exhibit vertebral identity transformations, show stem cell defects in the brain and gut. They groom and feed normally and we typically kill these by schedule 1 method at the first signs of distress, weight loss or pain.

Some of the DNA binding protein knockout mice are similar in size to their normal litter mates. They groom and feed normally. They have vertebral defects and stem cell defects in the gut. We typically kill these mice by Schedule 1 method at the first signs of distress, weight loss or pain.

The genetically altered basal body protein mutant mice show signs of ataxia at around post natal day 15, such as righting themselves slowly in comparison to their wild type litter mates and starting to drag their hind limbs. They also start to show a domed head at around day15. However, they are able to groom themselves and are able to suckle. These mice are killed before the ataxia progresses ie at postnatal day 15 or earlier. Beyond 15 days the ataxia progresses and animals are in distress by day 20.

For the new strains that we propose to develop for patient specific motor neuron disease/ciliopathy risk factors and for their knockouts we cannot predict the severity of the phenotype until they are generated. Once generated these animals will be monitored regularly for adverse effects and killed by Schedule 1 method if they show signs of distress.

One of the knockout mouse strain we propose to obtain from a collabrator shows no overt pathological phenotypic changes. These mice breed and feed normally but mice over 9 months of age develop leukopenia. In this case the mice will be killed by Schedule 1 before the onset of this phenotype.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Under breeding and maintance of GAA, all the Reporter transgenic strains such those expressing epitope tags, fluorescence tags, the Cre driver strains and conditional knockout mice with LoxP sites that we will use have no adverse phenotypes and so fall under the mild severity band.This is becuse they are not expressing any harmful mutations.

Currently 25% of mice from five of current genetically modified REDACTED show moderate severity as either they have gut or brain defects .

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Organs are not homogenous populations of identical cells but are heterogeneous and have a 3-D organization which depends on complex cell interactions. Hence, any analysis of the co-ordinated regulation of proliferation, differentiation and tissue patterning in any organ needs to be carried out in developing embryos and adult organisms. This is because such processes occur within a defined anatomical three dimensional tissue architecture containing the multiple cell types. Similarly, in order to study stem cells *in situ* and tissue homeostasis, an animal model is most appropriate.

What was your strategy for searching for non-animal alternatives?

Wherever possible, for evaluation of gene constructs and preliminary studies, we already make use of tissue culture models. We use embryonic stem cells to evaluate our CRISPR/Cas9 strategies prior to applying them to mouse embryos.

We have also been developing 3-D organoid models for carrying out biochemical studies using human induced pluripotent stem (iPS) cells or mutant mouse ES cells . I have been funded by a project grant for developing patient specific induced pluripotent stem cells as a disease model to reduce and replace animal models of motor neuron disease. We are also developing brain organoids from human iPS cells as a model for Fronto temporal dementia.

We also use early zebrafish embryos (stages upto 120hpf which are not regulated) for gene construct evaluation.

Why were they not suitable?

Tissue cultures although excellent to carry out biochemical and molecular biological characterisations of the functions of genes and genetic pathways are not entirely appropriate for our studies.
In undertaking studies such as on mammalian development or to study late onset neurodegenerative diseases which cannot be fully recapitulated in cell cultures we have had to consider the use of laboratory mice
.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- The KO mice will be maintained as heterozygous lines.To generate homozygous experimental animals heterozygous crosses will be set up which will produce offspring in Mendelian ratios ie 25% will be homozygotes,50% will be heterozygotes and 25% wild type.

- The Transgenic flourescent reporter, cell cycle reporter and Cre deleter mouse strains will be maintained as hemizygous lines.

- The conditional knockout mice ie floxed mice will be maintained as homozygous lines.

How we have arrived at the proposed number of 6 mice of each genotype for phenotypic analysis

.

For the new GAAs that we will generate and for the crosses with reporter or Cre strains of mice, we cannot fully estimate the phenotypes and standard deviations of the intercrosses. Hence we have used a crude method of calculation based on the law of diminishing return.

This method is called “resource equation” method. This method is used when it is not possible to assume about effect size, to get an idea about standard deviation as no previous findings are available or when multiple endpoints are measured or complex statistical procedure is used for analysis.

According to this method a value “E” is measured, which is nothing but the degree of freedom of analysis of variance (ANOVA). The value of E should lie between 10 and 20. If E is less than 10 then adding more animals will increase the chance of getting more significant result, but if it is more than 20 then adding more animals will not increase the chance of getting significant results. Though, this method is based on ANOVA, it is applicable to all animal experiments. Any sample size, which keeps E between 10 and 20 should be considered as an adequate. E can be measured by following formula:

E = Total number of animals − Total number of groups

In our case E=12 (6+6) and total number of groups is 2 with E=10 and therefore the numbers we have proposed is adequate. Once we have the mice and analysed the phenotype we will be able to do power calculations to confirm that these numbers are sufficient.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

- Since we are using GAA for our experiments it is not easy in all cases to predict the numbers we will generate simply because we will not only generate homozygotes and wild types to be used in our analysis but also heterozygotes in the case of our mouse strains show no phenotype.
- For each strain, the breeding nucleus is small consisting of 2 breeding pair replaced every 4 months.
- For the functional and histological assays we propose to compare at least 6 homozygotes from postnatal, adult and aged mice with their wild type (WT) type littermates if the mutation is fully penetrant as is the case with most of our strains.

What other measures apart from good experimental design will you use to minimise numbers?

To minimise the use of mice and mouse embryos for preliminary studies we use cell cultures and embryos of lower vertebrates such as zebrafish (stages up to 5d post fertilization which are non-regulated). The findings will then be confirmed using the mouse so that we only have to use the most appropriate and minimal number of constructs on a small number of mouse embryos and sacrifice animals at only the required stages.

Our breeding nucleus is generally small between 2-3 breeding pairs and colony numbers are managed efficiently to keep mouse numbers low.

We will also use refined technologies such as the Crispr/Cas9 system to generate knockdowns/knockouts and transgenic mice as these are emerging as more efficient technologies which will reduce the use of animals.

At appropriate places in the experimental approaches, I have indicated the *in vitro* techniques that will be used in conjunction with the animal experiments to minimise use of animals.

All of the mouse experimental approaches used are standard and well established techniques in my laboratory so failure of experiments is not very common.

We have a dedicated Statistician who we will consult, although the current developmental biology experiments we propose do not involve complex statistical evaluations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Models: The mouse has been chosen as the model in this study as it is the lowest vertebrate group in which studies of organogenesis, stem cells and patterning can be carried out as they share many similarities with humans. The developing mouse embryo is an extensively used model system for determining the role of normal and mutant genes in developmental processes.
The mouse embryo is a good model system for understanding vertebrate development for the following reasons:

a) well characterised genetic markers are available and the information from genome sequencing allows identification of functionally active genes

b) the gestation time of the mouse is reasonably short

c) conditions have been well worked out for the isolation and culture of pre-implantation and early post-implantation mouse embryos

d) it is possible to introduce new or modified genetic information into the pre-implantation and early post-implantation embryos that could perturb development or serve as markers to trace the cell lineages and follow expression of a particular gene product

e) it is possible to introduce the normal or genetically modified embryonic stem cell (ES) or cells from the inner cell mass into mouse blastocysts in order to generate injection chimeras and eventually derive transgenic mice that carry an altered gene.

The mouse models we are using to study the role of the basal body/ cilia proteins are conditional knockouts which are either temporal or spatial knockouts thereby minimising the number organs or stages that are affected.

Since we are investigating cellular and molecular mechanismswe use animals at the preclinical and the stages showing the earliest signs of clinical manifestation thereby minimising suffering and distress.

Methods

The majority of our methods for analysing the mutant mice are of mild severity which either involve isolating fetal forms or tissues from post-natal, juvenile or adult mice by Schedule 1 killing to anlayse the cellular, molecular and biochemical changes . These cause minimal sufferring and distress.

Our methods for investigating cell cycle/proliferation and protein synthsis is similarly are minimally invasive.

Conditional gene expression is also a refined approach to understnd gene function since we turn off/on the gene only in specific cell types or at specific times in development or life cycle.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We already use zebrafish embryos (up to d5 post-fertilization) or cell cultures to evaluate constructs and cellular phenotype prior to generating transgenic mice. Organs such as the cerebellum develop post-natally and intestinal epithelium matures post- natally and in such cases post-natal mice are the best models .

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Mice will undergo minor surgery for vasectomistaion or during embryo implantation under anaesthesia and are expected to recover quickly and will be given painkillers and post operative care just like people recovering in a hospital. They will be monitored regularly to ensure that they are not suffering from any infection or problems with wound closures.

We will use cell type and tissue specific knockouts i.e. conditional KOs to minimise the phenotypic consequences of gene deletions or over-expression.

Stock lines which show no adverse phenotype as for example - Reporter or Cre expressing mouse strains are maintained as homozygous line. Other strains which show adverse phenotype in the homozygous state are maintained as heterozygous lines. These contribute to maintaining smaller number of mice in the colony.

New mouse mutant lines that we will be generating will have very well defined monitoring scheme to identify stages and extent of suffering and distress.

In the case of newer transgenics or KOs REDACTED yet to be generated, we will consult with the NAWCO, NVS and Home Office inspector to decide on the steps for minimising distress and a humane end point that will allow functional analysis without undue distress to the animal.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use the Experimental design assistant and other resources from the NC3Rs to ensure that our experiments are conducted in the most refined and effective way. We will also use the updated ARRIVE guidelines in our reporting

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We use the information in the NC3Rs website to inform us of best practices in terms of the 3Rs.

Explain the choice ofspecies and the related life stages

Our aim is to understand molecular basis of stem cells homeostasis, neuro-developmental and neuro-degenerative diseases and the mouse is a good model system as it is a mammal and techniques to manipulate its germline are well worked out. In addition, aspects of neural development are similar.

For studying genes that regulate development, stem cell identity and maintenance, in self renewing tissues as intestine and on organs such as the brain, we will use embryonic , peri and postnatal stages as well as adult mice from strains which have been genetically modified. Such studies will provide an understnding of how these genes regulate developmental processes.

For studying genes that have been shown to be mutated in motor neuron disease by Genome wide analysis studies (GWAS) we will use post natal, juvenile and adult mice which have been genetically modified. This will enable to study early molecular and cellular changes before the overt manifestaion of the disease.

NON-TECHNICAL SUMMARY

132. Molecular basis of Gram-negative bacterial infection

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The global aim of this project is to study the ways in which bacteria which cause disease (bacterial pathogens) interact with the human body. In particular, we focus on infections caused by gut and lung bacterial pathogens. We study the mechanisms by which these pathogens cause disease, the impact of antimicrobial resistance (when bacteria become unresponsive to antibiotic treatment) and aim to develop novel treatment and/or prevention strategies.

A retrospective assessment of these aims will be due by 23 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Enteric (gut) infections remain a major public health issue, mainly in low and middle income countries. In particular, infections with pathogenic Escherichia coli are responsible for disease and death in young children. Currently there is no vaccine available for pathogenic E.coli infections and, as treatment with antibiotics increases the risk of secondary complications, treatment is limited to supportive treatments (e.g. oral rehydration).

On the other end of the spectrum, Klebsiella pneumoniae is a hospital-acquired infection that mainly affects unwell, mostly elderly patients in intensive care units. Lung infection with K. pneumoniae can lead to subsequent sepsis (multi-organ failure), which is often fatal. Importantly, due to the rapid spread of antimicrobial resistance, treatment of K. pneumoniae infections is becoming increasingly challenging.

Accordingly, it is essential that we increase our knowledge and understanding of the relationship between the pathogens and the host in order to combat these life threatening infections. Increased knowledge will aid the development of better treatments and vaccines and also the development of therapies involving bacteria which normally live in the healthy gut, which help to prevent infection. Such organisms are known as the gut microflora.

What outputs do you think you will see at the end of this project?

The outputs from this project will include modelling of serious gut and lung infections in humans. Basic science such as this is necessary to make advancements in clinical medicine. The overall aims of this project are to further our understanding of how these diseases develop and spread, and to improve global health.

Specifically, in the gut, our work will highlight the underlying factors that determine whether individuals develop mild or severe symptoms in response to bacterial infection. This will include understanding the role the immune system (the body's defence system against infection) and the normal gut microflora play during infection. Moreover, we aim to develop and evaluate novel vaccination strategies.

In the lung model the outputs of this project will include new understanding of the changes which occur during life-threatening sepsis. Further, many clinically-relevant Klebsiella pneumoniae are resistant to first-line antibiotic treatments. These infections are often mistreated in the clinic. We will investigate the effect of antibiotic mistreatment on the host and the pathogen.

These are emerging disciplines that will inform both scientists and clinicians, and the data will be disseminated via publications. We aim to enable public access to our work by paying for open access where possible. We disseminate our findings via the general press to inform the public of our work.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term (5 years), the project will contribute to basic scientific knowledge and set new parameters for studying bacterial infection. In the long term this knowledge will contribute to the development of more effective treatments for gut infection. Our novel vaccination strategy will benefit those interested in disease prevention via vaccination, which is an essential strategy in the face of increasing antimicrobial resistance.

Understanding the impact of antibiotic mistreatment will enable us to model a very real world situation, where antibiotic resistance has rendered many of our previous therapies ineffective. In the long term, the development of a robust model of Klebsiella lung infection, which produces all the physical characteristics of disease, will benefit those interested in developing novel treatment strategies. We aim to use new technology to stop experiments at earlier, less severe time points in keeping with the RSPCA's recent publication of a 'road map' toward ending severe suffering of animals used in research and testing.

How will you maximise the outputs of your work?

We routinely publish our work in leading scientific journals and present our findings in national and international conferences. We have track record of involving animal technicians, and welfare staff (e.g. NACWOs, NTCOs and NVSs) in our work and results. We tend to include unsuccessful approaches together with reporting successful ones to inform the community and reduce duplication of failed

approaches in animals (within our and at other institutions). We collaborate with the global infection research community using new techniques that provide rich data sets enabling fewer animal experiments to be required, yet providing more information.

Species and numbers of animals expected to be used

- Mice: 14250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will be infected with an enteric (gut) or pulmonary (lung) bacteria by oral gavage (delivery of bacteria via a feeding tube to the stomach) or intratracheal inoculation (delivery of bacteria via a tube into the lungs). In some cases this will result in clinical symptoms of infection including weight loss and illness.

Compounds such as drugs or antibiotics are delivered by either oral gavage, injection or via the anus. This is to study how disruption to normal bodily function affects the symptoms developed as a result of infection. We may collect blood from mice and/or image the mice during the course of infection to monitor infection progression. Where required for the above procedures, anaesthesia is given either via injection or inhalation.

The number of regulated procedures is dependent on the protocol used. Aside from symptoms developed as a result of infection, most procedures used in this project cause no more than transient discomfort and no lasting harm to the animals.

Experiments concerning lung infection are short (around 72 hours).

Gut infection experiments, depending on the type of mouse and pathogen, are longer and can last from 4 days to >3 months. In scenarios where mice develop symptoms of disease, these experiments will typically last less than 3 weeks.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Gut infection in non-susceptible mouse breeds (mice which spontaneously clear infection) only results in short-lived, mild, symptoms of disease and the mice spontaneously clear the infection after 20-30 days. Gut infection in susceptible mouse breeds (mice which, without intervention, would succumb to

infection) results in gut inflammation (colitis), diarrhoea, weight loss and disease symptoms including reduced ability to move, hair standing on end, and development of a hunched gait (bent walking posture). However, animals will be killed (to prevent excessive suffering) when weight loss exceeds 20%. Additionally, we will use an agreed scoring method to ensure that animals will not suffer moderate symptoms for more than 48 hours.

Infection with Klebsiella will not cause pain, but these infections do induce sepsis and multi-organ failure (septic shock). Infections will typically not last longer than 72 hours, except when appropriate antibiotics are administered to mice, curing the infection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol 1 (gut infection) is a moderate severity protocol. The majority of mice (85%) are expected to experience only mild severity in which they do not show visible signs of infection. Mice susceptible to infection will sometimes be allowed to develop some symptoms (reduction in mobility, hunched posture, raised hair) and 20% weight loss. This (moderate severity) is expected to occur in 15% of the mice.

Protocol 2 (vaccine development) is a moderate severity protocol. The majority of mice (70%) are expected to experience a mild severity in which they do not show visible signs of infection. Mice susceptible to infection will sometimes be allowed to develop some disease symptoms (reduction in mobility, hunched posture, raised hair) and 20% weight loss. This (moderate severity) is expected to occur in 30% of the mice.

Protocol 3 and 5 (lung infection) are severe in which mice develop multi-organ failure due to infection and septic shock. This is applicable to all infected animals, with 90-100% reaching this severity end-point.

Mice under protocol 4 (breeding) are not expected to develop any symptoms as the resulting genetic make-ups are not predicted to have a harmful effect (mild severity).

What will happen to the animals at the end of the study?

- Used in other projects

A retrospective assessment of these predicted harms will be due by 23 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We study the way in which harmful bacteria (pathogens) infect the lung and gut and cause disease symptoms. Initially we investigate these bacteria in non-animal models as much possible. However the true mechanisms of infection can only be revealed using relevant animal models as we find that non-animal infection data does not reflect what happens in a complex organism (e.g. mouse or human). We aim to model the ways in which bacteria cause disease in the context of the gut flora, immune responses, metabolism and diet. Moreover, while infection of cells in the laboratory is studied in hours, infection in animals/humans can last from a few days to many weeks, with a delayed development of disease symptoms after the initial infection.

The use of animals is an unavoidable consequence of studying the complex processes involved in models of human infection. Furthermore, there are no non-animal models of the complex immune system, therefore testing vaccine candidates can only be done using animal models.

What was your strategy for searching for non-animal alternatives?

Where possible we use non-animal alternatives, e.g. cells and tissue grown in the laboratory, for our work.

Why were they not suitable?

Our aim is to model infection in humans, which requires investigating pathogen/host/microorganism (gut flora) interactions as a whole. Moreover, the outcome of infection is dependent on external factors, e.g. diet, that is not reproducible in the laboratory. Accordingly, whilst we investigate some specific questions in laboratory-based systems, there are no alternatives to animals as a complete model of human disease, and therefore development of treatment strategies.

A retrospective assessment of replacement will be due by 23 September 2025

The PPL holder will be required to disclose:

> What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of experiments is based on previous experience and the number of mice is based on statistical calculations which determine the minimum number of animals needed in order to provide meaningful results.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Several different bacteria are routinely tested in the same experiment so that control mice (i.e. mice that have not been infected, for comparison with those that have) are shared, thereby reducing the number of animals (3Rs principles). All experiments are repeated to achieve scientific validation and to ensure reproducibility so that the results are trustworthy.

Each mouse is marked and analysed individually. Each group of mice is assigned an experimental identification randomly and, where appropriate, the analysis is done blindly (to prevent bias). Statistical analysis has been validated by external consultation (Institution's statistical advisory service) and vigorous peer review in high quality scientific journals. By using statistical software we are able to calculate the number of mice required for each experiment (power calculations) to enable theory-driven research whilst utilising the minimum number of animals.

End-points are traditionally time-defined in scientific experiments but this does not account for the specific biological differences between animals, so we have invested in a novel system to monitor mice, similar to those systems found in hospitals and are working towards being able to apply this to other infection models. This will enable us to collect more data per animal to reduce the number of animals required in our research.

What other measures apart from good experimental design will you use to minimise numbers?

We use hi-tech animal imaging techniques to reduce the number of mice used for testing and adhere closely to the 3Rs principles. Before imaging techniques were refined, we had to humanely kill a group of mice for each time point of interest in order to collect data. However, imaging techniques have evolved so much that we can now follow the same group of mice over time and record data at various time points, without the need to kill them. This has allowed us to reduce the number of animals required to achieve the objectives.

A retrospective assessment of reduction will be due by 23 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use mice to model gut and lung infections in humans. For gut infection, bacteria are given to the animal by oral gavage. This procedure does not typically cause pain, distress or lasting harm.

For lung infection mice are anaesthetised before delivery of bacteria through a breathing tube. This procedure does not cause lasting harm, although mice will develop disease symptoms as a result of the infection.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

As we aim to model human infection, we need to use adult mice, which have a developed microbiota (similar to those of humans). As we follow infection and symptoms over time, we have to use live animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

On a day to day basis we visually monitor the animals. When required, we also use a numerical scoring system based on visual symptoms and weigh the animals. Non-invasive measuring of heart and breathing rate will allow us to define precise, more humane endpoints and monitor animals in real time and therefore reduce harm.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We routinely follow the NC3Rs ARRIVE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We routinely follow the literature (both scientific and industrial/commercial) and conferences for new developments and technologies. We have evidence for this, as we have recently bought and implemented the MouseOX technology in our facility, which allows continuous monitoring of the health status of mice throughout an experiment.

Explain the choice ofspecies and the related life stages

We use mice because there is natural and specific mouse pathogen (*Citrobacter rodentium*) which 20 years of research by us and others has been established as a robust and accurate model for human gut infection with pathogenic *E.coli. Klebsiella pneumoniae* causes an infection cycle in mice (from pneumonia to sepsis), which mimics its infection outcome in humans.

As we study infection in the context of the natural gut flora (microbiota) and monitor immune responses, we need to use adult mice which have developed a mature microbiota and have a mature immune system.

A retrospective assessment of refinement will be due by 23 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

133. Molecular Regulation of Mammalian Development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall objective of this project is to increase our understanding of the molecular processes regulating mammalian embryo development. Particularly, we want to study the function of specific genes involved in this process.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The discovery that certain factors can 'reprogramme (transform)' mature cell types into stem cells holds great potential for new biomedical applications, such as cell replacement, drug testing and disease research. Reprogramming allows us to turn any cell of the body into a stem cell. However, the mechanisms involved in this technique are only just being identified and the success rate of the method remains very low. One way to improve our understanding of reprogramming is to study the natural programming mechanisms that begin after fertilisation in the mammalian embryo. In addition, basic scientific discoveries resulting from this programme of work will provide knowledge that would benefit couples undergoing reproductive technologies such as in vitro fertilisation.

What outputs do you think you will see at the end of this project?

We aim to study the onset of the gene expression event in mouse embryos. We aim to uncover new factors that control early embryogenesis and further investigate their roles during the embryo has the potential to become all the cell types in the body (totipotency). This work will bring novel information about gene function at the beginning of development

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Identification of molecular mechanisms will lead to a greater understanding of how totipotency is achieved/maintained and has important implications for reproductive technologies and areas such as regenerative medicine.

The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of infertility conditions and in the field of regenerative medicine.

How will you maximise the outputs of your work?

Findings will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings. We are preparing a major publication based on the results from the previous project and work has been presented at national and international conferences.

The transgenic animals developed will be valuable and made available to other scientists.

Species and numbers of animals expected to be used

- Mice: 13,100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Our project includes hormone Intraperitoneal injections. For in matured oocyte collection, only one hormone (PMSG) injection needed. To induce super ovulation, a second hormone injection (hCG) will apply 48 hours post PMSG inaction.

We will perform surgical procedure in the “Embryo Recipient” procedure.

Duration: 15-30 mins per recipients.

Procedures:

1. Recipients for embryo transfer will be rendered pseudo-pregnant by mating with a vasectomised sterile male

2. Under general anaesthesia a single/bilateral flank or midline laparotomy will be performed and genetically modified embryos will be implanted into the oviduct or uterus (AB-G).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

In order to provide eggs and early embryos, female mice will be given hormones to maximise the number of eggs and embryos produced. They are then killed by a humane method and the embryos collected, usually one or three days later. During the procedure these animals will only experience transient pain at the time of injection. Using molecular laboratory techniques we will identify and characterise the key factors involved in the regulation of gene expression during early embryo

development in vitro – so thevast majority of the mice we will use are bred and killed for egg and early (up to day 4) embryo harvest and not subject to any invasive procedures.

The ability to alter specific genes in the laboratory provides researchers with the opportunity to study the function of a particular gene. We will culture the eggs and embryos in specialist culture systems; assess their development and the effect of modified gene function. Very occasionally we may need to perform surgery on the mice, under general anaesthesia (for example to transplant some embryos into female mice or to perform a vasectomy on male mice). These are essential techniques (with moderate severity) but good surgical techniques, anaesthetic and pain relief will be used during and after surgery to minimise adverse effects. The mice are allowed to recover and will monitored closely post-operatively. Some mice will deliver at term and other pregnant females will humanely killed at specific time points in early gestation. At the end of the study all the mice will be humanly killed by an approved method.

We will also breed genetically altered (reporter) mice (to obtain eggs and early embryos). These mice have been generated under other project licences. The effects of the genetic alterations (a fluorescent marker tagged to a protein of interest) are negligible, and the animals suffer no adverse side effects of this alteration. These mice will be superovulated and mated to obtain early embryos, experiencing no more than the same minor discomfort at the time of injection, as the control mice described above.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The breeding and maintenance of genetically modified animals (Protocol 4) should not generate any severity level.

All mice undergoing superovulation (Protocol 1) will experience mild severity levels.

All mice used as embryo recipients will (Protocol 3) will experience moderate severity levels.

Protocol 2 involves the manipulation of oocytes/embryos up to the blastocyst stage

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will use mice mainly as oocyte/embryo donors with the remainder of the experimental work being carried out in the laboratory in vitro. There is no alternative to the use of animals for the basis of our work but in silico analysis will be used in order to minimise the numbers of animals used. We cannot obtain oocytes or embryos without the use of live animals.

What was your strategy for searching for non-animal alternatives?

ll proposed studies build on extensive data derived primarily from in vitro and biochemical studies carried out either by this group or by the international scientific community.

Why were they not suitable?

See above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Wherever possible, attempts will be made to reduce the number of animals used in order to address specific scientific questions, while making maximal progress in achieving the goals of the project. Experimental design is given priority, with regular consultation between all members of our collaborative groups. Numbers of animals used in each experiment are based on estimates of variability expected from our previous experience or from published data. Appropriate positive and negative control treatments are included where necessary. All procedures are carried out by highly-trained staff to maximise the success of vulnerable procedures such as oocyte/embryo microinjection and nuclear transfer.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Oocytes and zygotes will be obtained from superovulated mouse donors. Short interfering RNA(siRNA) molecules, DNA templates, cells or sperm will be injected into the oocytes/zygotes by microinjection. Negative control groups will consist of either a scrambled siRNA for the target gene of interest or a non-injected group/sham injected group, depending on the experiment. Previous experience using this technique in REDACTED has shown that at least 30 embryos should be successfully injected for each group. This number is obtained from a power analysis calculating that a sample size of 30 embryos per group will permit observation of a 5% significant difference in measured values, based on prior standard deviation. The concentration of each siRNA will be titrated to ensure that the lowest

concentration is used to deplete gene function in order to prevent off target effects. As these animals are superovulated the experiment will be repeated three times on different occasions to avoid bias from any one single animal. Differences in gene expression will be assessed by quantitative PCR (data analysed by Student's t-test and ANOVA). Protein levels will be measured by Western Blotting and/or immunofluorescence, or biochemical methods – such as chromatin/methylation analyses. Nuclear transfer experiments using pre-treated donor cells to alter the chromatin structure of the DNA of the donor cell before transfer may increase the efficiency of current nuclear transfer protocols. We propose to use immunocytochemical assessment of the chromatin in potential donor cells and molecular analyses of selected marker and reporter genes to study reprogramming efficiency of candidate chromatin remodelling proteins. The in vitro manipulation of chromatin status of different donor cell types may identify favourable epigenetic markers that would allow these cells to be sorted and used as nuclear donors, eliminating some of the 'lottery-effect' of choosing cells for embryo reconstruction. In most cases, the number of oocyte and embryo donor animals used will be minimised by superovulatory treatments, which increase the numbers recovered by approximately fivefold. We will also use molecular techniques that allow assay of single oocytes and embryos (and in some instances single blastomeres) reducing the degree of replication and numbers of observations required.

What other measures apart from good experimental design will you use to minimise numbers?

Careful statistical treatment of all data will be undertaken, gaining as much information as possible from each experiment. Whenever feasible, experiments will be consecutive to allow dissemination of results from previous experiments to influence current experimental design. A priori power analyses will be conducted prior to new experiments to determine an appropriate sample size to achieve adequate statistical significance.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse is selected as a model species for these studies for several reasons. Firstly, there is more information available about this species than any other in genetics, molecular biology and reproduction. Secondly, the short reproduction interval allows studies to be completed more quickly than in any other mammal. Finally, more consistent observations can be expected as inbred strains are maintained in a closely controlled environment. All mice undergoing surgery will receive pain relief (analgesia) and good post-operative care. Moreover, all of our animals are housed under pathogen free, environmentally controlled conditions. Animals are routinely monitored for the presence of pathogens that could potentially lead to infections.

[redacted]

Why can't you use a less sentient animal (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The age we will use is the standard.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

No answer provided

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We have adapted the most refined method to induce ovulation (Takeo and Nakagata, 2015 PLOS One).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will check related references, attend 3Rs meeting and discuss with other researchers.

Explain the choice of species and the related life stages

Mice :The mouse is selected as a model species as there is more information available about this species than any other in genetics, molecular biology and reproduction.

To investigate fertility issues we need adult mice to produce the oocytes/embryos we need for our experiments.

NON-TECHNICAL SUMMARY

134. Morphogenesis of the early mammalian embryo

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

[redacted]

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand how mechanical forces shape complex three-dimensional structures such as tissues and organs out of simple cell populations using the early mouse embryo.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Birth defects are one of the leading causes of infant mortality across the world, many of which can be identified early in pregnancy, however we have only limited ability to repair such defects in the womb. For adults, hundreds of thousands of people who are in need of new organs wait on long transplant lists, relying entirely on donors, and face the possibility of having to take immune-suppressant drugs for the rest of their lives. The options available to these patients would greatly expand if we were to one day be able to grow or generate new tissues and organs outside of the body or in a dish. While we have made significant advances in understanding how genes are regulated throughout development, and using stem cells and organoids can differentiate specific cell types and populations, we are not yet able to build more elaborate structures such as organs or even multi-layered tissues.

The work we propose will allow us to determine how the early embryo grows and develops from simple, homogeneous starting materials; how cells are organized to form tissues, how tissues coordinate to create layers and shapes, and what mechanical forces are required to fold these tissues into a functioning, moving organ such as a beating heart. Only with this knowledge can we begin to replicate these processes ourselves, using cell culture or organoids to generate tissues and complex shapes, to know when and where to manipulate and what to add and what to subtract. The ability to one day repair damaged organs, treat developmental defects in utero, and even grow whole, functional organs outside of the body will depend on our understanding of how the embryo builds such complex structures.

What outputs do you think you will see at the end of this project?

The successful conclusion of this project will result in at least several publications, collaborations, and the generation of a number of datasets and models that will be shared freely with the scientific community. Information gained from experiments will be used as a platform for further, more advanced studies that will continue to build off of the previous goals. Our insights and analysis from studying foregut formation will reveal mechanisms that are likely re-used throughout the development of a wide range of tissues and organ systems.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

In the short-term, datasets that are generated may be shared with collaborators or public databases to be used freely by the scientific community. At the completion of this project, all datasets, computational tools, technical drawings and specifications, computational models and tools used to generate publications or demonstrate advances will be shared openly with the scientific community. The knowledge gained from this project will enable researchers in other fields such as gastruloids or organoids to employ new techniques to make more complex structures and further advance the development of their systems. Additionally, advances in imaging and embryo culture resulting from these studies will allow researchers to study later and more complex stages of mammalian development.

How will you maximise the outputs of your work?

We will actively seek collaboration with other researchers who may have complimentary knowledge or may directly benefit from our studies, as well as ensuring all results and data are made freely and publicly available. Results will be shared both in publications and at conferences and meetings that are widely attended by the scientific community. Public engagement activities will help dissemination of the knowledge to the general public.

Species and numbers of animals expected to be used

- Rats: 300
- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Adult mice will be used to produce embryos either through natural breeding, super-ovulation which involves the injection of hormones at two timed intervals, or through embryo-transfer experiments where female mice are anesthetized and one or two small incisions are made in their back order to place embryos inside the uterus or oviduct. The majority of mice used will experience only no amount or only very mild pain or discomfort. Embryo transfer and super-ovulation protocols are only occasionally required, and the majority of experiments will rely on natural breeding of genetically altered mice to produce embryos, and before recovering those embryos the female is first humanely euthanized and experiences no pain or discomfort.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Only mild, temporary pain or discomfort is expected for all animals on this project, with the highest degree of pain experienced for animals undergoing vasectomy or embryo transfer procedures. These effects are temporary, lasting no more than a day or two and can be managed with pain medication and animals will be monitored like a human patient under a doctor's supervision, and are not expected to have any long term physiological or behavioural effects. Complications from these surgical procedures are very rare in our experienced animal facility.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Only vasectomy and embryo transfer procedures are expected to produce an uncomfortable degree of pain and discomfort, which is only temporary and will be managed with pain medication. Only a small number mice will be used for these procedures, and most will only experience either no or only a very mild amount of pain or discomfort. All other mice used in this project involve the breeding of males and females, which is not expected to cause any undue level of stress.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our understanding of how an organism develops from a single-cell of limitless potential, to all the complex cells, tissues, and organs that comprise an adult animal relies on our ability to observe and interrogate this process in nature. Mouse embryos are a close analog to human development, sharing many of the same genes and processes that shape organs and tissues. Birth defects seen in humans are also found in mice, allowing us to study these processes in the hopes of one day being able to correct them in the womb.

What was your strategy for searching for non-animal alternatives?

Because we understand so little about mammalian development, there are no synthetic or artificial alternatives that can replace actual embryonic development. Research into gastruloids and organoids

are the closest non-animal analog, however this field is still in a very young stage, and indeed would stand to benefit from the results of this project.

Why were they not suitable?

The generation of gastruloids or organoids can make approximations of some cell types or structures, but they do not form embryos or even functional organs, nor can they be used to validate "normal" development as we do not yet even understand what "normal" development is.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number was estimated from similar experiments performed over the past five years, taking into account the rate of failure, the frequency of false pregnancies, and the estimated number of embryos and observations that are needed in order to make statistically sound conclusions. The number of experiments needed to ensure confidence in observations and measurements is also guided by accepted numbers commonly used in literature. More conventional power calculations are not suitable in this case as much of the work is based on discovery and observation or measurements in an inherently stochastic system. It is not appropriate to employ standard deviation as a measure of confidence in a system where that standard deviation may instead represent the normal, natural variation.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

While it is impossible to control whether or not animals become pregnant nor the number of embryos they produce, we are able to estimate based on expected rates of failure generated from years of previous data for similar experiments, combined with the NC3R's Experimental Design Assistant where appropriate, the number of animals that would be required to confirm observations and measurements in a statistically significant way.

What other measures apart from good experimental design will you use to minimise numbers?

Ensuring a controlled breeding environment will help to reduce the number of false pregnancies. In certain cases, ultrasound can be used to verify pregnancy, reducing the number of females that are sacrificed unnecessarily for each experiment. Additionally, females used for breeding and super-

ovulations can be re-used in the same or other protocols. Continuous data analysis on results as they are obtained will allow us to continually refine the number of animals that are needed in order to achieve a statistically significant result.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use mice as our model organism to study early mammalian development. The vast majority of our protocols are designed to only cause minor, temporary, or no pain or discomfort to the animal, and no more than is expected to be caused by natural breeding behaviours. In the case of more severe procedures such as surgeries to implant embryos, or vasectomize males, these are one-time experiences, which will be closely monitored by trained animal staff and technicians in order to minimize any pain or discomfort experienced by the animal.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are a close, non-primate analog to human development, and an excellent model organism that has been well-studied for decades. Our understanding of mammalian development is so limited that there is no viable alternative that would achieve the same amount or quality of results.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be closely monitored whether it is for surgical procedures or during the course of normal breeding and husbandry. Changes in breeding behaviour for example can indicate a change in environmental conditions that causes stress for the animals, which can be identified and corrected. Local best practice guidance will be used unless stated. This guidance is reviewed annually by the AWERB and experienced NACWOs and veterinarians and reflects best practice from across the literature.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Surgery will be carried out according to the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017). In addition references such as A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes by Diehl et al. 2001, resources from NC3Rs (National Center for the Replacement, Refinement, and Reduction of Animals in Research, https://nc3rs.org.uk/3rs-resources), P. Flecknell (2015) Laboratory Animal Anaesthesia (Fourth Edition), S.L. Hoogstraten-Miller & P.A. Brown (2008), J. Bruce et al (2001), and other accepted literature as guided by the NVS.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The mouse development field is constantly evolving, and new breakthroughs are announced regularly in literature. Additionally, animal care staff are highly-trained and stay abreast of advancements in animal husbandry, bringing new techniques and procedures to scientists and assisting us with their implementation.

Explain the choice ofspecies and the related life stages

Mice have been an excellent model system to study mammalian development for decades; they are prolific breeders, a close analog for human development, and there are many genetic mutants and fluorescent reporter lines available. For our proposals, there is no other animal model that could serve as a viable replacement or give us a closer understanding of human development (save for primate species). We use adult mice to produce embryos that are used in experiments, and embryos before the age of viability in order to study how organs and tissues are formed.

NON-TECHNICAL SUMMARY

135. Motor circuitry in Health and Disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to understand how motor networks that coordinate movement develop and function and to understand how these circuits fail in diseases that affect motor systems.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our work will improve our understanding of how neural networks in the brain and spinal cord interact to shape motor behaviour. Since motor-related circuitry in zebrafish is highly conserved with those of mammals we expect our findings to uncover general principles about how neural circuits interact to engender behavioural flexibility. In addition, our work will identify early, presymptomatic defects associated with neurological diseases such as amyotrophic lateral sclerosis and Parkinson's disease. Little is known of the defects that occur during pre-clinical stages of these diseases and we hope that our work will help identify new therapeutic targets for slowing or preventing disease progression.

What outputs do you think you will see at the end of this project?

We expect to generate new knowledge relating to the fundamentals of motor control and the mechanisms underpinning neurodegenerative diseases of motor networks. Outputs generated by this project will comprise publication of peer-reviewed research articles, presentations at conferences and seminar sessions and public engagement at outreach events.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

By completion of this project, we expect our work to generate new knowledge on the basic principles of motor networks and the diseases that affect them. Outputs derived from our work will benefit a broad range of scientists within the academic community seeking to better understand the cellular and network mechanisms governing motor control and motor network diseases. Additionally, by completion of this project, outputs are expected to generate new insights and potential therapies for neurodegenerative disorders, thereby benefiting clinical researchers and medical professionals alike.

Members of the general public who are interested in aspects of motor control and disease of motor systems will also benefit from outputs generated during the course of this project as we will provide new insights into the mechanisms underpinning locomotion and early pathological process caused by degenerative diseases. In the longer term (5 to 10 years), we hope that new knowledge generated by this project will be essential for understanding and ultimately treating degenerative disorders affecting motor systems (such as ALS).

How will you maximise the outputs of your work?

We will maximise outputs generated by this project through i) publication of research findings in peer-reviewed internationally competitive journals. To maximise impact, we will ensure that work is published in Open Access format; ii) presentation of findings at scientific meetings and seminars; iii) attendance at outreach activities (such as REDACTED week and; iv) reporting of research findings on the laboratory website, which is accessible to the wider public.

Species and numbers of animals expected to be used

- Zebra fish: 4,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Male and female adult zebrafish will be grouped or paired in a breeding tank. They will be left overnight and after spawning (which occurs at dawn), eggs will be collected and adults will be returned to their holding tanks to recover for at least 2 weeks before re-breeding.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The large majority of the GA breeding stock used for this project harbour genetically encoded fluorescent reporters that result in no discernible behavioural phenotype. We therefore do not anticipate that adverse effects will manifest in these animals. The neurodegenerative disease models we aim to use can develop muscle weakness and/or impaired motor performance at adult stages of life. However, our experience is that these phenotypes emerge in fish that are >2 years old. As animals used in this protocol will be euthanised by 21 months of age, we do not expect fish to develop harmful phenotypes during the course of the protocol. The breeding protocol is itself not expected to have any adverse effects on animals used in this project.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

100% of animals are expected to be in mild severity category.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We study how vertebrates generate natural, flexible motor behaviours in response to sensory input. THis work must be conducted using in vivo models: a holistic understanding of motor circuitry in health and disease requires models that are capable of generating naturally evoked behaviour. This can only be realistically achieved with in vivo preparations.

What was your strategy for searching for non-animal alternatives?

We have used the Frame.org website to screen for non-animal alternatives but none were available.

Why were they not suitable?

To understand motor network function in health and disease, intact in vivo models that are capable of generating natural bouts of motor activity in response to sensory input must be used. It is not possible to do this with mathematical models or human tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

To maintain a breeding colony that can generate embryos on a daily basis, we will require around 100-200 fish per genotype. We anticipate using around 10 GM lines. As fecundity decreases after 1.5-2 years, we anticipate replacing breeding stocks 3 times during the course of the project.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The number of animals requested represent the anticipated minimum to maintain a viable breeding colony for the duration of the project.

What other measures apart from good experimental design will you use to minimise numbers?

Wherever possible, progeny that are not used for experimental purposes will be reared for maintenance of our breeding colony. In addition, we will seek to share tissues from animals that are Schedule 1 killed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We require a stock of adult GA zebrafish for generation of embryos and larvae for experimental study. Breeding protocols are not considered harmful and the majority of GA lines used carry fluorescent reporter genes that do not cause pain, suffering or harm. GA lines that harbour disease causing genes are not expected to show clinical signs until >2 years. To ensure that clinical signs do not occur, these fish will be euthanised before 21 months of age using a Schedule 1 method.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

To study motor network function, in vivo vertebrate models must be used. Zebrafish offer an ethically-oriented alternative to mammals as the early stage fish that are not protected under ASPA can be used for these purposes. We are required to use adult, breeding-age fish during this project so that embryos and larvae can be generated for study.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Health checks of our fish stocks are conducted twice a day. Fish displaying clinical signs are removed from the colony and killed via a Schedule 1 method. To maximise the success of breeding procedures and reduce metabolic and physical stress, fish will be cycled for breeding with individuals mated no more than every 2 weeks.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will adhere to the ARRIVE guidelines when designing, conducting and publishing research arising from this project.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We subscribe to the NC3Rs newsletter and will liaise regularly with our NC3Rs Regional Programme Manager to keep up to date with recent advances in the 3Rs. In addition, advances in the 3Rs will be monitored through attendance at conferences and symposia.

Explain the choice ofspecies and the related life stages

Zebrafish are an outstanding model for the study of vertebrate motor systems because their motor networks are functionally and anatomically similar to our own. Moreover, their progeny are tractable to a range of powerful in vivo molecular, imaging and physiological methods. Therefore, we can use these early stage fish as an ethically-oriented alternative to mammalian models.

Adult zebrafish will be used as we require breeding age stocks to generate embryos and larvae for experimental study.

Home Office

NON-TECHNICAL SUMMARY

136. Mouse models of calcium, bone and endocrine disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand the causes of disorders of calcium and bone metabolism such as osteoporosis, rickets, seizures (epilepsy), kidney stones, many cancers involving different organs, cataracts and diabetes. Understanding of the underlying biology of these disorders will also help with the development of new drugs, which is hampered by our current lack of knowledge of the abnormal physiological processess associated with these disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our research studies focus on identifying the genetic causes of complex disorders of calcium balance, bone metabolism, kidney failure and tumours of endocrine glands (e.g. pituitary, parathyroid, pancreas, adrenal, ovaries, testes) with the ultimate goals of improving diagnosis and treatments for patients with these diseases. To achieve these goals, we need to study the abnormal physiological consequences of the genetic mutations identified in patients, and the only feasible way to accomplish this is to generate mutant mouse models for these diseases.

The disorders of calcium balance, which may be present as increased or decreased levels of calcium in the blood or urine compared to normal, result in many symptoms, including kidney stones, abdominal pain, pathogenic deposits of calcium salts in soft tissues, psychiatric disturbances, excessive urine production, cataracts, involuntary muscle contractions, and osteoporosis, as well as other disorders that do not involve calcium such as cardiovascular disease and diabetes. Furthermore, calcium disturbances may have multiple causes including: single gene disorders of calcium balance or bone metabolism; endocrine (parathyroid gland) tumours, or tumours of other organs (e.g. lungs and kidneys) producing parathyroid hormone related compounds; kidney failure; or decreased parathyroid hormone secretion which can lead to lower levels of calcium in the blood. Many of these disorders are relatively common and place a heavy burden on health care systems. For example: osteoporosis affects ~3 million people in the UK and leads to increased risk of fractures; kidney stones affect ~8% of the population by the age of 60 and frequently reoccur; parathyroid gland tumours have an annual incidence of 1-3 per 1,000 individuals; and changes in the development of embryonic tissue that give rise to structures within the head and neck, from which the parathyroid glands usually develop, have an incidence of 1 per 4,000 live births. There is an unmet clinical need for many of these disorders, either due to lack of current treatments, or imperfect treatments. For example, the only current interventions for kidney stones are dietary, and there are no drugs, resulting in ~10% recurring each year. Parathyroid

tumours, or other cancers may be surgically removed; however, this is not always successful due to incomplete removal of the tumour and/or malignant growths away from the primary site, whilst conventional chemo- and radio-therapies are often ineffective for endocrine tumours due to their low growth rates. Current drug treatments for decreased parathyroid hormone production include calcium and vitamin D; however, these are associated with adverse effects including high calcium levels in the urine and kidney stones.

Our studies will help to understand the genetic causes, biochemical interactions, including hormone signalling, between different organs, in diseases where there are underlying disturbances of calcium. We propose to use mouse models, as mice maintain a high enough degree of similarity to humans in the regulation of calcium, and there are well developed techniques for modifying mouse genes, breeding and characterising the physical appearance and biochemical characteristics that result from these genes and their interaction with the environment. By using mouse models we will also be able to assess new and existing drugs, and dietary alterations, as well as providing new model systems in which novel therapies can be tested prior to their use in man. ***Thus, our studies are likely to increase knowledge of the disordered physiological processes associated with these diseases, as well as provide benefit to patients by improvements in diagnosis and treatments.***

What outputs do you think you will see at the end of this project?

We anticipate that the outputs will include new information, publications and new treatments for patients as follows.

Full examination of the physical characteristics regulating calcium in blood and bone as well as non-calcium characteristics in novel REDACTED will be performed, which will increase understanding of disease causes (pathophysiology), and testing of therapies will increase knowledge of drug actions (pharmacology).

We are continuing our genetic sequencing studies of patients with disorders of calcium balance, bone metabolism, kidney function and endocrine gland tumours which may uncover new candidate genes and thus novel REDACTED based on mutations in these candidate genes may be generated. The biological advances from these studies will depend on the characteristics of the novel gene candidates, as illustrated by our previous studies of such human disorders, which have revealed the involvement of factors regulating: gene expression, biochemical reactions, signalling mechanisms within cells, movement of substances into or out of cells, and hormones.

Thus, these studies will reveal new biological information that will be published in scientific journals. Furthermore, these mutant mice will provide models for testing existing and novel drugs, as illustrated by our studies of mouse models with disorders of calcium balance, and endocrine pathways, in which we have evaluated the effects of drugs that: mimic the effect of calcium or hormones, compete with the effect of calcium, and regulate gene expression.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short-term, our studies will help to understand genetic causes, cellular pathways and the interactions between different organs, in diseases underlying endocrine and metabolic disturbances of calcium. For example, we will assess at least 7 different models of calcium homeostasis disorders due to mutations in e.g. *Gna11*, *Ap2s1*, *Casr*, *Nfix*, *Prlr* and *Men1*. Using these models we will be able to assess existing and new drugs and dietary alterations, as well as providing new model systems in which novel therapies can be tested prior to their use in man. Thus, research scientists and clinicians in different disciplines (e.g. endocrinology, metabolic medicine, genetics, paediatrics, nephrology, skeletal biology, molecular biology, physiology, biochemistry, pathology and pharmacology) will derive benefit from the knowledge.

In the long-term, pre-clinical studies will provide evidence for future clinical trials for researchers to test drugs that are novel, pre-existing or repurposed. Beneficiaries may therefore include patients, clinicians and the pharmacology industry. We have a number of existing collaborations with pharma companies to test drugs and facilitate any promising results into clinical trials.

How will you maximise the outputs of your work?

Results will be published in high impact peer-reviewed journals and presented at national and international conferences. Collaborations will be established with international groups, and novel mouse lines will also be made available through archives, for example European Mouse Mutant Archive EMMA.

Species and numbers of animals expected to be used

- Mice: 65000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A typical experience for a mouse would comprise collecting blood by a needle from the tail daily for 5 days followed by analysis in a metabolic cage, followed by radiological imaging (e.g. by X-ray, DEXA or other scans) involving general anaesthesia to assess parameters of calcium, bone, kidney, and tumour metabolites followed by culling and removal of blood (a terminal bleed).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Adverse effects specific to mouse models related to disorders of calcium homeostasis, bone metabolism, rnal failure and endocrine tumours include:

- Polyuria, polydipsia, abdominal pain, muscle weakness, fatigue and cardiac arrhythmias due to hypercalcaemia (~1-5%)
- Tetany, muscle cramps, and seizures due to hypocalcaemia (<1%)
- Skeletal abnormalities impinging on the ability to move around the cage and/or consume solid food due to disorders of bone metabolism (~5%)
- Disturbances in balance and/or walking in a circular pattern due to an advanced pituitary tumour (<0.5% as they usually develop after the age at which these mice will be bred)
- Reduced mobility and/or feeding due to tumour effects (<2% as they usually develop after the age at which these mice will be bred)
- Increased urination or drinking due to disturbances in glucose metabolism (~10%)
- Weight loss and loss of condition due to metabolic disturbances (<5%)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of mice under this licence will be under the breeding protocols in which adverse effects will be mild or subthreshold for approximately 80% of mice and moderate for 20% of mice. A subset of mice (approximately 20%) will undergo the phenotyping or testing of agents protocols in which the development of clinical signs is required and they will have moderate adverse effects.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Regulation of plasma calcium levels requires the interaction of the parathyroid glands, bone, gut and kidneys, via circulating hormones and vitamin D. In addition, calcium has different effects on different organs such as the pancreas. As this represents a whole body system, it is not possible to investigate and understand disease development in isolated cells, and instead whole live animals are required. In addition, drugs need to be tested in whole animals so that the responses of all the different organs can be studied, thereby revealing on-target (i.e. efficacy) and off-target (i.e. side or adverse consequence) effects.

What was your strategy for searching for non-animal alternatives?

We are striving to develop cell models that may be able to replace some mice in some preliminary studies. For example, we are trying to immortalise and grow cells taken from mouse organs in the laboratory, and these could be used to test whether new drugs might be effective, before they are tested in live mice.

Why were they not suitable?

Regulation of calcium levels requires the interaction of multiple organs, it is not possible to investigate and understand disease development in isolated cells but instead whole live animals are required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals for each experiment are calculated based on effect size where known from previous studies or the literature using power calculations to determine the chance of detecting any variations between test groups. Where effects size cannot be pre-determined then either pilot studies will be performed to establish preliminary data that can be used in power calculations, or the resource equation of Mead will be employed to give an estimate of sample size based on the general rule that

the error degrees of freedom for a given experiment should lie between 10 and 20 to maximise the chance of detecting a difference between tests and avoid wasting resources (i.e. mice) for increasingly small gains in detection power. The number of animals estimated for each protocol are based on scaling up the anticipated number of experiments planned (based on estimates from our experience over previous years performing similar research studies to address similar questions and numbers of test agents), which are then combined to give the total number of mice for the project.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Animals are only bred as required to supply animals for experimental requirements. The number of animals required for the experimental studies is determined by power calculations to achieve an effect size. The group is in contact with statisticians who offer advice on statistical requirements. Where possible randomisation and blinding will be used.

What other measures apart from good experimental design will you use to minimise numbers?

In all our mouse work, we use statistical analysis to ensure that the minimum number of mice are bred for the study, and that we use only the number of mice that are required to produce meaningful and useful results in order to answer the experimental questions. We are able to study the effects of drugs in multiple organs within an individual animal, for example in mice which develop tumours in more than one organ. Similarly, we can image the same mouse several times to study the development of organs or tumours, rather than using several mice once. We are also trying to establish cells from mice that will grow long-term in the laboratory. These could be used to replace some mice for the early stages of testing of new drugs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use animal models of endocrine and metabolic disorders affecting calcium homeostasis, the skeleton and kidney functions as these are often interlinked in relevant human diseases, which include: familial hypercalcaemic hypocalciuria (FHH), autosomal dominant hypocalcaemia (ADH), endocrine tumour development, Marshall Smith syndrome and renal failure. The models we use are representative of disease in human patients and are closely monitored for signs of suffering when they are culled.

We are using well established analysis methods that have been developed by experts in mouse husbandry. We are using LASA guidelines for asepsis techniques such as injections.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Only mice will be used in our studies, and have been chosen as they represent the lowest mammalian species which allow the necessary genetic manipulations and display sufficient similarity to human organs and physiology.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have developed expertise and experience in mouse welfare, and have refined our tests to ensure that the highest quality data is generated for the least welfare cost.

We are keen to minimise severity and increase the welfare of these animals. To ensure this, we will use non-invasive tests that only cause temporary discomfort where possible. For administration of drugs, a small pilot study will be undertaken for new drugs, with increased cage observations and welfare checks to ensure that the drug is safe. We also aim to use long acting drugs where possible to reduce the frequency of dosing. During every test, mice are closely observed and anaesthetics or analgesics used when appropriate.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We conform to the ARRIVE guidelines on animal studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We attend termly gold standard animal welfare meetings at which a REDACTED representative of the 3Rs gives regular updates. We also consult the 3Rs websites for techniques and alternative models. We regular perform literature searches to keep up to date with advances in animal welfare.

Explain the choice of species and the related life stages

The level of calcium is tightly regulated due to its roles in multiple biological processes, and disturbances of this cause many common diseases, including kidney stones, osteoporosis, many cancers including different organs, rickets, seizures (epilepsy), cataracts and diabetes. Calcium

disturbances may have many underlying causes including defects in the calcium regulatory processes, hormone disturbances, kidney failure, and tumours, and many of these are not well treated by current drugs. Development of new drugs is hampered by our lack of knowledge of the underlying biology of these diseases, and we aim to understand this in more detail to aid the development of new and improved drugs.

Our studies will help to understand genetic causes, cellular pathways and the interactions, including hormone signalling, between different organs, in diseases underlying endocrine and metabolic disturbances of calcium. We will also be able to assess existing and new drugs and dietary alterations, and will provide new model systems in which novel therapies can be tested prior to their use in man.

We will use mouse models, as mice provide rapid and efficient breeding whilst maintaining a high enough degree of similarity to humans. We expect to use approximately 65,000 mice over the five years duration of the licence.

The maximum severity of this licence is expected to be moderate. The adverse effects experienced by any mouse will be monitored closely. The adverse effects of high calcium in the blood include increased drinking and urination, abdominal pain and muscle weakness, and of low calcium in the blood are muscle cramps and seizures (rare). Some of the mice may develop skeletal abnormalities, which may reduce their ability to walk normally. Some of the mice may develop tumours, which normally do not cause noticeable symptoms, but may occasionally interfere with normal movement. In order to study these human diseases, we have to allow them to develop in the mice; however, we will take steps wherever possible to reduce the adverse effects. All of the mice will be humanely culled at the end of the procedure.

NON-TECHNICAL SUMMARY

137. Mouse models of lung cancer progression & therapy

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to improve the understanding of lung cancer initiation, progression and disease spread (metastasis). Ultimately, by the use of our mouse models, we aim to develop new treatment strategies which can be applied to the clinic.

A retrospective assessment of these aims will be due by 18 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite years of research, the prognosis for patients with lung cancer remains dismal. The most frequent type, non-small cell lung cancer (NSCLC), accounts for 85% of all lung cancer cases and shows an overall five-year survival of 15%. The long-term survival for patients with advanced high-grade lung cancer has been limited by the frequent occurrence of resistance to chemotherapeutic drugs often established by the onset of parallel compensatory mechanisms (Jemal, A., et al. Cancer statistics, 2009). In order to identify novel genes involved in chemoresistance as well in lung cancer progression that could be targeted therapeutically, mouse studies are fundamental. In vitro model systems have contributed to our knowledge of cell migration and invasion and allowed dissection of the role of individual genes in these processes. However, full understanding of these processes can only be achieved using in vivo models.

What outputs do you think you will see at the end of this project?

This project not only will contribute to understanding of the mechanisms, involving non-coding RNAs, of solid tumour initiation, progression and metastasis but will also help with the development of new miRNA / lncRNAs agents for use as a therapy. The models we shall use will elucidate these underlying mechanisms in mice and allow us to test the efficacy of targeted and conventional therapeutic agents and ultimately in surrogates for individual patients.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Immediate beneficiaries from this research will be other academics across clinical and scientific fields, working in the field of lung cancer and non-coding RNAs. They will benefit from the potential outcome of this study that will lead to novel biological hypotheses. Potential other beneficiaries include pharmaceutical companies that actively develop novel medicines for cancer therapy, as well biomarkers for diagnosis and prognosis. Data from this study will enable the identification of molecules that could be exploited by pharmaceutical companies as novel therapeutic targets. Potential beneficiaries could be cancer patients, especially those with advanced disease, for whom at the moment a cure is not available. Lung cancer patients will be the direct beneficiaries of these discoveries in the long term for the potential development of treatments that will result in improved survival and/or enhanced quality of life.

How will you maximise the outputs of your work?

We shall publish our work in peer-reviewed journals, present the data at internal and external scientific meetings thus sharing our findings with the scientific community.

Species and numbers of animals expected to be used

- Mice: 5600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Some mice (bred under other Project Licences) harbour genetic modifications that pre-dispose them to the development of lung cancers when exposed to an appropriate agent such as Cre recombinase or a carcinogen. Furthermore, some genetic modifications allow us to track specific cells within the tumour (such as T cells expressing luciferase). In other mice, which are bred specifically to tolerate human tissue, tumours will be implanted under the skin of the mouse for ease of monitoring or into the lung or into the blood stream to study cancer spread (metastasis). Mouse cancer cell lines can be transplanted into mice sharing the same genetic background (so called syngeneic mice) without rejection. Tumour growth is not associated with pain during the period in which we conduct our observations. Tumour growth will be monitored regularly by either use of callipers for superficial tumours, or by imaging methods such as CT for internal tumours. For some procedures that involve surgery under general anaesthesia, such as implanting human tumour fragments or removing a primary tumour in order for secondary tumour to grow, we will administer pain killers (including contained in jelly) and monitor the mice closely during recovery.

Some mice may have either potential novel therapeutic agents or genetic therapy molecules, existing clinical agents or a placebo administered by a variety of routes, but usually either by mouth, or by

injection either under the skin or into the abdomen to study the effects on tumour growth and / or tumour composition. The mice will also have blood samples taken either from the tail vein or by sampling from a heart chamber under anaesthesia (in which case the animal does regain consciousness before humane termination). Occasionally mice may be administered an organ preservative whilst under non-recovery anaesthesia to allow us to undertake histology investigations on slices of selected organs.

Mice may be studied for up to 90 days after a period of therapeutic agent treatment for tumour growth. Fast growing tumours will be monitored daily.

Mice will be group housed in ventilated cages which have their environment enhanced with items such as tunnels, houses, nesting material and gnawing blocks.

At the end of any protocol mice will be humanely killed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The impact of the gene modifications are not expected to cause any adverse effects per se other than, in the case of the tumourigenic mutations, promoting the propensity to produce tumours. It is possible that the tumour growth might affect normal physiological functions (such as eating, locomotion or breathing) however, mice will be observed daily and any side effect that cannot be managed satisfactorily will be killed humanely.

Injections would only cause very transient pain.

After surgical procedures we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of mice are only expected to experience the mildest clinical symptoms due to tumour growth before they are humanely sacrificed. Additionally, some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery with a specialist tube. We will am to utilise the least stressful route of administration wherever possible.

A minority of mice will undergo surgery and these will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing this is not painful.

Finally, a small number of mice will be used for determination of metastatic potential of cells. As this will involve intra-cardiac injection of cancer cells we do not know where they may be distributed, and therefore know the location of metastatic tumour growth. There is a small risk that there could be Severe endpoints in these mice but will be mitigated by regular monitoring. After characterisation of the clinical signs it may be possible to reduce the severity band in future use.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 18 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While valuable studies of human cancer are performed using tumour material and cell lines derived from both mice and human samples, the mechanistic understanding of cancer pathogenesis requires use of living animals. In particular, cancer development and spread involves a plethora of interactions between cancer cells and their surrounding host and their behaviour is governed by multiple signals originating from both their immediate neighbours and from distant tissues.

Transgenic mouse models have been engineered to develop cancers, which accurately mimic their human counterparts, and have potential applications to test the effectiveness of novel cancer therapeutics. This cannot be replaced by in vitro studies or indeed even in different in-vivo models such as zebrafish or insects which remain far less complex than their murine counterparts.

What was your strategy for searching for non-animal alternatives?

We will use a variety of in vitro approaches to investigate how manipulation of nucleic acid based targets alter cell behaviour in cultured cancer cells (lung,) prior to undertaking in vivo studies.

Methods to be utilized include cell biology techniques to measure cell proliferation, survival, migration, invasion, etc., biochemical and molecular biology techniques such as western blotting, enzymatic assays, proteomics, RT-PCR, etc. to study protein function. In addition, we use molecular pathology (e.g. immunohistochemistry) to substantiate findings from our in vitro models in human tumour samples.

Why were they not suitable?

The study of cells in culture (in vitro) provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above.

A retrospective assessment of replacement will be due by 18 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume or tumour incidence following manipulation of a gene of interest or treatment with a drug can be determined using a minimal number of animals.

Data available from the literature or from pilot studies are used to perform power analysis to determine an appropriate sample size for the definitive experiment. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.

Based on past experience, group sizes of between 10 and 30 animals (dependent on the readout, fewer for transplanted tumours compared to spontaneous tumours in GM mice) per experimental group suffice. However for an experiment to be well controlled and meaningful, we may include more than one experimental group. For instance, in implantation experiments where we deplete a gene in a cell line using shRNA, we will use two independent shRNAs targeting the gene as well as a control shRNA. Moreover, we would typically examine more than one model cell line. Likewise, we may use several doses of a drug, or several different drugs or drug combinations to test a theory. Considering power, the

number of experimental groups, and the number of genes and drug targets we are interested in, we have then estimated the total number of mice to be used over the licence lifetime.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Use of in vitro methods limits the number of animals required for the in vivo investigation stage.

For transgenic models, efficient breeding strategy will minimise the number of mice used to obtain the desired genotype.

Experiments will be appropriately controlled and mice of the same age, genetic background and source used to reduce the variability of results and to produce highly consistent data. Wherever possible and appropriate, a single group of animals will serve as a control for duplicate experimental group. The proposed experimental designs and methods of analysis of the results will follow statistical guidelines and involve discussion with our bioinformatician scientist to provide sufficiently powered studies, minimizing the number of animals used in each experiment. The design of individual experiments will generally involve factorial designs, which maximise the information obtained from the minimum resource.

We will be conducting and recording our experiments to be able to publish our results following the ARRIVE guidelines [https://www.nc3rs.org.uk/arrive-guidelines] and will use randomisation, blinding etc. where appropriate so as to minimise biases. Furthermore, additional resources may be used to aid experimental design such as the NC3Rs experimental design assistant tool

(https://www.nc3rs.org.uk/experimental-design-assistant-eda).

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be performed if applicable and, after analysis of the results, group sizes for subsequent experiments will be determined based upon these data. As far as possible, multiple parameters will be evaluated in a single mouse. Live imaging of the same animal at multiple time points also greatly reduces the numbers required.

A retrospective assessment of reduction will be due by 18 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mouse models that we are currently using faithfully recapitulate the human disease. Moreover, the mouse genome shares 98% homology with human genome.

We constantly work to improve husbandry and procedures which minimise actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare in situations where the use of animals is unavoidable. We ensure to provide the appropriate anaesthetic and analgesic regimes as well as appropriate humane methods of culling within animal facility. We ensure no visualisation of procedures in other mice and transport arrangements between facilities in appropriate carrying boxes.

We will use non-invasive imaging procedures to follow lung cancer and metastatic tumours. When the scientific endpoint has been reached the animals will be killed before any humane end-point is reached.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Less sentient animals do not have lungs. Mouse is far more similar to humans than other animals having lungs e.g. birds or reptiles and this is critical both for using reagents like drugs developed for human targets and for translating findings to the clinic. Cancers develop over many weeks to months, so use of terminally anaesthetised animals or immature animals is not practicable. Also immature mice lack a functional immune system which is desirable in cancer research.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Assessment of the size of superficial tumours would usually be by callipers (usually of two diameters at right angles). The total tumour burden should not normally exceed 1500 mm^3 as calculated by the formula: tumour volume = ½(length x $width^2$). Sub-cutaneous tumours will be monitored at appropriate intervals (usually once a week and measured by callipers). If a tumour reaches approximately 2/3 of the maximum permissible volume, it will be measured more frequently.
Growth of internal tumours will be monitored by a combination of palpation and, where possible, non-invasive imaging.

Wherever relevant, animals will be provided with analgesia as detailed in the relevant Protocol to control adverse symptoms associated with any surgical treatment.

Provision of nursing support, such as mash, analgaesic gels.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).

We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)] administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.

Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23]

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our NACWO, NVS and HO inspector. I am also a member of the AWERB at the REDACTED.

Explain the choice of species and the related life stages

Mice are more comparable to humans than less sentient model systems (fish, invertebrates) in pathophysiology and show higher levels of conservation in nucleotide and amino acid sequences. This is important as we intend to use reagents such as small molecule inhibitors and antibodies that have been developed to target human proteins.

Moreover, non-protected species and less sentient species do not have lungs, so we would be unable to use them for animal models of lung cancer involving the injection of lung cancer cells in the organ where they are found in man. Embryonic stages would not provide us with a sufficient window to follow tumour development and besides it is not feasible to perform the desired interventions in embryos (such as inhalation of Cre-expressing virus). Therefore adult mice are to be used.

A retrospective assessment of refinement will be due by 18 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

138. Mouse models of mucosal immunology

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to discover ways in which the immune system maintains health through training by microbes. Particularly focusing on the role of the microflora and related cell signalling pathways.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There has been a rise in incidences of cancer, inflammatory bowel disease, allergies and metabolic diseases over the last half century. Mounting evidence suggests that our diet, along with our microflora that live within us, is instrumental in training our immune systems, which when not functioning properly can lead to an increased risk in all many diseases.

What outputs do you think you will see at the end of this project?

This work will provide new insight into how genetic and environmental risk factors increase the risk of developing chronic diseases such as cancer, inflammatory bowel disease and obesity. The information generated will also give insight into how the microbiome may be manipulated, through probiotics, antibiotics and/or diet, useful in the treatment of these disorders. The outputs will comprise of publications in scientific journals, as well as in the lay press, and will hopefully help to inform the public on how to maintain a healthy lifestyle.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

A major benefit of this work will involve the dissemination of these novel insights not only to the wider scientific community, but also the public, to improve societal knowledge of how to prevent these diseases. Dissemination will involve the publication of scientific papers and engagement with The REDACTED Press Office to report the findings of our research in the media (articles and interviews) as well as presenting our work at public engagement events.

How will you maximise the outputs of your work?

We will engage with The REDACTED Press Office to report the findings of our research in the media (articles and interviews) as well as presenting our work at public engagement events. My group has active collaboration with researchers at national and international levels. We will actively collaborate with other researchers using complementary approaches to maximise the outputs generated in this project, including through the sharing of available experimental data and animal tissue. Members of my group and I attend national and international scientific conferences to present our work. I also teach Undergraduate and Postgraduate students at The REDACTED and regularly discuss my own research in teaching sessions as well as hosting 6-8 research project students per year in my laboratory.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be bred in captivity to over or under-express certain genes that are known to play roles in various chronic diseases (such as cancer, inflammatory bowel disease, diabetes, etc). These genetic manipulations are known not to cause any noticeable harm to the animals in the normal, healthy state. These animals may then have their microbiome manipulated, for example through antibiotic administration, either in the drinking water or as an oral gavage to mimic human antibiotic usage. They also may be administered certain bacterial or fungal preparations that are known to be non-pathogenic components of a healthy microflora. The animals may also be treated with substances that will cause intestinal damage, such as inflammation or tumours. Induction of such damage is required so that we may find out ways to treat the inflammation or tumours through using immunomodulatory agents and/or microbial preparations.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Cancer causes morbidity in humans only at advanced stages, once the tumour prevents an organ from working properly. None of our animals will be left long enough for this to happen, but if the tumour was starting to impact on physiological functions, we would expect the animal to lose >20% of its body weight, appear hunched or lose interest in eating/cleaning. Animals which receive substances to induce intestinal inflammation will be closely monitored for any signs of ill health. Sometimes an animal will develop diarrhea, a normal response to intestinal inflammation. Occasionally, if chronic, the diarrhea may lead to weight loss and/or rectal prolapse, hunching or inactivity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

No animal will experience severe severity effects. It is not expected that any animal will experience moderate severity effects. If they do, it will only be very short term, as the animals are checked at least once daily. Any animal experiencing moderate severity adverse effects for longer than 24 hours will be subjected to schedule one and tissues harvested for analysis. At worst, 50% of animals on protocol 3 may experience some mild adverse effect, such as diarrhea and/or weight loss and 5% may experience moderate severity effects, such as weight loss over 20% or hunching. This is a 'normal' response to

intestinal inflammation (such as when humans are infected with a gastrointestinal infection) and animals will be monitored closely for sustained or overt weight loss >20% body weight or hunching which are indicators of suffering.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To be physiologically relevant, the study of host:microbe interactions requires the use of animal models, as currently in vitro intestinal models are insufficient to replicate certain critical functions, such as how the intestine responds to infection and how cancer cells evade the immune system.The mouse is chosen because it is a mammalian model, transgenic animals specific to the gene of interest are available and it is possible to manipulate the microbiome. Making mice the ideal model to assess the interaction of genetic vs. environmental factors in disease.

What was your strategy for searching for non-animal alternatives?

Our lab has extensively studied epithelial responses to microbial ligands, including LPS REDACTED secretory protein *in vitro*. We have also conducted preliminary *in vivo* studies using a Drosophila model of epithelial repair and we use simultaneous *in vitro* and *ex-vivo* human tissue models to inform our animal studies.

Why were they not suitable?

Whilst informative and providing us with preliminary data to support our *in vivo* aim, and narrowing down our lines of enquiry, we are limited when translating results from *in vitro*, non-mammalian and *ex-vivo* human systems to physiologically relevant pathologies and therefore other models support and reduce, but cannot entirely replace animal work. Certain epithelial functions, such as differentiation into multiple cell lineages, symmetric and non-symmetric cell division and the influence of non-epithelial cell types cannot be tested in *in vitro* models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on previous experiments and breeding strategies, approximately 1000 animals will be bred per year. This is accounting for animals that are genetically modified and wild-type controls, so 5000 animals total are estimated to be required. Approximately 10% of the mice used (about 500) may be purchased/transferred from approved suppliers and/or licenced institutions.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The proposed experiments and methods of analysis of the results have considered and will be discussed with an independent statistician at the The REDACTED. For most of the experiments sample sizes will be set using power analysis, generally using a significance level of 5%, a power of 80%, and a least practicable difference between groups of 25%. Otherwise, we will use the least number of animals to provide an adequate description, generally on the basis of previous experience. Post-hoc power analysis will be utilised during the course of these studies to update our knowledge of appropriate group sizes when the data becomes available.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding of genetically modified mice can involve relatively large numbers of animals. The transgenic mouse breeding strategy aims to generate as few ‘unusable’ mice as possible. The numbers used will be minimised by breeding separate transgenic/knockout and wild-type lines wherever possible. As breeding will generate both, male and female mice will be used for all procedures and analysis will account for potential sexually dimorphic responses. We will also make the data and tissues generated from these experiments available to collaborators both at The REDACTED and other institutions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice will be bred in captivity to over or under-express certain genes that are known to play roles in various chronic diseases (such as cancer, inflammatory bowel disease, diabetes, etc). These genetic manipulations are known not to cause any noticeable harm to the mice in the normal, healthy state. These mice may then have their microbiome manipulated, either through antibiotic administration, either in the drinking water, or as an oral gavage to mimic human antibiotic usage. They also may be

administered certain bacterial or fungal preparations that are known to be non-disease causing components of a healthy microflora. The mice may also be treated with substances that will cause intestinal damage, such as inflammation or tumours. Induction of such damage is required so that we may find out ways to treat the inflammation or tumours through using immunomodulatory agents. MIce which have had tumours induced in them will be aged to no more than 12 months. Cancer causes morbidity in humans only at advanced stages, once the tumour prevents an organ from working properly. None of our animals will be left long enough for this to happen, but if it did, we would expect the animal to lose >20% of its body weight, appear hunched or lose interest in eating/cleaning. If any of these indicators of suffering are detected, the mouse will be humanely killed. Animals which receive substances to induce intestinal inflammation will be closely monitored for any signs of ill health. Sometimes an animal will develop diarrhea, a normal response to intestinal inflammation. Occasionally, if chronic, the diarrhea may lead to weight loss and/or rectal prolapse, hunching or inactivity. Again, if this happens the animals will be humanely killed within 24 hours.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

As we are assessing the complex interaction of different cell types that have translational relevance to the chronic diseases experienced by human, we can not use species that are less sentient. Due to the chronic nature of diseases such as cancer, obesity and inflammatory bowel disease, we can not use animals at more immature life stages. Terminal anaesthesia would not be appropriate as the microflora changes, tumour development or intestinal lesions take time (weeks or months) to develop.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The most likely adverse effects on these protocols are weight loss and/or diarrhea. Weight will be monitored at minimum weekly (daily on protocol 3) and appearance observed daily at minimum. If any indicators of pain are observed, such as hunching, gurning or piloerection (caused by lack of self-grooming) the animals will be closely observed for a period of 24 hours, if no clear improvement is observed within 24 hours (i.e. lack of indicators of pain), the animals will be schedule 1 immediately.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow best practice guidance as provided by the nC3Rs to ensure that experiments are conducted in the most refined way, including guidance provided as part of the Experimental Design resources (https://www.nc3rs.org.uk/experimental-design) and by reporting our experimental data in accordance with the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines). For pain assessment we refer to the nC3Rs mouse grimmace scales.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We regularly monitor the NC3Rs website (https://www.nc3rs.org.uk/) for any news regarding advances in animal welfare and for any relevant events being held. We will also regularly attend scientific meetings with a strong 3Rs focus, including meetings held by the British Society for Immunology. We will also share best 3Rs practice with REDACTED colleagues through participation in the Universities Animal Welfare and Ethics Review Board (AWERB).

Explain the choice ofspecies and the related life stages

Mice are most commonly used as the mammalian model of choice to explore how genetic in combination with environmental factors influence disease development. Gene expression can be manipulated in these animals to allow scientists to define how specific genes work to prevent (or cause) diseases. Advanced methods involving genetic manipulation in certain cell types, rather than all the cells in the animal, allow us to define relative contributions of certain cell types and make manipulations more relevant to human conditions (i.e. translational). Mice are also the ideal model to study the relative contribution of microflora as they can be kept clean and their flora can be removed (i.e. germ free). Much of the research that has led to what we know about the role of microflora in diseases, such as cancer, has been carried out in mice.

Home Office

NON-TECHNICAL SUMMARY

Mucosal Immunisation to Covid-19

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To evaluate the use of bacterial spores as a vaccine delivery system focusing initially on the current Covid-19 pandemic.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The approach proposed has utility for the first stages in the development of mucosal vaccines. Mucosal vaccination is challenging and bacterial spores are attractive for this purpose. The current Covid-19 pandemic emphasises the need for mucosal vaccines which may be more appropriate for a disease of the upper respiratory tract.

What outputs do you think you will see at the end of this project?

The primary outcome of this work will be validation of the spore platform for delivery of immunogens to the mucosa and the production of mucosal immunity. This would lead to downstream challenge experiments and ultimately a major step forward for the development of human vaccines for which no vaccines currently exist.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term this work will evaluate and validate mucosal vaccine candidates that will be taken forward to challenge studies. This is an important first step in the program of pre-clinical events leading to human studies and new vaccines. In the current period Covid-19 is a global priority and so our efforts will be focused on validating the spore vaccine for early and rapid evaluation for a new mucosal Covid-19 vaccine.

How will you maximise the outputs of your work?

REDACTED would like to publicise its results and raise awareness. This would occur through publications, conferences and participation with advocacy groups, learned societies, special interest groups and public health agencies

Species and numbers of animals expected to be used

- Mice: 2,450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be housed in appropriate groups and administered an immunogen by a mucosal route. Control groups will also be run in parallel for example, animals receiving an appropriate buffer (naive) or non-recombinant spores ('sham group') by the same delivery route. In addition, animals may also be immunised using a parenteral route to determine the immunogenicity of the antigen expressed on spores. This serves as an important control for ensuring the antigen is immunogenic.

During this procedure animals will be periodically sampled for analysis of antibody responses, this being via tail bleeds. After the study end animals will either killed using a schedule 1 procedure or taken forward to a challenge experiment (but out of the scope of this project licence).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

No impact or adverse effects are expected from the immunisation and sampling procedures described here.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For the majority of animals the severity is mild but for those under an AB procedure a proportion (<5%) will be Moderate.

What will happen to the animals at the end of the study?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

With current scientific product development of a human vaccine with either prophylactic or therapeutic properties it is necessary to first demonstrate that the prototype vaccine is: a) immunogenic and capable of producing a mucosal or systemic immune response, and b) immunised animals are protected from

challenge with the live pathogen. These are the two most important criteria for progressing with a vaccination approach and must be addressed fully before any consideration of entering human clinical trials. We are not aware of any human vaccine that has entered clinical evaluation without the completion of pre-clinical studes in animals.

What was your strategy for searching for non-animal alternatives?

Currently, there are no non-animal alternatives available. It is worth emphasising that the decision to enter animal testing is itself determined by a number of in vitro tests that taken together support evaluation in animals. While in vitro tests are not confirmatory of efficacy they play an important role in the decision to evaluate in animals and the likelihood of success.

Why were they not suitable?

A disease caused by a microorganism (virus or bacterium) is nearly always multi-factorial, that is, the manifestations of disease result from a number of independent events. For example, for a virus this would include the impact of a multitude of cytokines produced in the host and for bacteria the production of toxins, attachment to a substrate, induction of innate immunity etc. Most of these events can be assessed individually using in vitro tests and taken together provide an indication that a test product may work but only using an animal model can this be categorically defined as positive or negative.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous studies will have used power calculations to determine group sizes and the validity of these calculations demonstrated from previous studies. As a rule, numbers of animals used per group should be sufficient to enable statistical significance between groups. Since the studies contained here have the same primary objectives we can use the same group sizes. If the primary objective will be different a new power calculation will be performed to determine animal numbers.

A typical study in mice would be 50-70 animals . For 5-7 studies per year for mice with overage this is equivalent to 3,000 mice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In the long-term animal numbers are reduced by careful project design reducing the need for further experiments. A core tenant of the design of animal experiments is the correct use of statistics (for interpretation of significance) and power calculations (to determine group size). The level of variability in some primary endpoints necessitates larger numbers to achieve statistically and biologically meaningful data. The most appropriate statistical tests Mann-Whitney (or the students t-test) for significance and ANOVA for analysis of variance between groups.

What other measures apart from good experimental design will you use to minimise numbers?

In our experience for studies are to be undertaken where large number of animals are to be used then small pilot studies using 2-3 animals/group are preferable. This is particularly important where a challenge dose must be determined or a dosing regimen established. Although statistical significance is not determined, in the long term, this avoids a negative outcome involving large numbers of animals.

Additional factors are to ensure the use of the same animal supplier (where possible) and the use of similar aged animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice will be used to evaluate mucosal immunity. This is achieved by mucosal delivery of the immunogen in parallel with control groups consisting of the immunogen alone administered by either a parenteral route (injection) or by a mucosal route if necessary.

The least invasive route of substance administration and using flexible gavage needles will be used where possible. Negative control groups (baseline groups) will be minimised whenever statistically feasible.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice a are used since these are the lowest vertebrate group that can be used for evaluation of in vivo immunity.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Improvements in any process can always be made and we are receptive to any suggestions as well as our own assessments. We are keen to consider and if possible implement non-aversive handling of animals as well as practices for enrichment of quality of life for animals housed under solitary conditions. We will implement these where possible using only suitably trained staff and discussion with the REDACTED unit and NACWO representative as necessary.

To minimise discomfort of repeated procedures such as anaesthesia, we will combine treatments under a single anaesthetic event wherever possible. The anaesthesia will preferably entail the use of inhalation agents whenever possible. Least invasive route of substance administration and needle gauge will be used where possible. Negative control groups (baseline groups) will be minimised whenever statistically feasible.

Expertise at the Designated Site further enhances animal welfare, by providing close collaboration with dedicated animal care staff and veterinary consultants, and ready access to highly skilled advice.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

NC3R guidelines. We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult all the relevant references listed therein.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By interaction with the Head of Animal unit at REDACTED and the NACWO Representative. Continuous monitoring of publications and the NC3Rs website for new and alternative models that could be implemented as part of this project and relevant information is circulated by AWERB. Whenever possible we will implement these refinements into our studies.

Explain the choice ofspecies and the related life stages

Mice will be used to evaluate the ability of vaccines. Adult mice are routinely used for evaluation of immune responses by the scientific community. Mice can also be used for challenge experiments. Although out of the scope of this project licence vaccinated animals could be evaluated subsequently in challenge experiments against the relevant pathogen. For example, immunised mice can be assessed for protection to influenza A.

Mice	adult
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We want to find out how putting drugs into tiny particles improves their activity as medicines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Medicines must be discovered by first discovering the active ingredient and then once an active ingredient is identified it must be developed into a medicine (e.g. a tablet, injection, eye drop or suppository). Sometimes the nature of the active ingredient makes it hard to make it into a medicine because it is fragile and easily destroyed when taken or because it cannot get inside the brain to treat brain diseases or it cannot get to the retina to treat diseases of blindness. Sometimes cancer drug active ingredients are hard to develop into medicines as they need to get in large quantity to the cancer itself and not to anywhere else. This is because when cancer drug active ingredients end up in healthy tissue, this causes side effects.

Putting medicines into tiny particles made of other materials (e.g. fats, carbohydrates and proteins) protects the active ingredients from destruction and helps these active ingredients get to where they need to go in the body. The tiny particles in question are really really small and are less than 1/100th of the width of a human hair in diameter.

We wish to study how these tiny particles work and how they shuttle drugs around the body so that ultimately we can design particle-based medicines to treat various conditions, e.g. brain diseases, diseases that cause blindness and cancers.

We have already used our knowledge of these tiny particles to create a pain medicine candidate and licensed this to a United States (US) company, for further development. This company will test this medicine in humans and see if it can replace the opioid pain killers (e.g. morphine and fentanyl) used currently. 17,000 people die every year from using opioids to control their painful conditions in the US and so a safer replacement will be welcome and extremely timely.

Furthermore we have used these tiny particles to create a dry-eye medicine which has been licensed to a US company and this company will again test this medicine in humans and see if it can replace the current approved medicine. The current leading dry eye medicine takes six months to show an effect. The licensing company believes that the medicine that we created could make patients respond faster.

Our success in the past, as described above, means that in the future, as well as benefiting patients, the work that we are doing is very likely to help the economy by building new companies, where relevant. Furthermore as the REDACTED owns the intellectual property that we generate from REDACTED funded projects, the REDACTED will reap benefits from the sale of such companies or the licensing of our discoveries.

What outputs do you think you will see at the end of this project?

At the end of our project, we expect to have learnt more about the way these tiny particles work in the body. If the way that these tiny particles work, as medicines, is better understood we will be able to design new medicines to treat brain disorders, diseases of blindness and some cancers. We will publish our work in scientific journals to allow other scientists to learn from our work and we may even develop some new medicines, if the data is promising. We have developed medicine candidates that will undergo clinical testing by others (e.g. the cyclosporine eye drop formulation and enkephalin formulation mentioned above) using these tiny particles in the past.

Industrial manufacture of these nanomedicines will have a limited environmental impact as we are currently using a waste product (chitin) to prepare our nanoparticles. However there will of course be an environmental impact as with all industrial manufacture (e.g. production of waste materials and energy usage).

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term (2 - 5 years), our work will benefit other scientists as they will learn from our published findings. Our work will also benefit the scientists working on our programmes as well as ourselves as we will all learn something new about the way these tiny particles work as medicines.

In the medium term (5 - 10 years), our work will benefit the economy if new medicines are developed or are in the process of being developed as these discoveries will lead to money coming to the REDACTED when these discoveries are out-licensed to third parties.

Ultimately in the long term (10 - 15 years), if new medicines are developed and approved for sale, our work will benefit patients who suffer from brain diseases such as chronic pain or dementia or patients who are at risk of blindness. Finally our work may even benefit cancer patients.

How will you maximise the outputs of your work?

We will work with other scientists and engineers to make sure that we fully understand what these tiny particles are capable of as medicines. For example, we already collaborate with physicists as well as with eye doctors. These collaborators help us to understand how the formulations that we are developing may be used (e.g. clinicians) and help us understand the mechanisms of action of various potential medicines (e.g. physicists working with us on gold nanoparticles).

We will make sure that any findings that may be used to make new and improved medicines are taken forward either by establishing a new company or by licensing our findings to an established company

so that the medicines may be developed.

We will publish all of our work, even when the results of the experiments show that the tiny particles are unable to shuttle active ingredients to particular areas. This will help scientists understand these particles better and inform others on which avenues to pursue within the discipline.

Species and numbers of animals expected to be used

- Mice: 6000
- Rats: 4000
- Rabbits: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The animal will be bought from a reputable company and then transported to our animal house where it will live for 7 days with food and water supplied in order for the animal to get used to the new environment. Environmental enrichment will be in the cage so that the animal is not bored.

On Day one of the experimental phase of the project, the animal will be dosed some of our tiny particles and the dose will be such that it is unlikely to cause harm as the particles would have been tested in cells first. The animals may be dosed more than once and the dose volumes will be within the acceptable limits. Animals may be dosed with solids or liquids and via different routes. The animals will be killed after a suitable period of time and their organs and blood taken for us to analyse. Sometimes blood will be taken repeatedly from one animal over a one or two day period but this will be no more than 10% of the total blood volume over a 24 hour period and no more than 15% of the total blood volume over a 48 hour period. The animal will be humanely killed at the end of this study.

Some animals (mice and rats only) will be disease models (e.g. a pain model to test if the analgesics are working) and so they may be subjected to moderate pain in order to see if the tiny particles reduce this pain. A typical pain experiment may involve the animal having its tail dipped into hot water of 50 degrees centigrade. 50 degrees centigrade is just hot enough for a human to immediately withdraw their hand but not hot enough to cause scalding. The animal will be able to immediately withdraw its tail from the water if it feels painful and will keep its tail in the hot water longer if the tiny particles are giving the animal pain relief. Another typical pain model is a nerve damaged model. In all cases we will measure the pain relief felt by the animal. The animal will be humanely killed at the end of this study.

Only healthy rabbits will be used for our studies.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We intend to obtain results which will tell us that the tiny particles are working in the animals either to bring about relief from a disease state or that they go to areas in the body where we want the particles to go.

Some animals may suffer weight loss of more than 15%, moderate pain, show signs of discomfort by remaining hunched over or make unusual sounds. We do not expect more than 5% of our animals to show these effects.

Some animals may suffer from the anaesthetics that we give them and have an unexpected effect that shuts down their organs. We do not expect more than 2% of our animals to show these effects.

Common effects like bruising after we have withdrawn blood may affect about 10% of the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect 90% of mice to have mild effects and 10% of animals to have moderate effects.

We expect 90% of rats to have mild effects and 10% of animals to have moderate effects.

We expect 95% of rabbits to have mild effects and 5% of animals to have moderate effects.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The tiny particles that we are testing are carried by the blood to the various organs and so we need to test them in the presence of flowing blood. This can only be done in live animals.

What was your strategy for searching for non-animal alternatives?

We considered the use of computer models and organs grown in laboratories.

Why were they not suitable?

The computer models are not sophisticated enough to really mimic blood flowing in a mammal and to mimic all the cells and organs in a typical mammal.

The organs grown in laboratories do not have a well developed blood stream that we can use and test how the tiny particles shuttle medicines around these laboratory grown organs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers below are the upper limits for our animal numbers.

We will always first conduct a pilot experiment to measure the size of the response and by how much it varies and this will be used to decide how many animals are needed in each group. The animal numbers in each experiment, given below, come from experiments that have been conducted in our laboratory previously. Group sizes have been determined using statistical methods

Mice - For group sizes of at least 5 animals and with a test and one control group and sampling at 8 time points, we estimate that each experiment will need about 100 animals (including the pilot studies) and we will conduct about 12 experiments per year and hence will need 6000 over 5 years.

Rats - For group sizes of at least 5 animals and with a test and one control group and terminal organ sampling at 6 time points, we estimate that each experiment will need about 80 animals (including pilot studies) and we will conduct about 10 experiments per year and so we will need 4000 over 5 years.

Rabbits - For group sizes of at least 5 animals and with a test and one control group and terminal organ sampling at 4 time points, We estimate that each experiment will need 50 rabbits and we will conduct about 2 experiments per year and so we will need 500 rabbits over 5 years.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We need each experiment to yield meaningful data that we are able to use. This will limit the overall number of animals used, as experiments then do not need to be duplicated.

We used published guidelines to design our experiments (e.g. the PREPARE guidelines and the NC3Rs' Experimental Design Assistant).

We have used power calculations to make sure that our experiments contain enough animals so that we are able to detect any differences in our samples.

What other measures apart from good experimental design will you use to minimise numbers?

1. We will carry out pilot experiments to see how big our signal is and by how much it varies. We will then use this information to calculate the best group size for our experiments that will give us reliable data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use healthy mice, rats and rabbits to study where the tiny particles go in the animal. These models are best as there will be no presence of disease in these models and we will make sure that the dose that we select for our main studies have been shown not to cause harm in a pilot study of a few animals.

When we want to measure whether the particles work in the animal as potential medicines, we may use disease models, but these disease models will be such that the disease/condition does not cause severe harm.

We plan to use pain models but have chosen pain models that do not cause excessive suffering. Pain models include: dipping the animal's tail into hot water of 50 degrees centigrade, standing the animal on a hot plate of 50 degrees centigrade, lightly damaging a nerve supplying the hind limbs or injecting the animal with a compound that causes paw inflammation. All of these pain models cause the least pain and suffering for the animals but allow us to know if the medicines that we are developing for painful conditions actually work.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The tiny particles need to be tested in mammals with a blood flow that is comparable to that found in human beings.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will minimise animal suffering by making sure that the tiny particles that we give the animals have first been tested on cells and will give them at a dose that theoretically will not kill the cells in the first instance. We will then take the dose up slowly observing for any harm along the way and stopping the experiment if we observe harm that is above our moderate limit.

We will observe all animals for a period after dosing to make sure that we can pick up any unexpected bad effects. In any event we will check our animals daily if we are doing longer experiments.

With any surgery or other use of anaesthetics we will monitor the animals after the procedures to make sure that we pick up any unexpected bad effects.

Apart from when specifically testing in a pain model. we will give the animals analgesics if we observe them to be in pain (e.g. after surgery) and will give the animals analgesics beforehand if we anticipate any procedures may cause pain (e.g. before surgery).

All surgery will be done under general anaesthesia.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use the ARRIVE and PREPARE guidelines.

We will use the LASA Administration of Substances guidelines.

We will use the LASA Guiding Principles for Preparation for and Undertaking Aseptic Surgery

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will read the literature and monitor updates to the NC3R, PREPARE and ARRIVE guidelines. These are laboratory practice guides that tell you how to conduct animal experiments in a way that minimises animal harms.

Explain the choice ofspecies and the related life stages

We need to study where the tiny particles go in the body and so we are using adult mice, rats and rabbits as these are the lowest vertebral life forms that are able to provide us with meaningful results.

We need to study how the medicines made from these tiny particles work and so we are using adult mice, adult rats and adult rabbits, as these are the lowest vertebral life forms that are able to provide us with meaningful results.

NON-TECHNICAL SUMMARY

141. Natural killer cell therapy for viral infections

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim is to develop new ways of activating natural killer cells to combat viral infections, especially COVID-19.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

COVID-19 is currently causing a worldwide pandemic, with over 20,000 deaths in the UK alone. Currently we are in the midst of an emergency with respect to this viral infection and it is critical to devise new methodologies to prevent spread of infection. We propose that one method would be to activate natural killer cells to limit infection in infected individuals. This approach is distinct from other strategies and based on our original fundamental science.

What outputs do you think you will see at the end of this project?

The main output is to find a new way to treat COVID-19. We will determine if the vaccine is safe in mice prior to human studies.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The main benefit will be the general public as the work forms the basis for a new treatment for COVID-19. This may take up to 2-3 years. The academic community will also benefit through presentations at conferences and publications. In the short term (6 months to one year) the benefit will be to the academic community through presentations. Publications would be anticipated within 2 years.

How will you maximise the outputs of your work?

The works will be presented to the academic community at national and international meetings and also through the scientific literature to disseminate the findings. We will also disseminate the work locally through academic meetings and presentations. Significant findings can be disseminated through the REDACTED press office and also public engagement activities such as "Pint of Science". The work may have benefit to other RNA viral infections especially flaviviruses, which we can indicate through the academic press, such as through review articles and presentations.

Species and numbers of animals expected to be used

- Mice: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In a typical experiment adult KIR-transgenic mice will receive two DNA vaccine injections into the thigh muscle. These injections will be given one week apart and injections will be into alternate thighs. The mice will be monitored for any adverse events related to the vaccine. They will have blood taken via the tail vein on one occasion. The mice will be killed humanely one week later, using a Schedule 1 method and a post-mortem examination of the internal organs performed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals may experience local irritation to injections. This is usually mild and passes within 24 hours. We anticipate that by operating within the guidelines for blood drawing and with careful monitoring then animals are not expected to experience significant adverse effects related to these procedures.

.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We anticipate the vast majority of animals will have severity scores of mild, and that only in rare case will they have a severity score of moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use animals to develop and test our vaccine strategy. The ultimate goal of this project licence is to devise a new way to treat human viral infections, especially COVID-19, but this an assessment of safety in animals before we can move to human studies.

What was your strategy for searching for non-animal alternatives?

We have gained as much information as possible from our previous in vitro experiments. However safety testing requires testing in an animal experiment before using in humans.

Why were they not suitable?

We have not identified a system that can faithfully recapitulate the response to a vaccine that targets natural killer cells. We have been unable to identify a suitable in silico or in vitro model for this work. In general these types of model systems do not recapitulate a whole animal experiment that is required prior to using a potential therapeutic in humans. This is because generating an immune response requires multiple steps and the interplay of many different immune cells in a co-ordinated fashion within a localised environment. This interplay cannot be readily or faithfully reproduced in tissue culture conditions to the standards required to inform a clinical trial. Furthermore, unanticipated toxicities cannot be readily identified in in vitro model systems

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number required based on the number of different experiments that we require to investigate safety of the vaccine, and perform the relevant controls, that will allow us to find unanticipated side effects related to the vaccine. In general we find that the vaccine is safe and well tolerated from studies in cancer immunotherapy. If we use 5 animals per grouping then this will allow for 20 different experimental conditions including control unvaccinated mice. We propose that this number will be sufficient for regulatory submission based on previous vaccine studies at our institution.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In the design phase we have used inbred mice to reduce intra-group variability and allowing reduced mouse numbers for experiments. We have collected information from previous use of the vaccine in mice to help determine the likelihood of clinical effects related to the vaccine.

What other measures apart from good experimental design will you use to minimise numbers?

We have previously tested the vaccine in mice and not observed any specific toxicities. We therefore have made an assessment of the number required for these experiments and will use the minimum required to observe any clinical toxicities. We need to perform these studies to gain sufficient clinical data to submit for regulatory approval. We had not previously planned to use the data from our previous

work for regulatory approval as they were designed as a scientific investigation of NK cell responses to cancer to assess immunogenicity rather than safety, so mice were subjected to the minimum monitoring required for the investigative purpose. We do not feel that the previous level of monitoring would be sufficient for regulatory approval.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use a genetically altered immunocompromised mice as our animal model (KIR-transgenic (KIR-Tg; KIR+/+Kb−/−Db−/−). This is the most relevant model as it is the only animal model available that expresses the human KIR gene KIR2DS2. Therefore it is the most relevant to the human situation and so by using this it is most refined for our purpose. By using the best available model this ensures that the fewest possible animals are required for our project.

We will use injection of DNA by the intramuscular route as this is the method that generates a known immune response and side effects are mild and transient. We will use venepuncture from a superficial tail vein as this is the least harmful method for taking a sample of peripheral blood. In general mice will be kept for only a week after vaccination and then killed to minimise the risk of experiencing any lasting harm.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are the least sentient mammal species with an immune system similar to humans. The KIR-Tg mouse
represents the most relevant animal model for these studies as it is the only animal strain that expresses the human KIR2DS2 gene which we are targeting.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Environmental enrichment, good husbandry and frequent monitoring ensure high welfare standards. Few adverse effects are anticipated but, should any occur, rapid steps will be taken to ameliorate them

or humanely kill humanely affected animals. All animals will be maintained by qualified and experienced animal technicians who are familiar with the models. Mice will be handled using non-aversive methods eg not picking up by the tail, but moved using a tunnel or a cupped hand.
Overall, we have found under our existing PPL that the severity of most experiments is 'mild'.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use the NC3Rs as a resource for our animal studies and experimental design. We will use information available in the NC3Rs website (https://www.nc3rs.org.uk/3rs-resources). Guidelines contained there include "Responsibility in the use of animals in bioscience research" and the "ARRIVE" guidelines for reporting the use of research using animals.
We will also use information from Norecopa and will follow PREPARE guidelines (https://norecopa.no/prepare) for all animal experiments.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed through the regular meetings of the animal facility and the user groups which occur every 3 months. Additionally, we receive e-mails to update us about changes in policy or practice. We will also check on-line databases to identify any changes such as the NC3Rs, Altweb and Norecopa web pages. Any changes will be implemented directly through the experimental design, and if necessary through a project license amendment.

Explain the choice ofspecies and the related life stages

We are using mice as these are the least sentient animal that we can perform these experiments on. As the vaccine targets a uniquely human gene (KIR2DS2) then a transgenic animal is required to test the safety of the vaccine. We are using adult mice as these are the most resilient life stage and allow the experiments to be standardised. In general they will be studied between weeks 12-16, well before age-related effects will be observed.

NON-TECHNICAL SUMMARY

142. Neural Control of Reproduction

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Rats	neonate, juvenile, adult, pregnant
Mice	pregnant, neonate, adult, juvenile, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To determine the neurophysiological mechanisms behind the timing of puberty and subsequent reproductive function in adulthood.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Consequences of altered pubertal development in both man and animals, early or delayed, is linked to a myriad of reproductive, sexual, behavioural, mental or other health issues with lifelong social, health and economic implications. Further knowledge is needed on the basic mechanisms underlying puberty control, not only to improve health and social outcomes in modern society but also to increase the potential for applied aspects of puberty control in the farming sector, leading to improvement of production, welfare and sustainability.

What outputs do you think you will see at the end of this project?

Outputs will include new information about the central control of the hypothalamic-pituitary-gonadal axis, with a focus on the mechanisms upstream of the GnRH pulse generator. This will encompass reproduction in adulthood as well as pubertal development under normal and pathophysiological conditions. The aim is to publish these findings in academic journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The primary, immediate benefit of this scheme of work will be to advance fundamental scientific knowledge about the central control of the hypothalamic-pituitary-gonadal axis, with a focus on the mechanisms upstream of the GnRH pulse generator. Our investigations include both reproduction in adulthood as well as pubertal development under normal and pathophysiological conditions. The aim is to publish our findings in academic journals. The information is likely to be of interest to physiologists and neuroendocrinologists with an interest in the mechanics of reproductive physiology or stress.

A more long-term secondary potential benefit relates to possible clinical application of our findings to reproductive dysfunction or stress-induced disorders observed in humans. Work in abnormal thermoregulation may have specific applications for cancer patients and postmenopausal women suffering extreme hot flushes. Our investigation of the regulation of the hypothalamic-pituitary-gonadal axis under stressed conditions may provide targets for the development of pharmaceuticals for the treatment of ovulatory dysfunction. The work relating to the central mechanisms involved in differential stress responses may also be of value in generating pharmacological treatments for stress-related disorders such as anxiety and depression.

How will you maximise the outputs of your work?

Our methods and results will be published in a variety of journals including some that are open-access so that this work reaches the wider scientific community. Results will also be presented at meetings as well as national and international conferences. We have collaborations with researchers from other institutions, including internationally, which ensures that this work reaches other fields as well as our own.

Species and numbers of animals expected to be used

- Mice: 2500
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A maximum of five general anaesthetics can be administered, although animals will typically undergo no more than two surgical procedures (and therefore only two anaesthetics will be required).

The typical mouse procedure involves injection of extremely small quantities of a light sensitive proteins into the brain, followed by implantation of a micro fibre-optic probe to allow for optogenetic stimulation and/or brain cannula for administration of pharmacological agents (none are expected to carry adverse effects). This procedure is often done at the same time as removal of the gonads. Animals will then undergo blood sampling. Some animals (30%) may be subject to environmental stressors to examine the impacts of stress on the reproductive axis. These are not expected to have persistent, long-term effects and animals will be taken care of accordingly on the off-chance the intended severity threshold is exceeded. The typical duration of the studies is 6 weeks and not more than 6 months. However, studies using animals exposed to early life stressors and followed into adulthood will typically last for 8 weeks, but not more than 6 months.

The typical rat procedure involves implantation of an intracerebral cannula, mainly for administration of pharmacological agents. Again, this may be done at the same time as gonadectomy. Rats will also be implanted with catheters for automated blood sampling. Certain animals (50%) may be subject to environmental stressors but these are not expected to have presistent effects. Typical duration of studies is 6 weeks and not more than 6 months.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

1. The inevitable adverse effect of surgery is pain. Any animals undergoing surgical intervention of any kind will receive a mandatory pre-operative analgesic dose, and post-operative analgesia as required: animals will be individually assessed and monitored during the post-operative period, and given appropriate analgesia in accordance with any signs of pain they display. If, after 48 hours post-surgery they have not returned to normal (i.e. normal movement, well-groomed) and still show any of the following signs: hunched posture, piloerection, weight loss exceeding 15% compared with age matched controls, the Named Veterinary Surgeon will be consulted on their condition, or they will be humanely killed.

2. No adverse effects are anticipated when the animal is under general anaesthesia. However, it should be noted that possible lightening of the anaesthetic may occur; this is determined by a response to pinch, or by the eye blink reflex; additional anaesthetic is administered under such circumstances. Animals will be monitored for anaesthesia and recovery.

3. Possible adverse effects of developmental/early life stressors: for neonatal handling there is a possible increased likelihood of cannibalism; this is exceptionally rare. To minimise this risk gloves will be worn when handling the neonates and the scent of the home cage will be spread over the neonates before reintroducing the dam. During rearing, animals will be carefully monitored for appearance of any abnormalities. Animals showing any signs of ill health will be monitored closely in consultation with the Named Veterinary Surgeon, and if necessary killed by schedule one procedure. It is to be noted that no adverse effects of post-weaning social isolation on health or growth rates of the animals are expected.

4. Possible adverse effects of non-developmental stressors:-

a. A possible adverse effect of restraint stress is distress as evident by struggling which leads to injury. Animals will be observed continuously during restraint and removed from device if necessary.

b. A possible adverse effect of an acute immunological challenge, which is typically lipopolysaccharide (e.g. Escherichia coli) injected intravenously or intraperitoneally, is a transient fever and/or loss of appetite with weight loss. If adverse conditions remain for more than 12 hours the animal will be killed by a schedule one method. However, as the doses typically used are very low, it is extremely unlikely that illness caused by this immune challenge will be anything other than very transient (typically lasting 1-3 hours).

No adverse effects are expected nor have we observed them for the following stressors, i.e., insulin-induced hypoglycaemia, noise, predator odour, raised ambient temperature or cage switching.

5. Adverse effect of adrenalectomy is disturbance to electrolyte balance, which is minimized by salt replacement in the drinking water. No further adverse effects are expected from adrenalectomy, as

adrenal hormones will also be replaced in the drinking water.

6. Adverse reaction to administration of drug (e.g. intracerebroventricularly, intravenously) is extremely rare. If this occurs the animal will be killed by schedule one method.

7. A possible adverse effect of implanting catheters, osmotic mini-pumps, transmitter devices, brain fluid or optic cannulae, or cranial screws for the attachment of tether-swivel assemblies which is minimized by using aseptic surgical techniques is infection at the wound site (rare). The animal will be treated with antibiotics on advice of the Named Veterinary Surgeon and the wound closely monitored. The experiment will be terminated and the animal killed by a schedule one method if no improvement. Wound breakdown following surgery (incidence very uncommon) is a possibility and re-suturing under general anaesthesia with recovery performed on one occasion only.

8. No adverse effects are anticipated with the use of the tether-swivel assemblies.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of animals will undergo surgical procedures (moderate severity) and approximately 25% may be exposure to stressors (mild to moderate severity). After recovery from surgical procedures, the majority of animals will under go blood sampling procedures to monitor luteinising hormone pulses in the blood as a measure the brain oscillator called the GnRH pulse generator that controls reproduction. This oscillator is exquisitely sensitive to stress so the animals are extensively handles and habituated in order to visualise the normal pattern of luteinising hormone pulses.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The programme will use both in vitro techniques and animal procedures. The in vitro work will include examining biological activity in selected cell lines and tissue to elucidate signal transduction pathways and gene expression using molecular biological techniques. However, animal work is essential because the control of the GnRH pulse generator depends on integrated physiological systems.

Indeed, it is impossible to study the operation of the GnRH pulse generator by using cultured cells alone. For example, to measure the impact of stressors such as psychological/nutritional perturbations (e.g. restraint/food withdrawal, which are relevant to anxiety/anorectic models), requires a cognisant animal model. However, studies at the cellular level (e.g. signal transduction mechanisms or factors involved in neuropeptide receptor gene expression) give vital information that can be used in a complimentary manner to results obtained from these in vivo studies.

We also intend to use brain slices from animals killed by Schedule 1 methods where possible (cervical dislocation followed by decapitation and the use of an oscillating microtome to look at specific events, for example the expression of GABA/glutamate/kisspeptin during puberty).

What was your strategy for searching for non-animal alternatives?

Non-animal alternatives include examining biological activity in selected cell lines and tissue to elucidate signal transduction pathways and gene expression using molecular biological techniques. In silico techniques can be used to model GnRH pulse generator firing.

Why were they not suitable?

Although these methods will be integrated alongside animal work, the control of the GnRH pulse generator depends on integrated physiological systems and therefore requires use of a whole organism. Indeed, it is impossible to study the operation of the GnRH pulse generator by using cultured cells alone. To measure the impact of stressors such as psychological/nutritional perturbations (e.g. restraint/food withdrawal, which are relevant to anxiety/anorectic models), requires a cognisant animal model.

Examination of specific events such as the expression of GABA/glutamate/kisspeptin during puberty requires use of fresh tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have drawn on years of previous experience to ensure we use the minimum number of animals required. Statistical power analysis before initiating experiments will also be used to ensure that we only use the minimum number of animals required to produce valid statistical comparisons between the groups.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The design of individual experiments will generally involve factorial designs, to maximise the information gathered using the minimum number of animals. Most measures taken will be quantitative, in which case sample sizes will be set using a power analysis, using a significance level of 5% and a power level of 80%, with a least practicable difference between groups of 25%. This will generally result in group sizes of ~8 per treatment group, although in cases where very small and delicate structures in the brain are being targeted as cannulation or lesion sites, it is necessary to include more animals per group to ensure sufficient data can be collected if some of the cannulae/lesions are not on target. For design of complex experiments, advice of a statistician will be sought.

What other measures apart from good experimental design will you use to minimise numbers?

Use of factorial designs will maximise the information gathered using the minimum number of animals. We will also use in silico methods to mathematically model the interaction of these neuroendocrine pathways, this reducse the number of animals used in future experiments. Tissue from killed animals will be further utilised e.g. analysed to examine specific events such as the expression of GABA/glutamate/kisspeptin during puberty and the expression of stress related neuropeptides. This ensures a small number of animals are made use of as much as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rodents are the lowest vertebrate group which will allow reliable electrophysiological studies and in which the reproduction control systems have been well characterised. They are excellent for monitoring the activity of the GnRH pulse generator either electrophysiologically or via collection of serial blood samples for measurement of luteinizing hormone pulses.

Due to small overall size, a mouse model is may not be suitable for some of the work; it is still the most common option for genetic alteration studies. As rat strains with our required genetic manipulations become available, they will be used to give the improved range of measurements and interpretation that cannot be provided by mice.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rodents are the lowest vertebrate group which will allow reliable electrophysiological studies and in which the reproduction control systems have been well characterised. Investigating the control of the GnRH pulse generator depends on integrated physiological systems and therefore requires juvenile or adult animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be monitored throughout all experiments to minimise pain or discomfort as a result; animals deemed to be suffering will be removed via a Schedule 1 method. Pre-operative analgesia will be administered to all animals undergoing surgery, and no animals will undergo experimental procedures if displaying any signs of pain. Most surgical procedures or drugs we propose to administer have limited, if any, persistent adverse effects. Neurotoxic lesioning of brain nuclei may very occasionally have unpredictable side effects such as loss of mobility or appetite, but in such cases, the animals will immediately be killed humanely if showing signs of ill health, such as weight loss, piloerection, ungroomed or hunched appearance.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs) guidelines as well as ensuring we keep up to date on practices in the current literature to ensure our experiments are conducted in the most refined way.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will keep up to date on new advances in the 3Rs through the NC3Rs newsletter as well as regularly checking the 3Rs website.

Explain the choice ofspecies and the related life stages

Rodents (i.e. rats and mice) are the lowest vertebrate group which will allow reliable electrophysiological studies and in which the reproduction control systems have been well characterised. They are excellent for monitoring the activity of the GnRH pulse generator either electrophysiologically or via collection of serial blood samples for measurement of luteinizing hormone pulses.

Since we are examining the effect of early life stress on reproductive function during puberty and in later

adulthood, neonatal and juvenile animals will be used as well as adults. We also have our own breeding protocol which therefore includes use of pregnant animals.

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project, that is built upon our previous achievements and innovative findings, is to provide new insights into the fundamental primary molecular mechanisms that control the behaviour of nerve cells in high-order functions such as learning and memory, as well as motor activity and metabolism in health and disease. At the same time, we will also explore the potential of novel candidate molecules resulting from our work for their potential to prevent initial degenerative steps in disorders such as Huntington's or Alzheimer's diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Advancing knowledge into these mechanisms is paramount to new or improved treatments for neurodegenerative diseases such as Huntington's (HD) or Alzheimer's (AD), and metabolic diseases such as obesity, diabetes.

HD is a rare genetic disorder caused by a defect in a single gene, namely a poly-Q expansion in the Huntingtin protein (HTT). It typically develops in adult life and induces progressive degeneration of brain nerve cells, leading to motor, cognitive, and psychiatric abnormalities and ultimately death. It affects between 10.6–13.7 individuals per 100,000 in Western populations. This devastating disease course generates a considerable societal burden, impacting social functions, employment and health care provision, as well as family members and carers. The care burden rises rapidly in advanced stages of disease, and overall UK cost for HD patients are estimated at £195M/year. No effective HD treatments currently exist, and several clinical trials have failed.

AD is the most common type of neurodegenerative dementia, accounting for 60 to 80% of dementia cases. It affects more than 24 million people worldwide. The majority of cases manifest as a late-onset sporadic form. Although progress has been made about the molecular pathogenesis of AD, we still do not fully understand the aetiology of the sporadic form. The most desirable solution is to delay its onset or to prevent it from developing. Currently there is no cure, and treatments available can only delay/slow the symptoms but are not able to stop disease progression. Overall UK cost for dementia is around £26 billion a year.

Control of food intake and energy balance, which is essential for animal healthy life, is a primary target of investigation due to the fact that dysregulation of these leads to metabolic dysfunctions such as obesity, type 2 diabetes. An estimated £14 billion pounds is spent a year in the UK to treat these and their complications. However, it is not well-established which neurons in particular nuclei of the brain control particular physiological functions, which is paramount to design more effective treatments.

What outputs do you think you will see at the end of this project?

This work is expected to provide new fundamental knowledge and publications about the molecular mechanisms that control the behaviour of nerve cells particularly in high order functions such as learning and memory, as well as locomotor activity and cell metabolism. This will advance our understanding about how molecular processes misfunction in disease. Overall, we may identify pathways and factors involved in the initial stages of neurodegenerative processes which could lead to the discovery of new strategies with the potential to prevent disease onset and treating disorders like Alzheimer's or Huntington's. As for the metabolic studies we will further define basic molecular mechanisms and eventual new ways to design more effective treatments for disorders such as obesity.

We anticipate that these primary benefits will be realised in the short- to medium-term, i.e. within the timeframe of this licence. This programme of work builds upon the successful achievements of the previous project licence. All methods required to achieve the proposed objectives are well established and I have been successfully using most of these methods on my current project licence. The most critical mouse models are already in place and the team has highly-relevant expertise in these. Thus, it is highly likely that we will successfully realise the primary benefits of this programme of work. Moreover, discovery of novel potential drug targets with the discussed approach could lead to the opportunity to engage with industry for translational studies (long-term benefit). We have already discussed with industries the potential of some of these studies. They believe that a small molecule screen could be a viable approach once a particular target is more corroborated. Therefore, in the short term (by mid-PPL) we envision to have done more mechanistic studies of the above findings and medium-term (end of PPL and shortly after) to have the characterization done in an appropriate model of disease, getting ready for an eventual small molecule screening in the long-term.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

These studies have a transforming potential for the human patients as there are no effective treatments for preventing or delaying this type of disease, or even to improve symptoms. The development of effective treatments would also have a positive impact on the economy since the progressive and devastating course of these diseases is a considerable societal burden, impacting social life and employment of patients as well as family members and carers. Therefore, the impact of these studies is mainly a long-term benefit. Moreover, any discovered mechanism can be explored in other neurodegenerative disorders such as Parkinson's disease, as each initially affects select brain neurons. Our hope is that treatment could be used to prevent the damage at early stages of the disease. Another possibility that we also aim to explore (as outlined in objective 3) is to reactivate dormant NSCs in the context of a diseased brain to explore whether particular brain functions could be ameliorated. Finally, we also hope to advance knowledge of basic molecular mechanisms underlying metabolic disorders such as obesity contributing to design more effective treatments.

How will you maximise the outputs of your work?

Findings will help first of all researchers in my team, and others at this REDACTED working on neurodegenerative diseases and fundamental basic mechanisms. Moreover, results will be made available to other scientists through publication in peer-reviewed journals, presentations at scientific conferences and meetings, and collaborations. This will allow us to share our novel findings not only

nationally but also internationally, as we have previously done and is evident from my publication record over the years.

Under the previous/current project, we published 9 papers and 2 book-chapters of methods so far (and 5 more are currently being written), and we presented our findings at international scientific meetings. The mouse models developed so far and any valuable future models we will produce will be made available to other scientists interested in our models, as already done in the past and during the last 4 years.

REDACTED

Species and numbers of animals expected to be used

- Mice: 11000.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The work has been organized in stages, first of all, a precise analysis of the genetically altered mice will be obtained from mice humanely killed, which will suffer only transient pain and distress due to either schedule 1 or non-schedule 1 killing. Once preliminary information is collected, we will then proceed with in vivo functional validation of the identified gene(s)/cell type involving brain injection and delivery of substances to modulate gene function, full recovery, administration of substances, monitoring of behavioural activity or metabolic phenotype, perfusion fixation under terminal anaesthesia.

For example, 60% of mice on a moderate protocol involving surgery, will experience surgery and injection of substances into CNS, full recovery, administration of substances, monitoring of behavioural activity or metabolic phenotype, perfusion fixation under terminal anaesthesia.

Or on another moderate protocol, approximately 15% of animals are likely to experience moderate levels of severity. This is because they will undergo surgery for intracranial administration of substances, full recovery, repeated blood sampling, dosing of substances, and behavioural tasks, perfusion fixation under terminal anaesthesia.

On a moderate protocol testing for metabolic dysfunctions where some animals could show alteration of fat/glucose metabolism, so about 80% of the animals are likely to experience moderate severity. They typically will undergo one of the steps outlined in the protocol, e.g. administration of substances, followed by one of the step options, then perfusion fixation under terminal anaesthesia.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most of the animals will be used in a protocol with a mild severity limit. Animals produced under this protocol are not expected to exhibit any harmful phenotype. In the case of unexpected and unwanted harmful phenotypes, the animal will be humanely killed, or in the case of animals of particular scientific interest with an unanticipated harmful phenotype, advice will be sought from the NVS/NACWO.

Five protocols have a moderate severity limit; they involve ageing and/or surgery, or analysis of metabolic phenotypes. A smaller proportion of the animals will be used in these protocols, and we envisage that for many of the animals, the actual severity will be mild.

In particular, mice will be behaviourally tested at different stages, and so mice will be aged. These animals are not expected to show specific problems as they age. In some, after 12 months of age, learning will deteriorate quicker than normal mice. However, ageing animals will be monitored closely, including weighing, clinical examination and body condition scoring in consultation with the NVS, and any adverse effect due to a particular behavioural test will be dealt with accordingly.

In case of adverse effects of ageing that include skin and dental abnormalities, eye conditions, reduced organ function, tumours, as explained in each relevant sections of this PPL they will all be appropriately mitigated.

Other mice, instead, will be anaesthetised and have surgery to inject substances into their brains: some substances will mark nerve cells so that we can monitor and manipulate them; other substances will damage cells so that we can model disease processes. Animals that have had surgery are expected to recover quickly and will be given painkillers and post-operative care so that any adverse effect due to surgery will be treated according to the effect presented.

Some mice on another specific protocol will be analysed for metabolic dysfunctions. Also, in this case, there are no significant adverse effects expected.

We have set up a Protocol to obtain tissue for ex vivo analysis. The majority of animals are likely to experience mild severity because they will be aged to the appropriate stage, and only a small percentage of mice will be aged beyond 18-20 months (and up to 28M). Care will be taken for this phase. Animals exhibiting any unexpected unwanted harmful phenotypes or in case the severity is likely to exceed moderate will be killed, or in the case of animals of particular scientific interest with an unexpected harmful phenotype, advice will be sought from the NVS/NACWO.

Finally, one last Protocol, combines ageing/behaviour and surgeries with the administration of substances; therefore, mice on this protocol will be monitored closely including weighing, clinical examination and body condition scoring in consultation with the NVS, and any adverse effect due to a particular behavioural test will be dealt with accordingly. Seemingly, for those undergoing surgeries, any harmful effect due to surgery will be treated according to the effect presented.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals will experience no more than a mild severity, this includes:

(a) breeding of genetically altered animals, which is expected to result in a phenotype with mild effects;

(b) administration of anaesthesia except for the sole purpose of killing;

(c) pharmacokinetic study where a single dose is administered and a limited number of blood samples are taken (totalling < 10 % of circulating volume) and the substance is not expected to cause any detectable adverse effect;

(d) superficial procedures, e.g. ear and tail biopsies;

(e) administration of substances by subcutaneous, intramuscular, intraperitoneal routes, gavage and intravenously via superficial blood vessels, where the substance has no more than mild impact on the animal, and the volumes are within appropriate limits for the size and species of the animal;

(f) feeding of modified diets, that do not meet all of the animals' nutritional needs and are expected to cause mild clinical abnormality within the time-scale of the study.

A small proportion of animals will experience a moderate severity, this includes:

(a) Surgical induction of CNS disease-relevant phenotype, full recovery, surgery for removal of devices (e.g. cannula for the implantation of osmotic minipump);

(b) Ageing beyond 18-20 months.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The type of investigation outlined in this project cannot be carried out in cell culture as this lack information about the networks of neurons that are found in an intact brain. Furthermore, cell cultures or organoids do not replicate disease progression.

While other organisms such as yeasts, worms, flies and zebrafish are excellent models for studying the cell cycle and many developmental processes, mice are far better tools for asking questions about the immune, endocrine, nervous, cardiovascular, skeletal and other complex physiological systems that mammals share.

Also, the use of computer models, modelling, for instance, behavioural systems or processes, biochemical, or physiological events are not appropriate for the programme of work outlined in this application because many cellular parameters are unknown especially those regarding disease progression.

Manipulation of mouse genetics provides a unique opportunity to study the molecular basis of complex cell-cell interactions in vivo. The increasing availability of cell-type specific promoters gives extraordinary power to the generation and analysis of precise mouse models that undoubtedly will help to dissect the complexity of the brain. Lately, by combining precise mouse genetics and ex-vivo tissue analysis such as transcriptomic analysis (by RNA sequencing) together with bioinformatics we have been able to uncover unexpected findings regarding early changes occurring in neurodegeneration in select neuronal types. This will also allow, in the future, to compare these findings with diseased human tissues.

What was your strategy for searching for non-animal alternatives?

Cell cultures or organoids, computer modelling, other organisms such as yeasts, worms and flies.

Why were they not suitable?

The alternatives considered above are not suitable for the programme of work outlined in this application because they either do not replicate disease progression or because we do not know all cellular parameters, e.g. regarding disease progression; or because other organisms do not share complex physiological systems with mammals.

Once this knowledge is achieved, it will also facilitate the use of alternatives to a living protected animal in a regulated procedure.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on our relevant experience working with small rodents such as mice. As well as power calculations.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Generation of very precise and specific genetically altered mice results in more defined, less variable and hence more relevant data. This correspondingly reduces the number of animals necessary to

obtain significant results as well as improves the quality of life of the animal.

We will plan, conduct and record our experiments with the aim to publish our results according to the ARRIVE guidelines. In general, to reduce potential sources of variability and biases (e.g. sex, weight, genetic status, etc.) we will use, for example, blinding, randomisation in our experimental design where appropriate.

Where suitable mouse lines already exist, animals will be obtained from the relevant supplier. Otherwise, we will generate the required lines (including conditional knockouts) with the help of specialized services. This part of the programme will be implemented by the Transgenics Officer, who has the expertise required to deliver satisfactory results (i.e. healthy animals of the desired genotype). We now use CRISPR/Cas9a which should bring benefit both to the reduction of the numbers of animals used and the ability to create more refined genetic mouse models. Validation and characterization of edits introduced by CRISPR/Cas9a will be done on both the molecular and phenotypic level to assess their biological relevance. A variety of assays can be used, they will help to yield various types of information. These include characterization of the nature of the edit on the sequence level, biochemical level as well as on the functional level.

Efficient colony management ensures that only colonies that are actively being used are mated and produce animals. Those that are no longer required are cryopreserved and closed at the earliest opportunity. We now archive sperm as the main method of cryopreservation which reduces the number of animals required to secure a line.

Generally, we use power analyses to aid our experimental design and our own experience (25 years) as well as others from the literature. We will continue to use good practice in experimental planning, including statistics such as power and breeding calculations using current breeding figures to predict the number of matings required for experimental cohorts. We will measure production and breeding performance and ensure the minimum numbers of animals are used in the programme, as done so far. The statistical analyses (and software/code for implementation) that we use for our experiments are now well established and have been frequently peer-reviewed. Nevertheless, we continually strive to improve the analyses, and, take advantage of Statistical Consulting services, as well as online tools (such as the NC3Rs' Experimental Design Assistant).

Also, well-trained people will perform surgical methods. This, together with maximal care, will reduce the loss of animals recovering after an experiment.

If pilot studies are necessary to test a method or hypothesis, dose range finding, and/or to implement the 3Rs, they will be carried out using small groups of animals; based on our own experience as few as 2-5 animals per pilot study are sufficient to reach a robust decision point.

Where necessary, and following best scientific practice in the field, control groups (including, in some cases, sham surgical controls) will be used to help us interpret the effects of experimental interventions. For example, for some experiments necessitating the intracranial injection of a toxin or other agent designed to induce a subtle, disease-relevant phenotype, an important control would entail intracranial injection of vehicle. The number of animals undergoing surgical procedures in control groups will be kept to a minimum through (1) the use of ‘within animal controls’ e.g. injection of toxin/agent in one brain hemisphere, and injection of vehicle in the other hemisphere; (2) timely comparison of small groups of sham surgical controls with non-surgical controls to reach a robust decision point, e.g. if a difference

were not detected, then it would not be necessary to use further sham surgical controls in that series of experiments; and (3) taking account of the published evidence.

Higher number of animals in the breeding protocol is because most of the mice are used to harvest tissues after schedule 1 method, or perfusion, exsanguination under terminal anaesthesia; or some mice having short breeding life because e.g. they develop an age-dependent obesity due to particular mutations; or for some experiments certain substances can only be administered to one sex (e.g. mifepristone cannot be administered to females because it blocks also the progesterone receptor).

What other measures apart from good experimental design will you use to minimise numbers?

Measures currently implemented

Generally, we ensure that the breeding of GA REDACTED be as effective as possible without compromising the genetic integrity of the lines. We normally use for breeding GA animals with no harmful phenotype. We usually obtain the maximum possible data from a single animal. For instance, perfusion-fixed tissue obtained for ex vivo histological analyses after addressing our primary aims on the particular protocol is archived for future studies. We will continue this in this project.

In addition, with the new established protocol of purification and sorting from young adult and aged mouse brain we have been able to perform analysis on <200 purified neurons, as well as on single neurons. This has allowed us to use very few mice per age/condition analysed and to reduce the overall number of mice considerably. To give an example, the ex-vivo protocol established allows to consider each animal as a biological replica, whereas standard protocols would require to combine 4-5 animals per each biological replica. We have now published these methods so that also the scientific community can benefit from them. We will continue to use these methods and refine them further.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

1. Animal models

a) We are creating genetically altered mice that allow us to delete/activate genes of interest in specific cell types and/or at specific stages in the life of the mouse. The mouse models described above in the project plan are the most refined for the intended purpose because by targeting only certain cells you avoid unwanted side-effects.

b). In general, the severity level is mild but there are some occasions when it is necessary to allow GA animals to age in order to sufficiently model the human diseases; for instance, this is the case with aggregates in AD. By leaving the mouse to age (typically up to 18-28 months) the phenotype reaches a point where we can assess the full extent of neuronal degeneration. However, these are very few mice, that might experience adverse effects of ageing.

2. Behavioural testing

The behavioural tasks we use include elevated plus maze, fear conditioning, radial maze, water maze that are in general not repeated on the same cohort of animals. We also use the novel object recognition, the open field (OF), CatWalk, and rotarod that are usually repeated on the same cohort of animals up to five times. All of these tasks are well established in the literature. Number of trials per day is based on published literature and our own studies. In general, the procedures involved do not give rise to adverse effects. Here are a few examples of the tests we perform:

Fear-conditioning test involves a mild foot-shock; sensory perception of the shock used in fear-conditioning has been determined in the past through shock threshold assessment, and the commonly used one gives rise to an annoying stimulus in the mouse that is still enough to generate an associative learning process. Classical conditioning in the brain has mostly been studied in two paradigms: Foot-shock fear conditioning and eye-blink conditioning. These two forms of conditioning are subserved by very different neural mechanisms. We will use the foot-shock paradigm, which covers the neural circuits of interest. At the moment there are no other paradigms that would effectively substitute for the foot-shock fear-conditioning paradigm. However, the foot-shock used in this paradigm is very mild and according to published literature (maximum of two or five conditioning trials co-terminated with 2sec 0.5 mA footshock, which does not lead to excessive vocalization (see Musumeci et al., J Neurosci 2009 • 29(32): 10131–10143). This is typically on one occasion during the life of the mouse.

The Radial maze testing involves that mice are food deprived approximately to 90% of their free-feeding body weight for the duration of the experiment (around 20 days). In general, this procedure is not giving adverse effects. However, in case of animals drop below 85% of their free-feeding body weight they will be switched to a regular diet, and humanely killed upon no recovery within 24-48 h. Although mice on this task can either be food or fluid restricted, we have been using the former throughout all our experiments, and we will continue to do so to be able to compare results. Nonetheless, food and fluid deprivation or restriction are both considered to be acceptable procedures as long as suitable monitoring protocols are implemented, such as routine weighing and target weights. days). In general, this procedure is not giving adverse effects.

The Morris Water Maze (MWM) Involves that mice are placed in water of a comfortable temperature (22-25ºC) and are trained to locate a platform just below the surface of the water (which is made opaque), and are left swimming for 60-90 seconds until they have found it. If they do not find the platform in 90 seconds, they are placed on it, then removed from the tank and dried. A potential adverse effect is hypothermia (drop in body temperature, reduced swimming speed) in this event mice will be removed from the WM and dried with towels. A heating pad will be available for mice exhibiting signs of stress. Moreover, if mice show fatigue /exhaustion (struggling to swim and to remain on the water surface) the trial will be immediately terminated. Rest period between trails will be increased and / or maximum trial time will be reduced.

The rotarod is a test to evaluate motor coordination, balance, and motor learning. In this test, mice are examined for their ability to maintain their balance on a rotating bar that accelerates 7.2 rpm/min. Over the course of each 5-min trial, the speed of the rotarod accelerates from 4 to 40 rpm. Suitable padding on the floor is provided to avoid injuries. The amount of time before a mouse falls from the rod is measured. Mice undergo three rotarod trials per day for two consecutive days with an intertrial interval of 15 min. There is very little chance of injury when a mouse falls off the rod because they would land on a mat, however animals will be checked for any injury before being returned to their cage.

The open Field is a test that offers a unique opportunity to systematically evaluate novel environment exploration, general locomotor activity, as well as an initial examination for anxiety-related behaviour in rodents.

Behaviour of GA mice is the ultimate readout in order to understand biological mechanisms. Therefore, we will continue to use different behavioural tasks and we will continue to refine them so to obtain meaningful results from the minimum required number of animals.

3. Appropriate surgical methods (which include short time surgery, aseptic environment) and post-operative care (such as analgesia, easy access to food and water) will help to minimize the occurrence of adverse effects. Animals will be given time to recover before any other step will be applied (postoperative recovery of animals and survival up to 16-weeks (typically 4-8 weeks)).

Other methods include:

4. Glucose tolerance test (GTT) and/or insulin tolerance test (ITT) to be carried out on adult mice. Prior to tests, mice will be fasted overnight or for 6hrs (GTT) or just 6hrs (ITT). For GTT studies, mice will be injected intraperitoneally (IP) with a D-glucose solution (2 g/kg body weight). For ITT, mice will receive an IP injection of human insulin at a dose of 1 U/kg of body weight. Venepuncture or venesection blood glucose concentration will be measured at a few different times after challenge using the commercially available blood glucose meter and test strips. Five to ten microliters will be withdrawn for each time point. However, no more than 10% of circulating blood volume will be removed at once or 15% in 28 days.

5. Different types of diets. Some of the mutants showing the metabolic phenotype will be fed different types of diets, such as high-fat diet to study the nature of obesity such as abnormally increased appetite, and/or consumption of food. However, this is only for short period of time before they are returned to their normal diet or killed experimentally.

6.Administration of substances. The substances to be administered should not in themselves cause pain, suffering, distress or lasting harm. Drugs/vehicles will be administered at established concentration/volumes and via routes most appropriate to mice as shown by other investigators or by our own experience. If testing a new drug where little or incomplete knowledge is available we will set conditions in a pilot experiment starting from the lowest doses.

Examples include the following:

- Some mice will be given a substance that labels the DNA or the cell by routes suitable for the species and procedure (e.g bromodeoxyuridine (BrdU)). In general, it will be by intraperitoneal injection

(IP) or in the drinking water (1mg/ml) up to 7 days followed by a few-weeks survival before brain dissection after terminal anaesthesia.

- To achieve induction or suppression of transgene expression we will treat some mice with drugs such as tamoxifen that per se has no toxic effect on mouse at well-established concentration. The administration of tamoxifen can sometimes lead to adverse effects, such as transient loss of body weight (<15%) and/or changes to body condition (e.g. piloerection) and behaviour (e.g. mobility, gait, posture). However, in our experience, systemic administration of tamoxifen using dosing regimens that induce robust transgene expression in the brain (e.g. daily intraperitoneal injections of tamoxifen at 30-50 mg/kg (in corn oi), for 5 consecutive days) does not significantly impact on the animals' body weights, conditions or behaviours.

- Some mice will be treated either with agonist-antagonist substances to activate or deactivate neuronal receptors such as neurotrophin receptors, related receptors, or related to this programme of work; or functional analogs (such as dexamethazone or corticosterone) to be able to study feedback inhibition in particular brain structures such as the hypothalamus of GA mice and respective controls; or other substances that mark cells (e.g. florescent dyes, biotinylated molecules); or substances that have potential for slowing, halting, reversing or otherwise ameliorating brain dysfunction in animal models of disease.

Typically, these compounds will be administered on one occasion only, or for 24 hours in the drinking water and no significant welfare, problems are expected in such a short time.

- Some aged animals intracranially injected (after 4 or 8 weeks) or aged animals carrying the appropriate genetically modified alleles will be administered substances such as small molecules once per day for a prolonged period (for 3 to 4 months or up to 5 months if necessary) or twice daily for not more than a week, via the most appropriate route including oral gavage. All substances will be administered at doses known to be non-toxic, based on experience and dosages reported in the literature, and at volumes by following guidelines. All animals receiving substances will undergo routinely increased monitoring while underdosing regimen. Bodyweight and behaviour (e.g. lack of grooming, or coat condition) of all animals receiving substances will be regularly monitored. Oral gavage is a commonly used method of administration; it is performed with care by competent persons. Among oral administration methods, oral gavage is the most accurate and reliable method for administering substances into the gastrointestinal tract. This is because it eliminates risks of variability in intake between individual animals. However, it is more invasive compared to other oral administration methods. Therefore, to minimise adverse effects, especially during chronic administration, we will use the smallest possible volume of a substance by not exceeding the maximum amount of 10ml/kg (10µl/g). We will investigate the properties of the substance, such as possible toxicity, from previous studies. We will apply the fewest possible number of doses so to minimise the risk of complications upon repeated gavages in the same animal. Animals will not be gavaged more than twice a day for more than a week. For chronic administration, it will be once per day for more than a month (for 3 to 4 months or up to 5 months if necessary). Moreover, adverse effects will also be minimised by the performance of the procedure by competent investigators or trainees.

- In a minority of experiments, we may administer substances using a single osmotic minipump (or a similar device) to allow for slow/steady dosing with a profile that is not readily achieved through repeated and timed acute administrations. These methods are highly refined for the purpose.

- Some mice will be subjected to micro-injection (into specific regions of the brain including hypothalamus, hippocampus, different cortical regions, amygdala and ventricles) of agents such as nucleic acid vectors, (including viral vectors packaged within viral particles), with, for example the Cre recombinase gene sequence inserted, or other recombinases, or shRNA (to silence genes of interest related to this programme of work); biocytin, visual beads, and neural tracers. These vectors/substances have already been tested by others and not reported to induce particular welfare problems.

- Some of the virally transduced animals engineered to express a diphtheria toxin (DT) receptor on the surface of a specific cell type (after 1 or 2 weeks) will receive diphtheria toxin (DT). These animals are normal until exposed to DT, which acts as a potent inhibitor of protein synthesis and kills only those cells that express the DT receptor. This is highly refined methods to ablate only the desired cells in the brain.

- As for the administration of substances such as mifepristone (a glucocorticoid receptor antagonist, that has been shown to produces clinical and metabolic benefits in patients with Cushing's syndrome), there are no adverse effects reported in literature at the dose used in this protocol and for several weeks' administration in the drinking water (literature and our own work) except that in mice with glucocorticoid induced metabolic changes leading to obesity will ameliorate the symptoms and help to validate mechanisms.

- Some of the virally transduced animals engineered to express a G-protein coupled receptors, Designer Receptors Exclusively Activated by Designer Drugs (DREADDs) on the surface of a specific cell type (after 1 or 2 weeks after intracranial transgene induction) will receive a drug-like small molecules such as clozapine-N-oxide (CNO) to modulate neuronal activity. These animals are normal until exposed to CNO, that for instance has been specifically shown to modulate feeding circuits (leading for example to increased food intake, meal numbers etc)., or other neuronal circuits. Drug-like CNO are relatively metabolically inert in rodents, and no side effects have reported when used at appropriate concentration in control animals lacking the engineered DREADDs. Likely route: intraperitoneal (IP) injections in the first instance, subcutaneous injections (s.c.) or in the drinking water if necessary.

The maximum frequency of injections (IP) will be up to twice daily and spaced approximately 8h from each other typically for a period of 2 weeks and no more than 3 weeks. If an inert substance such as CNO (at proven efficacy from the literature) is to be injected more often, the period between injections won't be less than 5h and the duration of the experiment will not exceed a week.

In all cases of administration of substances or withdrawal of body fluids, we will use whatever technique is considered to be the most refined in terms of the scientific objectives and animal welfare.

7. Induction of CNS cell dysfunction

The induction of CNS cell dysfunction, by chemical means will likely change the animals' behaviour. We will regularly assess the behaviours, body conditions and body weights of animals after induction procedures. The behavioural changes will vary according to the CNS cell type(s) affected, the agent used to cause cell dysfunction, degeneration, and the time elapsed since the causative procedure. In the case of causative procedures targeted to the basal ganglia, the resultant behavioural changes will

typically manifest as alterations to motor function (e.g. slower locomotion, subtle changes to gait), potentially relating to partial sensory neglect and/or cognitive deficits.

Behavioural changes can manifest within a few days of the causative procedure (e.g. after intracranial injection of neurotoxins such as 6-hydroxydopamine). Some behavioural changes may be subtle, such that they can only be detected after rigorous quantitative testing of the animals' behavioural performance.

In the case of animals receiving unilaterally-targeted procedures, changes in motor function may only manifest on one side of the body (e.g. a tendency to move in a certain direction, an asymmetry in forelimb use when rearing, and/or an asymmetry in the quality/quantity of grooming due to the partial loss of dopaminergic neurons affected by the lesion). From the literature, it is uncommon for these behavioural changes are reported to not significantly affect the animals' ability to eat, drink and groom. In most cases, the induced dysfunction, degeneration of the CNS cell population(s) will not be complete. In most cases, CNS cell dysfunction, degeneration will be induced by unilateral targeting, rather than by bilateral or systemic targeting. In the case of bilateral or systemic targeting for induction by chemical means, doses of the causative agent will be carefully titrated to ensure only partial coverage and that, accordingly, behavioural changes do not significantly affect the animals' ability to eat, drink and groom. Moreover, these mice will be used in one or two weeks after the procedure to achieve our objective.

8. Humane end-point

Routine health monitoring post-operation or during treatments using scoring sheets will help identifying early point of suffering such that humane end-point can be applied. Separate recording score sheets will be used for surgical (like stereotaxic injections) and non-surgical (systemic drug administration) procedures.

9. Individual housing

Typically, single-housing is not required unless there is no practical alternative (e.g. if only a single male or female of the desired genetic status is born in a given litter, or it is part of procedures like behavioural tasks (such as the radial maze); or occasionally when mice fight, or when stud males are temporarily removed from matings, or if group housing could compromise the clinical monitoring and/or treatment of an animal (as advised by the NVS). The duration of individual housing will be kept to an appropriate minimum. Where appropriate, individually-housed animals will be given extra enrichment (such as tunnels) in their home cages. Where appropriate, animals will be re-housed with replacement cage mate(s) to provide companionship.

10. cage enrichment

Some animals that have to undergo cognitive behaviour, due to concerns that complex environmental conditions will increase variation in the experimental results, will be provided only with environmental enrichment like nesting material.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

In the past century, the mouse has developed into the most useful mammalian model system for genetic research. This is not only because of its genetic and physiological similarities to humans, but also because of the ease with which its genome can be manipulated and analyzed.

While other organisms such as yeasts, worms and flies are excellent models for studying the cell cycle and many developmental processes, mice are far better tools for asking questions about the immune, endocrine, nervous, cardiovascular, skeletal and other complex physiological systems that mammals share.

Mice naturally develop diseases that affect these systems, in addition, certain diseases that afflict humans but not normally mice, such as cystic fibrosis, Alzheimer's disease, Huntington's disease can be induced by manipulating the mouse genome and the environment, see for instance (Saito T et al., Nat Neurosci 17, 661–663 (2014)).

For complex intercellular interactions in a developmental context such as the nervous system, it is essential to look at in vivo biology. This is the most efficient and most effective way of assessing the function of proteins in this context, and to manipulate their genes using molecular genetics technology.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We always strive to implement and refine procedures. In general, potential refinements include increased monitoring, post-operative care, management of pain and training of animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

- NC3Rs online guidelines, practical information, and other online resources.
- Asepsis guidelines (LASA ideally, Home Office at a minimum).
- Laboratory Animal Science Association (LASA) that provides advices for care and welfare, education and training, ethics and policy and regulation of animal research.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through literature updates, seminars, meetings, as well as interaction with NIO and NC3Rs Regional Manager, as done so far.

Explain the choice ofspecies and the related life stages

The type of investigation outlined in this project cannot be carried in cell cultures as they lack information about the networks of neurons that are found in an intact brain. Furthermore, cell cultures or organoids do not replicate disease progression.

Manipulation of mouse genetics provides a unique opportunity to study the molecular basis of complex cell-cell interactions in vivo. The increasing availability of cell-type specific promoters gives extraordinary power to the generation and analysis of precise mouse models that undoubtedly will help to dissect the complexity of the brain. Using different life stages is required to carry out longitudinal analyses of brain function and behaviour at several pertinent life stages of the animals.

NON-TECHNICAL SUMMARY

144. Neural regulation of circadian rhythms

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to investigate the neural mechanisms, from behavioural input to cellular physiology, that drive the mammalian circadian clock.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The circadian clock is responsible for setting and regulating both behavioural activity, sleep-wake cycles, through to internal hormonal rhythms. Disruptions in the functioning of the central circadian pacemaker has devastating effects on health e.g. depression, cancer onset and physical wellbeing. Thus, by understanding the way in which the circadian clock functions, we will be able to all begin developing novel therapies, both behavioural and pharmaceutical in improving over all health.

What outputs do you think you will see at the end of this project?

The key outputs will be adding to the knowledge of circadian clock function though journal publication, public engagement and external scientific meetings.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the first instance, the wider scientific community which will use outputs to inform the development of future projects. In the long-term, it can be envisaged that our outputs may also inform transnational research into circadian related disorders and their treatments in humans.

How will you maximise the outputs of your work?

We will aim to publish all data that is generated by this work, positive or negative. In addition, we will form collaborations, when natural, to support and increase the probability of generating outputs for publication and public engagement.

Species and numbers of animals expected to be used

- Mice: mice- 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be singly housed, and motion activity recorded using infrared sensors, for approximately 8 months. Mice may be injected, either i.p. or via surgically implanted cannulas, with pharmacological agents to disrupt or enhance the robustness of circadian rhythmicity. In experiments designed under a repeated measures protocol, this maybe up to 5 injections per animals.

For measuring pupil light reflexes, mice will be temporarily restrained for up to 1 minute whilst pupil measurements are taken. Mice may undergo this procedure multiple times.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are little or no adverse effects to animals that will undergo behavioural and pupil light reflex recordings. Animals that have received injections may feel discomfort at the administration site, however this should be acute and last only a few hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The overall severity would be mild, however any surgical procedures would be in the moderate category. Throughout the course of the project licence we anticipate only a very small proportion of mice undergoing surgery thus being placed in the moderate category. The proportions are likely to be 90% mild and 10% moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studies in vitro alone are insufficient to show a candidate cellular abnormality is relevant to a given disease. This requires translation of molecular and cellular mechanisms into behavioural and electrophysiological measures that can only emerge with intact whole nervous systems and whole organisms. Also, the complex physiology in our proposed projects involves, many of the neural, hormonal and behavioural mechanisms interacting with one another, necessitating the use of animal models.

This project aims to elucidate the underlying mechanisms by which circadian entrainment is possible in mammals. Entrainment involves a complex neural network that cannot be modelled in vitro and requires an intact physiological system. In addition we require complex structures, such as the eyes, to decode light information for processing by the circadian clock. Previously we have considered using neural ‘clock’ cells grown in in vitro, however these cells have proven difficult to work with and do not lend themselves in addressing our project aims.

The administration of pharmacological compounds either systemically or centrally may result in mild transient discomfort however, at present; there is no alternative route by which such drugs can be given. Further, cannula implantation is the only non-terminal method available that allows central drug administration and in vivo behavioural/ physiological effects to be monitored.

In order to study the light induced responses of retinal photopigments and understand how they function as a network to regulate behaviour, an intact physiological system is necessary. Further, drawing out age related changes is impossible using current in vitro techniques, as the aging process is very complex and impairments are usually a result of a number of physiological alterations through time. Consequently, there is no realistic alternative to the use of intact animals to address this objective. In theory, it would be possible to undertake these experiments in humans; however, no subjects have yet been identified with impaired melanopsin activity.

Ageing is a complex and multisystem process. We are proposing to investigate this in an intact physiological system, which is currently impossible to do in the in vitro modelling.

What was your strategy for searching for non-animal alternatives?

We have considered using an immortalised circadian clock cell line; these cells are good for molecular work but are not suitable for investigating whole systems level physiology and complex neural networks.

Why were they not suitable?

These immortalised cells are not suitable for investigating complex behavioural responses and neural networks.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use statistical power analysis to ensure that the minimum number of animals is used for these experiments. Statistical significance will be set at $p<0.05$ and power to >0.8.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In order to minimise the use and surgical stress on animals we will employ a within subjects experimental design. This will reduce animal numbers, as each animal will serve as its own control. In adidtion, we will use homozygos breeding pairs where animals are not required to be littermate contols. All comparisons will be made using a repeated measures ANOVA with statistical power analysis based on a significance level of $p<0.05$.

Variability will be regulated by using littermate controls where appropriate and using stable REDACTED such as C57BL/6J Jax model.

What other measures apart from good experimental design will you use to minimise numbers?

We will tightly regulate our breeding strategy's as to minimise the unnecessary generation of animal stock.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice show excellent circadian behavioural responses and have been used for a number of years within the circadian biology field of research. They also provide the best model for transgenic manipulations. Hence, we propose the use of mice as data collected from our studies can be readily compared with that already published and, in parts, serve as control data when comparing with transgenic models. In addition, we will collect genotyping tissue from ear punches as oppose to tail clipping, whenever possible in order to minimise animal suffering.

To date, the mouse presents with the greatest potential for genetic modification over any other vertebrate species.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The only alternative to using transgenic models for these experiments would be to employ pharmacological, surgical or environmental manipulations. These have been used before; however, in our proposed approach the associated neurophysiological pain is much reduced. Examples would be where drugs have been injected intraocularly rupturing the eye capsule to silence specific photoreceptors. This method is significantly severer than the generation of a transgenic mouse line. Furthermore, genetic manipulation is a much more reliable tool for generating reproducible and clearly defined phenotypes, extending the utility of our observations. We will only employ intraocular injection in cases where no transgenic is available to address our research objective. Following intraocular injection animals will be required to recover from anaesthesia for a very short time (1 hour) and then culled. Pupil light reflex recordings will be taken during this 1 hour of recovery. The reason why we cannot measure pupil size with animals under anaesthesia is due to the lack of a stable pupil size under the influence of such drugs.

The monitoring of circadian molecular mechanisms can be achieved in Drosophila and will provide good robust evidence for their role in mammals; however do not provide detailed inferences on their physiological regulation by other complex efferent neural inputs such as feeding, social interactions. In addition, less sentient protected animals such as zebra fish, can provide detailed behavioural circadian outputs however are limited for understanding complex neural networks that are found in the mammalian brain.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animal suffering will be minimised throughout each experiment. During behavioural experimentation we will provide good husbandry and environmental enrichment, when this does not interfere with experimentation. Prior to experimentation animals will be regularly handled in order to acclimatise to the experimenter and restraint. All surgical procedures will be undertaken using aseptic techniques and appropriate analgesic administration will occur during and or post-surgery as required. Post-operative care will consist of pain management and regular monitoring (every 20 minutes for the first 2 hours and then at regular intervals as appropriate).

All experimenters will have superior training prior to conducting any experimentation. In the first instance, they will observe each procedure and then undertake these on their own whilst being supervised by the trainer. Only when the trainer is completely satisfied the procedure has been carried out competently will the experimenter be allowed to continue without supervision.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will consult the nc3r's website for up-to-date information as well as regular documents that are circulated through our AWERB.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The nc3r's website provides an outstanding resource of information. We will review this website on a regular basis for relevant information. In addition, our local AWEB provides us with an excellent platform, to discuss the 3R's, where this is a long standing item on every agenda.

Explain the choice ofspecies and the related life stages

Typically, we will use adult mice. Mice are an ideal species due to the availability of transgenic models that present as excellent tools for research into physiology and disease. We use adult mice as these will present with the most robust and measurable circadian rhythms.

NON-TECHNICAL SUMMARY

145. Neurovascular breakdown in ageing and disease and the development of novel vascular based therapies

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	aged, adult, juvenile
Rats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Neurovascular coupling is a mechanism that regulates blood flow in the brain. It is thought a breakdown in neurovascular coupling may be an important factor in disease and ageing, particularly dementia. This project license will investigate how neurovascular coupling is operating in healthy brain and how it goes wrong in disease. We will also develop new treatments to change baseline blood flow and/or neuronal activity to assess whether this slows down or stops progression of the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Even though we have known about the existence of neurovascular coupling for over 130 years we still do not know how it works. As the breakdown of neurovascular coupling is becoming increasingly linked to brain disease, especially dementia it is more important now than ever to understand firstly how it works in the normal brain as well as trying to understand how it is going wrong in disease. Due to the advent of new technologies it is now possible to target the vascular system for potential new therapies and this will form the third part of this project license.

What outputs do you think you will see at the end of this project?

Outputs from this project will primarily be in the form of peer reviewed scientific publications in leading neuroscience journals. These outputs will be across three general areas: basic mechanisms of neurovascular coupling, how neurovascular coupling goes wrong in disease and finally effects of neurovascular treatments to cure brain disease.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

There will be immediate, mid and long term benefits of these outputs.

Our research will help improve the use of brain scanning techniques that are used on human patients. By understanding exactly what these techniques are measuring in the brain we will be able to increase their accuracy and effectiveness. In the mid-term our research will also address the critical question of whether neurovascular coupling is breaking down in disease. If this is true, for example in Alzheimer's disease we may develop a new way of detecting the disease earlier. Early detection will allow more time for existing drugs to work and our results may isolate parts of the brain that need to be treated to

slow down or even cure the disease. In the longer term if we can develop therapies that can slow down disease in our animal models of disease there would then be potential to translate these into human treatments

How will you maximise the outputs of your work?

The project license holder and deputy already have a strong international collaboratitive network involving teams from New Zealand, Canada and the USA. Throughout the course of this project we will see to reinforce these collaborations by applying for international network grants to extend the scope of the research. We routinely publish all of our experimental results including negative findings. Indeed one of our recent papers showed that neurovascular coupling deficits reported in a mouse with Alzheimer's Disease may an artefact. This finding although showing a negative result was really important to publish and share with the scientific community.

Species and numbers of animals expected to be used

- Mice: 2700
- Rats: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

We will use wild type control animals and Genetically Altered animals for this project. The GA animals either will have a disease (e.g. Alzheimer's) or be bred with proteins called opsins in specific brain cells that we can then stimulate using light with optogenetics. For the animals with disease, we want to assess whether neurovascular coupling is breaking down in disease and develop new treatments to test on them. For the optogenetics, we want to assess how a specific cell, for example an interneuron is involved in regulating blood flow in the brain and to potentially use stimulation of that cell in the treatment of disease.

Generally, acute non-recovery experiments will be used in the first instance to assess basic response and control stimulations. Then we will use chronic recovery experiments in separate animals that last in general for several months. These experiments may include a period of training or pre-treatment for the animal, followed by surgery to implant an imaging chamber to the skull. We have been doing these surgeries for a number of years and the animals recovery quickly. Then the animal will enter a phase of longitudinal recording from the brain, either with recovery anaesthesia or awake. Followed usually by a final acute non-recovery experiment before the animal is killed by schedule 1 method or transcranial perfusion to collect the brain for post mortem histology.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some animals will undergo multiple surgical procedures and anaesthetics. In general the animals recover quickly and well from both procedures and anaesthetised imaging studies. Animals used in awake imaging protocols will need to be restrained, we will use positive reinforcement training in the first instance but food and water deprivation may be used. Some animals will have an altered diet (e.g. high fat western diet) for the duration of the study. Many of the chronic experiments under protocol two can last up to several months.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

In all acute anaesthetised experiments all animals the severity will be non-recovery. In our chronic experiments all animals that have cranial implants will be at a moderate severity. For the breeding protocols a vast majority of the animals will be in the mild severity band

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To understand neurovascular coupling in the brain, it is necessary to generate relevant biological data. The use of animals is therefore unavoidable. Rats and mice are the animal models of choice for research in this area due to the well-defined brain structure and function. That is, the sensory cortex these animals functions in a way very similar to human brains. Our expertise in using these animal models for research has been developed over a 20-year period. Consequently, the expertise and skills are already in place to ensure that the number of animals used is minimised by a consistently high quality of practice from the outset. We will also use specific mouse strains that reflect human disease such as Alzheimer’s and they will provide important information about disease progression. As a general strategy, anaesthetised preparations will always be used in the first instance to address all objectives, and where new or modified techniques are employed. New techniques may then be introduced into the awake preparation. This will ensure that the number of animals required for chronic awake studies is reduced and that minimal stress is placed upon the awake animals.

What was your strategy for searching for non-animal alternatives?

As we need a functioning brain with a circulatory system there are no non-animal alternative for this work. In future artificial systems may exist for modelling of the responses we expect to see (called in silico medicine) but at present they are not available.

Why were they not suitable?

They cannot simulate the concerted action of millions of brain cells and a reactive vascular supply.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal estimates are based on previous research and ongoing experimental work in the laboratory. In all experiments we routinely use statistical software and robust pilot data to calculate the numbers of animals need to reach appropriate statistical power in all our experiments. We can therefore achieve robust scientific results with appropriate groups sizes. All our grant applications have specific sections dedicated to the statistical calculation of group sizes and we have to adhere to ARRIVE guidelines with respect to randomisation and blinding in our experimental approach and analysis. Our estimate of animals is the minimal number of animals needed to generate scientific data that is statistically robust.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Our group have used the NC3R's Experimental Design assistant and G-Power software to generate group size estimates need to achieve robust significant results with appropriate groups sizes with the fewest animals needed to achieve appropriate statistical power. A specific example of our experimental design is we have recently published where we used a 2-factor ANOVA repeated measure design to assess neurovascular breakdown in the J20 Alzheimer's mouse. As we were able to repeatedly measure the same mice over a period of 4 months (blood flow response to sensory stimulation) we were able to achieve robust results using only 10 animals.

What other measures apart from good experimental design will you use to minimise numbers?

We will liaise with our biological services unit to ensure all breeding protocols are efficient as possible and where possible all non-transgenic animals will be used as controls. All our group size estimates are based on robust pilot data. We are also actively collaboration with an academic team in New Zealand who use computer modelling of our data to understand potential mechanisms to explain our results. This modelling work will allow a more targeted approach in our future work. Finally, we are one of the leading laboratories in using multiple techniques in the same animal simultaneously and over multiple recording sessions. This allows the collections of higher quality data from fewer animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Our approach will be to use non-recovery terminally anaesthetised animals in the first instance to refine experimental approaches. Then we will use chronic experiments where we can repeatedly take measurements from the same animal over many months. This reduces the number of animals needed compared to using multiple animals at separate time points. We carefully train all staff before they are allowed to perform experiments and animals are constantly monitored during studies to ensure suffering and stress are kept to an absolute minimum.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have to perform longitudinal studies for this project as we need to assess disease progression as part of our studies and develop potential new therapies as part of the project. We cannot use less mature animals because neurovascular coupling isn't established in very young animals and our main disease of interest is Alzheimer's which only occurs in adult or old animals. In our opinion the rodent model is the least sentient animal we can use while still being able to compare to results seen in humans

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We already operate high standards in monitoring and post-operative care of our animals. We have daily contact with the Biological Services Unit and the named animal care and welfare officer to pick up on the earliest signs of potential distress in our animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will keep up to date with the NC3R's ARRIVE guidelines and update members of the team in all aspects of best practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The project license holder is a member both the REDACTED Animal and Welfare Ethical Review Body to keep up to date with new developments and best practice. A member of our research groups has held a grant from the NC3R's.

Explain the choice ofspecies and the related life stages

This project will use young, adult and aged rats and mice.

A key aspect of this project is to assess how neurovascular coupling is changing in health, disease and ageing. Therefore, we need to perform experiments across the animals lifespan. We chose the rodent model as we have 20 years experimental experience and it is the lowest form on sentient life that have a comparable brain and circulatory system to that of humans.

Home Office

NON-TECHNICAL SUMMARY

146. New therapies for mitochondrial optic neuropathies

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this project is to develop and test new therapeutic interventions in mouse models of inherited mitochondrial optic neuropathy.

There are two key elements to the experimental strategy: firstly, to characterise the abnormalities in genetically modified mice that arise from alteration in genes that cause optic atrophy, and secondly, to determine the effectiveness of novel therapeutic interventions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inherited optic neuropathies are genetic conditions in which the optic nerve is damaged with the loss of cells called retinal ganglion cells leading to atrophy of the optic nerve. There are currently no effective treatments. Since the commonest form of inherited optic neuropathy is dominant optic atrophy, with an incidence of 1:10,000 to 1:50,000, the problem is of significance to society. The importance of this work will be that it will generate data that will lead to new treatments for optic neuropathy being rolled out to patients. The project will evaluate new potential treatments specifically for the protection and repair of retinal ganglion cells. The project will provide supportive evidence for developing early clinical studies of novel therapeutic interventions and predict their likelihood of success in man. The beneficiaries of the project will ultimately be patients with inherited optic neuropathies. Novel treatments have the potential to have substantial impact on the quality of patient care in this disease and subsequently on the patients' quality of life. In achieving these benefits, we will also generate a deeper understanding of the mechanisms of development of the disease, which will also lead to potential benefits in diagnostic testing, early intervention and potentially even prevention.

These benefits are worthwhile because in the developed world two out of three blind people have retinal disease, with 20% of these due to retinal ganglion cell degeneration and optic atrophy.

What outputs do you think you will see at the end of this project?

The project will generate new information and publications and may see new therapies that can be developed further for the benefit of patients with mitochondrial optic neuropathies.

Knowledge generated in this project will also contribute towards future socio-economic impact as new data may be used to develop markers to improve diagnosis and track disease progression. Better understanding of the underlying
mechanisms that drive retinal ganglion cell loss in these conditions will potentially lead to improvements both in the short term

(public awareness, mechanistic discovery) and long term (therapeutic target development) for a significant number of individuals in the UK and worldwide.

This project will also generate peer reviewed publications in international journals, further grant funding applications, conference platform presentations and posters, and new collaborations. The novel therapeutic strategies are all likely to be suitable for intellectual property protection if they are promising and this will be sought.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The expected benefits of this research will be realised as the project advances, and will be pre-clinical data for novel therapeutic interventions in optic neuropathy. The project will provide supportive evidence for developing early clinical studies of novel therapeutic interventions and predict their likelihood of success in man. The beneficiaries of the project will ultimately therefore be patients with inherited optic neuropathies. Novel treatments have the potential to have substantial impact on the quality of patient care in this disease and subsequently on the patients' quality of life. In achieving these benefits, we will also generate a deeper understanding of the mechanisms of disease, which will also lead to potential benefits in diagnostic testing, early intervention and potentially even prevention. The realistic time frame for benefit for patients is 5 to 10 years.

How will you maximise the outputs of your work?

I am already establishing new national and international collaborations and will continue to do so throughout the project. I am actively seeking to utilise and share the mouse models I work on with colleagues who have promising therapies that require pre-clinical data. I am also seeking out industry partners to further these goals.

I will work with third sector charities and patient support groups to disseminate the results of our research and contribute to local and national events (including scientific conferences and patient groups). I am regularly invited to speak at patient events and this will be an ideal dissemination opportunity with the interested community of patients. Public awareness will also be enhanced through open access publication of results, and by dissemination of the results. I will also continue to work with both schools and adult audiences to increase the general public understanding and awareness of mitochondrial dysfunction and the devastating effect it can have on vision loss.

I will make timely publication of our results in high impact, open access journals a priority. I will deposit any large data sets in central open access repositories. The research team will attend national and international conferences . These meetings will allow us to meet other academics, patients, health care workers, government policy makers and third sector investors and let them know the results of our work.

I will engage in discussions to explore the potential for commercialisation and assess any outcomes that should be protected as intellectual property. In this way if there are discoveries made that could help patients in the future we can ensure that we maintain a lead in this field.

Species and numbers of animals expected to be used

- Mice: 600 mutant mice per annum over 5 years , or 3000 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, mice will be bred, maintained, some will be aged and phenotyped and some enrolled in therapeutic intervention studies. Those in the intervention administration study will have phenotyping before and / or after intervention.

The optimisation of the GA breeding strategy is key in reduction of the numbers used under this project. The project requires both wild type and heterozygous mutant mice- hence we have to breed wildtype and heterozygous mice as well as cross heterozygous mice with other heterozygous mice. All mice generated are valuable to the project.

Within each experimental cohort the minimum number of animals will be a minimum of 3 per genotype (wild type versus heterozygous versus homozygous mutants). However, in order to achieve statistically significant results these numbers may need to be increased by multiples, depending on the magnitude of the effect/ phenomenon being observed. Statistically meaningful data comparing wild type phenotype to heterozygous or homozygous mutants will be obtained. The ideal cohorts will comprise littermates, or will have been age and sex matched.

Phenotyping data will be collected which is qualitative and descriptive, including photographs of the eye. Where measurements are made for quantitative data care will be taken to use the minimum number of animals in order to obtain a statistically significant result and reproducibility.

The phenotyping will typically involve non-invasive assessment of ocular and retinal and optic nerve structure and function. Photographs and scans of the retina and optic nerve will be taken and vision assessed by psychophysical and electrophysiological tests.

Administration of substances as therapeutic interventions will be either drops, subconjunctival injection, intraoclur injection (as is often the case with medicines used to treat patients with retinal disease) or oral. Novel compounds would typically be tested at two or three dose levels around the expected pharmacological dose, using initially no more than 3 animals per group. For comparisons using larger groups, group size will be estimated by power analysis. Unless there are good reasons otherwise, designs will compare several compounds and/or dose levels and factorial experimental design will be used when applicable.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Mouse models of inherited optic neuropathy generally correlate well with human disease and therefore enable us to get better understanding of the disease mechanisms and potential routes to treatment. Although the genetic changes and diseases are chronic in duration, animals do not normally show any alteration in behaviour or feeding or significant widespread problems and most animals will experience very low severity, namely sight loss. Sight is not a main sense in mice as they depend much more on whiskers.

However, in order to reduce impacts and adverse effects for the animals the research plan has sought to refine and minimise animal suffering by the incorporation of the mutual-exclusivity of some of the procedural options, which prevent unreasonable levels of cumulative severity from occurring. The range of tests outlined are mostly non-invasive, and as such the severity of the testing is ‘mild’. Where a test is more invasive it will incorporate anaesthesia, with or without recovery. Many of the tests, such as fluorescein angiography, electroretinogram recordings from the retina and optic nerve and imaging the retina are considered non-invasive in humans. In this work animals will need to be immobilised and pain relief will be administrated. The tests will be carried out under the same session of general anaesthesia or sedation, thus minimising stress and potential harm to the animal. This also reduces handling, testing times and general anaesthesia exposure. In summary, all semi invasive or invasive procedures will be carried out aseptically. Peri- and post-operative analgesia will be provided; agents will be administered as agreed in advance with the NVS. Animals will be monitored until a full recovery is made from the anaesthetic. If clinical signs are exhibited post-anaesthesia, further monitoring will be undertaken using the Health Monitoring Score Sheet (appendix 1). In the uncommon event of post-anaesthesia complications, animals will be killed unless, in the opinion of the NVS, such complications can be remedied promptly and successfully using no more than minor interventions

The administration of substances, or interventions, are of low severity in the main, although injection in the eye may be moderate and carried out under general anaesthetic and analgesia.

Where animals have to be housed separately they will receive environmental enrichment in their cages, with tubes and nesting in which they can hide as well as chew sticks as an activity item. In previous work, we also refined the experience of the singly housed animals by using raised lids in the cages so they could climb around and see the animals in their neighbouring cages. We will also ensure to take care not to alarm the mice with sudden noises are movements in the holding room.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

75% mild, 25% moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The whole animal visual system and retina and optic nerve pathophysiology is needed to test the mechanisms of disease and to conduct pre-clinical trials of novel therapeutic interventions.

Investigating the complex processes involved in inherited optic neuropathy, which consists of many different cellular and tissue interactions in the retina and optic nerve, requires animals to establish the outcome of these processes in living animals. Non-animal alternatives cannot reveal the complex responses generated as a result of the administration of therapeutic interventions, and can only take us part of the way towards understanding the ramifications of any new treatment. Animals have to be used because it is not possible to remove tissue from the eyes of living patients who may be tested with new therapeutic agents without any data on their toxicity or effectives. The whole animal model provides the only way of assessing distant neurological effects of mutations in the causative genes.

What was your strategy for searching for non-animal alternatives?

My research utilises cell lines and primary cell culture extensively on an ongoing basis and I shall continue with this research in addition to the mouse work applied for .

Why were they not suitable?

Cell and culture models, ex vivo and in vitro , are suitable for some of the assays. The retinal tissue from mutant mouse is needed to provide more physiologically relevant data.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The research requires the use of both wild type and heterozygous mice and hence no mice are wasted as a result of our breeding strategy. The number of animals used will be minimised by careful design of experiments using contemporaneous control groups and statistically appropriate group sizes, which includes between 4-8 mice in each group. To minimise animal usage we will investigate the cellular effects of therapeutic interventions in vitro by establishing cell lines before using these agents in the mice. The use of tissues for organ and cell culture from genetically modified and wild type control animals will allow complex molecular and biochemical experiments to be undertaken and will minimise the use of live animals.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have based the numbers on previous experience with pre-clinical trial of a drug used in mitochondrial optic neuropathy. The online NC3Rs Experimental Design Assistant has been used to check our assumptions and predictions.

What other measures apart from good experimental design will you use to minimise numbers?

The optimisation of the breeding strategy is key in reduction of the numbers used under this project. The project requires both wild type and heterozygous mutant mice- hence we have to breed wildtype and heterozygous mice as well as cross heterozygous mice with other heterozygous mice. All mice generated are valuable to the project.

Within each experimental cohort the minimum number of animals will be 3 per genotype (wild type versus heterozygous versus homozygous mutants). However, in order to achieve statistically significant results these numbers may need to be increased by multiples, depending on the magnitude of the effect/ phenomenon being observed. Statistically meaningful data comparing wild type phenotype to heterozygous or homozygous mutants will be obtained. The ideal cohorts will comprise littermates, or will have been age and sex matched.

Phenotyping data will be collected which is qualitative and descriptive, including photographs of the eye. Where measurements are made for quantitative data care will be taken to use the minimum number of animals in order to obtain a statistically significant result and reproducibility.

Novel compounds would typically be tested at two or three dose levels around the expected pharmacological dose, using initially no more than 3 animals per group. For comparisons using larger groups, group size will be estimated by power analysis. Unless there are good reasons otherwise, designs will compare several compounds and/or dose levels and factorial experimental design will be used when applicable.

The sharing of tissue will be an important part of our strategy because we can carry out many experiments on cells from tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice are suitable as the chosen species for this project because they have a well-characterised genome, considerable data is available about their normal visual function and physiology and it is possible to generate mice with specific genetic modifications to study. The time taken to generate the cohort of mice required in the experiments is relatively short. The mouse eye, especially the retina and optic nerve, has considerable homology to the human eye.

The methods comprise examining the mouse to measure its visual and neurological function. This is done in a way that is very similar to a human eye clinic assessment - such as measures of visual acuity, retinal and optic nerve appearance and imaging by special cameras through a dilated pupil and assessment of function through electrophysiology. The methods are mainly observational or non interventional.

The adminstration of potential novel therapeutic interventions will be either by eye drops, eye injection, or through food or water.

All animals will be closely monitored for distress and signs of ocular inflammation and appropriate steps to minimise harm to the animals will be taken following discussion with the Named Animal Care and Welfare Officer (NACWO) / Named veterinary Surgeon (NVS).

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mouse models are the least sentient compared to other species, whilst still correlating well with human disease and allowing more depth to probe disease mechanisms because of the availability of reagents and ability to genetically alter mice. Although the genetic changes and diseases are chronic in duration, animals do not normally show any alteration in behaviour or feeding. Sight is not a main sense in mice. These models have an excellent track record in preclinical testing of agents which are now used in man.

We study the effect of genetic mutations that lead to optic atrophy and blindness in humans and use mice which have the same genes mutated. This results in loss of vision but in mice the visual loss is not as significant since the mouse is less reliant on vision than humans.

However, to study the damage we need adult mice and the loss of vision often only advances with age. Other species would not mirror the human retina quite so well and the genetics of some species makes them unsuitable. Pre-clinical testing of new therapies also requires them to be explored in a mammalian retina. The testing is delivered over a period of days, weeks or months in some cases, by eye drops. food or water or injection and therefore animals that have been terminally anaesthetised are not suitable.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The research plan has sought to refine and minimise animal suffering by the incorporation of the mutual-exclusivity of some of the procedural options, which prevent unreasonable levels of cumulative severity from occurring. The range of tests outlined are mostly non-invasive, and as such the severity of the testing is ‘mild’. Where a test is more invasive it will incorporate anaesthesia, with or without recovery, for example, Protocol 3. In this protocol, all the tests, such as fluorescein angiography, electroretinogram recordings from the retina (ERG), and retinal and optic nerve (a battery of test considered non-invasive in humans; animals will need to be immobilized; pain relieve will be administrated to prevent electrode placement causing any discomfort) will be carried out under the same session of general anesthesia (GA) or sedation, thus minimizing stress and potential harm to the animal. This also reduces handling, testing times and GA exposure.

Where animals have to be housed separately they will receive environmental enrichment in their cages, with tubes and nesting in which they can hide as well as chew sticks as an activity item. In my last PPL, we also refined the experience of the singly housed animals by using raised lids in the cages so they could climb around and see the animals in their neighbouring cages. We will also ensure that the care staff and relevant PIL holders do not alarm the mice with sudden noises are movements in the room.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Published guidelines on the NC3Rs website provide a regular source of up to date guidance.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I am part of a community of researchers with shared experience and knowledge of animal work and we share data and techniques and attend training both locally and nationally. There is a regular review of methods ongoing and the 3Rs are highlighted by seminars and workshops and conference events. The online 3Rs training provided by the NC3Rs is incorporated into practice regularly.

Explain the choice ofspecies and the related life stages

I plan to use mice which are genetically altered to carry mutations which model human mitochondrial optic neuropathies. It not possible to achieve the objectives of this project without using animals for the following main reasons:

Firstly, the tightly controlled genetic background and environment of the mice is impossible to achieve in any human clinical study.
Secondly, investigating the complex processes involved in inherited optic neuropathy, which consists of many different cellular and tissue interactions in the retina and optic nerve, requires living animals to establish the outcome of these interactions in living animals. Non-animal alternatives cannot reveal the complex responses generated in response to the administration of therapeutic interventions, and can only take us part of the way towards understanding the ramifications of any new treatment.
Thirdly, animals have to be used because it is not possible to remove tissue from the eyes of living patients. Fourthly, it is not ethically or otherwise possible to administer new therapeutic agents to human subjects without sound data from animal studies.
Lastly, the integrity of the visual system is particularly important if we are to provide accurate assessments of the degree of retinal ganglion cell recovery. The whole animal model provides the only way of assessing distant neurological effects of mutations in the causative genes.

I will use adult and juvenile and embryonic life stages. Adult mice are needed for breeding, and ageing. Juveniles can be aged and with age express more of the relevant phenotype. Embryonic life stages can provide cells for ES work and this can be very useful for disease modelling and therapeutic testing.

NON-TECHNICAL SUMMARY

147. New Treatments for chronic ocular disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to develop genetically-targeted therapies for chronic ocular conditions such as age-related macular degeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Age-related macular degeneration (AMD) is the most common cause of blindness among the elderly in the industrialised world and accounts for 8.7% of all cases of blindness worldwide, particularly in people older than 60 years (Wong 2014). AMD is most prevalent in populations of European ancestry with approximately 1–3% of the total population suffering from an advanced form of AMD REDACTED

In the UK, the Royal National Institute of Blind People (RNIB) estimate there are around 600,000 people with sight loss due to AMD, with 70,000 new cases each year diagnosed, and this is expected to more than double to 1.3M by 2050.

The disease is caused by damage to the macula, which is the part of the eye needed for sharp, central vision. AMD is a complex, multifactorial disease which is difficult to manage and is classified into early, intermediate and late stages (Khandhadia 2012, Ferris 2013). AMD includes two morphological sub-types: neovascular AMD and the atrophic form, also called geographic atrophy (GA) (Chakravarthy 2010). Whilst there are highly effective biological therapies for the neovascular (or wet) form, there are no currently approved treatments for the atrophic (or dry) form.

REDACTED

What outputs do you think you will see at the end of this project?

The main outputs from this project will be the generation of data to support the progression of gene therapies programmes to clinical evaluation in chronic ocular disease. The data will either be supporting clinical development directly (e.g. will form part of the nonclinical data package for regulatory submission to conduct a clinical trial) or indirectly through the development of the gene therapy platform for future therapies.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

These outputs may be used by REDACTED to progress its gene therapy programmes by supporting clinical trial applications/approval in the short term (2-3 years per project) with the hope of successful

treatment of dry AMD patients through clinical development and ultimately to market in the mid-long term (3 – 10+ years). It may also be used by REDACTED to support the development of its gene therapy platform, which may generate Intellectual Property in the short term and lead to improved therapies in the longer term. These outputs may also be presented at scientific congresses and published in peer-reviewed journals thereby benefiting the field as a whole throughout the term of this project and beyond.

How will you maximise the outputs of your work?

Data from these studies may be presented at scientific congresses or workshops (posters or talks) and published in peer-reviewed scientific journals and patent applications, thereby benefiting the entire field.

Species and numbers of animals expected to be used

- Mice: 1500
- Rats: 480

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, each mouse will receive a single subretinal injection of vehicle or vector under general anaesthetic. Blood samples (approx. 50uL for mice) may be taken at baseline and up to weekly during the 4 week procedure. Blood samples (approx. 100uL for rats) may be taken at baseline and up to weekly during the 4 week procedure. (see Table 1 in Step 1 for volumes) after which time the animal will be euthanised by an appropriate Schedule 1 procedure. In some cases, the animal may be anesthetized up to weekly for non-invasive ocular imaging (fundoscopy, OCT). In some cases, the animal may be terminally anesthetized for ocular imaging and/or terminal blood sampling, followed by Schedule 1 method. Tissues will be taken post-mortem for analysis.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals are expected to have pain due to the subretinal procedure that will be transient (days) and effectively treated by local and/or systemic analgesia. Artificial tears are applied during the subretinal procedure to counteract eye dryness. AEs are likely to be very uncommon (1-5%) with a maximum severity category defined as moderate. AEs associated with subretinal injection may include subconjunctival or vitreous haemorrhage (routinely self-resolved and do not require treatment), endophthalmitis (treatable with topical antibiotic), and on rare occasions the development of cataract or retinal detachment.

All animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Regarding the transient retinal detachment due to subretinal injection, mice are nocturnal animals with poor visual acuity. Therefore, it is accepted that they can cope with loss of vision without any appreciable detriment. Uncommonly animals that fail to do so or exhibit signs of pain, distress or of significant ill health, as assessed by the NVS, will be killed by a Schedule 1 method. Any animal not fully recovered from the surgical procedure within 24 hrs or showing general signs of ill health that are likely to exceed the limit of severity (moderate category; such as piloerection, lethargy, up to 15% body weight loss, grimace score reading of pain – see Table 2 above), will be humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most animals are expected to experience up to moderate severity due to the surgical procedure, however this is expected to be transient and will be alleviated by the use of anaesthesia during surgery and analgesia post-surgery.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We currently use in vitro cell-based systems for much of our work to screen and characterise AAV vector candidates prior to in vivo testing and have looked into replacing the need for animal work through the use of more complex in vitro systems such as 3D organoid cultures and patient-derived induced pluripotent stem cell (iPSC) models but these are currently not suitable for this purpose. Assessing both AAV vectors and a complement-targeted therapeutic approach requires a fully functional ocular/immune system that cannot currently be modelled in vitro. However, we will aim to reduce the number of animals used in testing by substituting in vivo models to show efficacy of treatment with in vitro readouts, such as in vitro assays for complement activation. We will also minimise the number of rodents to test in vivo by implementing in vitro screening of treatments prior to animal studies.

What was your strategy for searching for non-animal alternatives?

We have considered complex in vitro systems (in which the retinal architecture is represented) such as 3D organoids (‘retina in a dish’)primary RPE and patient-derived induced pluripotent stem cell systems.

Why were they not suitable?

Assessing effectiveness of both AAV vectors and a complement-targeted therapeutic approaches requires a fully functional ocular/immune system which are not present in current in vitro/ex vivo models. However, we will continually monitor this field with the intention of replacing animal studies with non-animal alternatives if suitable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers have been estimated based on previous studies with AAV vectors conducted by Gyroscope therapeutics at CRO’s and academics, showing appropriate effect sizes and statistical significance. Power calculations are routinely employed to check that the number of animals per group will demonstrate statistical significance. . If internal data is not available, data from published literatures can be used as a source for power and sample size calculation. The number of studies per year is based on current and project work plans but may be lower if alternative methodologies to replace such studies are developed over the next 5 yrs.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The use of prior data as stated above will allow selection of appropriate group sizes likely to produce statistically-meaningful data, which will reduce animal numbers needed for this work. In vitro screening to select vector candidates will also be conducted prior to animal work using several techniques, including flow cytometry, western blotting and ELISA. Only the lead in vitro screened vector candidates will be tested in vivo to reduce the numbers of animals used..

As part of our Experimental Design, we will use the minimal number required per group that gives valid data based on our experience with similar mouse expression studies using this AAV gene therapy platform. Power and sample size calculation will be used to ensure that detection of significant difference is achieved with the smallest sample size.

What other measures apart from good experimental design will you use to minimise numbers?

In many cases, the numbers of animals required will be reduced by longitudinal measurement of responses, e.g. by serial blood samples or by optimised protocols for intravital imaging. Longitudinal usage provides essential information on the effect or not of any treatment, while at the same time reducing the number of animals required to obtain such information.

Unnecessary variation in the animal cohorts that could result in requiring more mice will be minimised by use of gender and age-matched controls housed under identical conditions.

Pilot studies will always be employed when the outcome of the study cannot be predicted with any certainty (such as first-time use of new platform/technology or therapeutic transgene or change in surgical procedure (changing from unilateral to bilateral subretinal administration, for example)). This will ensure dose and animal numbers can be optimised before embarking on any animal intensive studies, thus minimising the overall use of animals. Care will be taken to harvest animal tissue required for developing assays for assessment of in vivo studies from control animals from previous studies to negate the need to cull animals for this purpose and reducing animal use further.

As an example of optimisation of our animal approaches we may assess the impact of bilateral subretinal administration of AAV vectors. We currently administer AAV vectors by subretinal unilateral injection to mice. To reduce the number of mice used per experiment we may assess the impact of bilateral subretinal administration of AAV vectors on animal welfare (i.e. body weight, food and water consumption) and behaviour and compare this to baseline data generated by our current unilateral administration of AAV vectors.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The rodent is the ideal organism for these investigations for three main reasons:

Firstly, it is the long-standing choice for gene therapy research with lots of historical data available This is due to the structural similarities between the target retinal/associated ocular structures in the mouse and human (i.e. similar sclera, choroid, RPE, photoreceptor (PR) layer, outer and inner nuclear layers, ganglion/nerve fibre layers, inner limiting membrane), and commonly used laboratory strains of mice are phenotypically and genetically characterized and do not show common retinal degeneration and mutations leading to retinal disease (Chang 2013). It is therefore recognised as the best first species to undertake ocular research in.

Secondly, there is a large number of well-characterised models and reagents available permitting the thorough, incisive, and comprehensive obtainment of information from the experiments undertaken. Thirdly, there are highly effective methods of longitudinal monitoring, e.g. an array of well-established methods used in human clinical eye examinations have been adapted for use with rodent eyes to assess the retina in a non-invasive manner. These methods include indirect ophthalmoscopy and optical coherence tomography (OCT), all of which will contribute to the reduction of the numbers of animals required. Such techniques are also focused on animal welfare, e.g. better imaging stations and methods requiring shorter times under anaesthesia.

Negative control groups (baseline groups) will be minimised whenever statistically feasible.

References

Chang et al., (2013) Survey of Common Eye Diseases in Laboratory Mouse Strains. Invest Ophthalmol Vis Sci. 54 4974–4981.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are the preferred animal model for the evaluation of ocular gene therapies as the retinal architecture is very similar to Man despite the lack of a macular. Primates, who do have a macula, are not used instead for ethical reasons. Mice therefore represent the least sentient suitable species for these studies.

More immature stages of the mouse cannot be used for two reasons: firstly, the retina is still developing in the neonatal mouse, therefore the anatomical structure does not represent the therapeutic target

(mature retina). Secondly, the vector must be administered by subretinal injection which in the small mouse eye causes a level of procedural damage. This is exacerbated in the neonatal eye.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Subretinal injection is a clinically established route of administration of therapeutic agents in humans. We will use the state-of-the-art technique and equipment adapted to rodents. We will consistently monitor the literature to ensure that we are using the most up to date and refined approach.

To minimise discomfort of repeated procedures such as anaesthesia, we will combine treatments under a single anaesthetic event wherever possible. The anaesthesia will preferably entail the use of inhalation agents whenever possible. Least invasive route of substance administration and needle gauge will be used where possible.

All animals will be monitored, with additional monitoring post-vector administration. All animals will receive appropriate operative care in terms of anaesthesia and pain management both during and after the procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We expect all recovery procedures will be carried out aseptically (see the Appendix 4 HO Minimum Standards for Aseptic Surgery, as well as other guidelines e.g. LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery). Peri-operative analgesia will be given and maintained after the procedure for as long as is necessary to alleviate pain. Animals will continually be monitored for signs of pain and distress, especially post-operative, by use of the grimace scale; *https://www.nc3rs.org.uk/sites/default/files/documents/Guidelines/MGS%20Manual.pdf.*

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through working very closely with the REDACTED and by maintaining an awareness of the National Centre for the Replacement, Refinement and Reduction of animals in research (NC3Rs website - Arrive guidelines; Animal Research: Reporting of In Vivo Experiments), best practises will be continuously adopted.

Explain the choice ofspecies and the related life stages

This data cannot be generated with current in vitro systems. Since AAV vectors have been shown to transduce the mouse retina effectively following subretinal injection, with a similar tissue distribution as primate, the mouse has been shown to be an effective system for the evaluation of gene therapy vectors.

Subretinal injection can be performed on younger animals (neonatal) however the subretinal procedure is challenging and is associated with a higher degree pf procedural damage which could confound results. The adult mouse is therefore the best model.

Home Office

NON-TECHNICAL SUMMARY

148. New vaccines and anti-cancer immunotherapies

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of this program of work is the discovery and development of new therapies and therapeutic combinations for the treatment of solid tumours and of new vaccines for infectious disease prevention.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will generate data describing the safety, efficacy and tolerability of potential new vaccine candidates against several infectious diseases. Similar data will be generated for potential new anti-cancer agents.

The data generated during this project will be used to select the strongest candidates for potential new vaccines that will prevent disease. Likewise, new anti-cancer agents will be identified with the potential of increasing the range of medicines available in the fight against cancer.

The field of anti-cancer microbial therapies is just beginning to develop, and the data generated in this project has the potential to influence the progress and direction of the entire field. Through scientific publications and patent applications such data will advance everyone’s knowledge of how the immune system fights tumours and how this can be helped by bacteria.

What outputs do you think you will see at the end of this project?

This project will result in safety, efficacy and tolerability data for potential new vaccine candidates against several infectious diseases and for potential new anti-cancer agents.

The data generated during this project will be used to progress the strongest candidates into clinical development with the intention of developing marketable products. Data from this project will be also be used for filing new patents and will be disseminated through the patent publication pathways.

In addition to patent applications, scientific publications and conference presentations will be used to disseminate key scientific findings and promote the general advancement of the two fields studied.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our approach is at the forefront of scientific and drug development in the field of anti-cancer microbial therapies and the data generated in this project have the potential to influence the progress and direction of the entire field. Such data will advance the scientific community's knowledge of how the immune system fights tumours and how this can be helped by bacteria.

Selection and characterisation of new medicine and vaccine vaccine candidates will lead to their further development (e.g. in clinical trials) and could potentially lead to new vaccines and anti-cancer therapies being introduced to the market. These products have the potential to prevent disease in or cure a significant number of people across the world. In particular, some of the vaccines we are developing are aimed at fighting infections in low/medium income countries and are poised to help tackle global health issues.

How will you maximise the outputs of your work?

This work will provide data regarding the safety and potential efficacy of new vaccines and anti-cancer therapies. The studies will result in knowledge and hypothesis generation in relation to anti-cancer therapies and will drive the development of the microbial therapeutics field.

Data and knowledge from this project will be shared with the wider scientific community by the means of scientific publications, conference presentations and patent applications.

We will be pursuing scientific collaborations with academic partners.

Species and numbers of animals expected to be used

- Mice: We expect to use around 9200 animals over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most animals used in this project will receive one of the new medicine candidates. These can be vaccine candidates tested for their ability to elicit responses likely to provide protection against infectious disease, or the candidates can be novel anti-cancer medicines evaluated for their ability to inhibit tumour growth. Some animals will in addition undergo procedures aimed at data gathering, such as imaging. All animals will be closely monitored for weight loss, behaviour changes and clinical signs during treatment periods.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

As we try to identify and develop new medicines for cancer treatment and new vaccines for infectious diseases, studies conducted under this licence may induce some adverse effects in some of the animals. Typical adverse effects include changes in appearance, for example ruffled fur, or changes in behaviour, e.g. the animals may become subdued. Other effects may include reduction in body weight and/or reduced eating. The larger proportion of animals used in these studies will, however, not experience any noticeable adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For the majority of animals the severity level will be mild. However, as stated above, in some studies the animals may experience some adverse effects, but these would only cause the animal a moderate level of distress which will in most cases be transient. At the end of the study, the animals will be humanely killed. After the animals are killed samples of body tissues are sent to laboratories for close examination to give more information about the biology, mechanisms of action and overall effects of the potential new medicines.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding the mechanisms of action and assessing the effectiveness of potential new medicines requires the presence of a fully developed and functional immune system. Currently this cannot be reproduced outside of a living organism. Indeed,
the assessment of the anti-tumour efficacy of anti-tumour candidates cannot be efficiently modelled in vitro due to the complexities of the tumour microenvironment that cannot be fully replicated in a laboratory setting. Similarly, for the evaluation of new vaccines' ability to induce good protection against infection, a fully functional immune system is required.

What was your strategy for searching for non-animal alternatives?

We will aim to reduce the number of animals used in candidate testing by substituting challenge models to show efficacy of vaccination with in vitro readouts, such as neutralising antibodies assays. We will also minimise numbers of candidates to test in vivo by implementing rigorous in vitro screening candidates with high bars for in vivo translation.

We will use cell culture techniques to identify most promising anti-tumour candidates. We will also work on development of innovative cell culture techniques (such as 3D culture) to further replace in vivo screening.

Why were they not suitable?

Improved in vitro screening techniques will reduce numbers of animals used by reducing the numbers of candidates that qualify for in vivo screening and will at the same time improve the quality of candidates brought forward for in vivo screening.

However, there is a point in biological research when in vitro experiments cannot provide all the necessary conditions to further research. In vitro models can mimic certain aspects of the of disease. They cannot, however, reproduce the complex interactions between different cells and mediators or reproduce the functional changes that occur as part of the ongoing disease process. The scientific community has established extensive in vitro systems to confirm the existence of a particular mechanism. But it is only with in vivo experiments that we can establish whether new medicines targeting such pathways will be efficacious and safe.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A typical experiment may include up to 60 mice and we might run approximately 150 studies over 5 years testing new medicine candidates alone or in combination. Thus, the expected number of animals to be used under this licence is estimated at 9200.

We will use power calculations to determine the minimum numbers of mice required to demonstrate a phenotypic effect, e.g. tumour growth inhibition or immune response generation. We will consider randomised block design for our studies where possible to further limit the number of animals used. All models used will be assessed such that we shall employ the minimum severity of disease (e.g. tumour burden) required to show an effect.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To ensure we use minimal number of animals required to obtain meaningful and relevant data, we have extensively consulted available literature, attended experimental design and statistical courses, discussed with statisticians and NC3R staff and tested online tools provided by the NC3R.

What other measures apart from good experimental design will you use to minimise numbers?

In many cases, the numbers of animals required will be reduced by longitudinal measurement of responses, e.g. by serial blood analysis for antibody response or by optimised protocols for intravital imaging. We have developed tools that will allow us to study the biodistribution of our candidates longitudinally in a single cohort. Hence, effects of new medicines may be measured after one, two or more doses in the same group of 10 mice, rather than having 10 mice sacrificed after each dose. Such longitudinal usage provides essential information on the biology and efficacy of the candidate while at the same time reducing the number of animals required to obtain such information.

Unnecessary variation in the animal cohorts that could result in requiring more mice will be minimised by use of gender and age-matched controls housed under identical conditions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse is the ideal organism for our investigations for three main reasons. Firstly, there is lots of historical data available for hypothesis-building and predictions.
Secondly, there is an immense spectrum of well-characterised models developed over the years to cause minimal distress and suffering while providing meaningful data. Thirdly and in line with the previous point, development of highly effective, reproducible techniques for longitudinal monitoring and innovative techniques focused on animal welfare provide the best setting for the purposes of this project.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The human immune system is intricately complex and modelling it for assessment of new medicines requires models in vertebrate animals whose immune systems have been studied and can be, to a good degree, compared to human. Mice are the lowest vertebrate group on which plethora of reliable information on the function of the immune system is available and where well characterised and minimal severity anti-cancer models have been developed.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To minimise discomfort of repeated procedures such as anaesthesia, we will combine treatments under a single anaesthetic event wherever possible. The anaesthesia will preferably entail the use of inhalation agents whenever possible. Least invasive route of substance administration and needle gauge will be used where possible.
Negative control groups (baseline groups) will be minimised whenever statistically feasible.

Expertise at the Designated Site further enhances animal welfare, by providing close collaboration with dedicated animal care staff and veterinary consultants, and ready access to highly skilled advice.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult all the relevant references listed therein. (Reference: NC3Rs/BBSRC/Defra/MRC/NERC/Royal Society/Wellcome Trust (2019) Responsibility in the use of animals in bioscience research: expectations of the major research councils and charitable funding bodies. London: NC3Rs.)

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will continuously monitor publications and the NC3Rs website for new and alternative models that could be implemented as part of this project. In addition, articles on advances in the 3Rs are regularly published on the REDACTED internal
REDACTED Users News Forum and other relevant information is circulated by AWERB. Whenever possible we will implement these refinements into our studies.

Explain the choice ofspecies and the related life stages

The adult mouse is the ideal organism for these investigations for three main reasons.

First, it is the long-standing choice of immunologists with lots of historical data available for hypothesis-building and predictions and it has successfully identified the key operating principles of the immune system on which major clinical advances are based, e.g. the successful introduction of checkpoint inhibitors for cancer immunotherapy.

Second, and reflecting the first point, there is an immense spectrum of well-characterised models and reagents available permitting the thorough, incisive, and comprehensive obtainment of information from the experiments undertaken.

Third, there has been a development of highly effective, reproducible techniques for longitudinal monitoring, e.g. in vivo imaging, thereby reducing the numbers of animals required for parallel, staged

analysis. Such innovative techniques are also focused on animal welfare, e.g. better imaging stations requiring shorter times under anaesthesia.

NON-TECHNICAL SUMMARY

149. NF-kB and its role in cancer, inflammation and replication stress

Project duration

5 years 0 months

Project purpose

None selected

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Cancer is now the major cause of death from disease in all age groups in the United Kingdom with approximately 300,000 new cases and 150,000 deaths each year. The lifetime risk of developing cancer is currently 1:3 and this is expected to rise towards 1:2 as life expectancies increase. Research

into the onset and progression of cancer and chronic inflammatory diseases is currently being widely studied and it has been accepted that a family of proteins, called the nuclear factor-kappa B (NF-κB) family, has important roles in both.

Previous experiments from our laboratory have shown that the NF-κB family of proteins are important for the development of tumours. This is very complex, and as yet far from being fully understood. The NF-κB family of proteins are known to turn on and off genes in the cell, but we are unsure about which of these genes are turned on or off by NF- κB in cancer, or indeed in inflammation, which if is not resolved, can lead to cancer. The objective of this project is to understand the signalling events, and by this, we mean understand which components of the cell talk to and interact with one another as a result of the activation of the
NF- κB proteins, which in turn are promoting and driving the onset and development of inflammation and cancer. We hope to therefore identify new mechanisms and genes associated between NF-κB and cancer, and use these to develop new targeted treatments for the disease.

The NF-κB family of proteins have well studied roles in inflammation, however, when inflammation is not resolved, or is not controlled correctly by the cell, this can lead to cancer. We will use animal models, to determine how inflammation and cancer are inter-linked, and importantly the role of the NF-κB family of proteins here. Once again, we will assess changes in the genes NF- κB is controlling in this context.

We aim to use animal models of both cancer and inflammation alongside animals with known genetic changes to NF-κB to gain further insight into the mechanisms by which NF-κB acts during the onset and progression of cancer and inflammation. By understanding these biological processes, we hope to identify and test new therapeutics to treat these diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Improved understanding at the level of cells and molecules of how organ inflammation and cancer occurs, not only advances science but helps identify new drug targets and medicines for pre-clinical testing and drug discovery.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will only use mice in this project of work, and expect to use approximately 15000 animals over a five year period. The animals will either be bred in-house or purchased from an authorised supplier.

This programme of work requires this number of animals as a some of the colonies of mice have complex breeding requirements. For example, the mice that are genetically altered to develop blood cancer can only be successfully bred using males. This is because the females may not be well enough, or live long enough to wean their young. We therefore never use these females as breeding animals. They can be used experimentally but not mothers. Only male animals carrying this genetic mutation are used to provide future offspring carrying the mutation for both breeding (male mice) and experimental (male and female) animals. The way these mice are genetically modified to develop blood cancer, means that only one mouse in every four that will carry the correct genetic mutation causing the cancer. For every four mice we breed, only one will go on to develop blood cancer. Although some of the mice that do not carry the genetic mutation, will be used as control animals (i.e. ones carrying no mutations at all) for comparisons, or used as breeders with the male blood cancer mice mentioned above, this does
further increase the numbers we need to breed

.

Another colony which are genetically altered to express only one copy of the NF-kB regulated gene Claspin, which is needed by the cell to respond to DNA damage and stress, also require more complex breeding strategies. The females within this colony have reproductive issues, and take much longer, or fail completely, to have successful pregnancies. This is something we will investigate further as part of this programme of work, but also requires us to breed more of these animals than a standard genetically modified colony in which the animals are fertile, as many cannot reproduce, and our aim is to determine why thes animals have impaired reproductive function within these studies.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Procedures include administration of new and existing therapeutic agents, surgical interventions (removal of part of the liver to mimic liver removal in patients which is known to cause damage in people) and implantation of tumour cells. The following protocols listed on this project licence are classed as ‘moderate,’ and alongside a description of each there are adverse effects are discussed:

The breeding of genetically modified animals, within this project includes animals that develop tumours. Hence, adverse effects include tumour associated weight loss, inactivity or hunched posture.

Studies that are used to induce either short term or long term fibrosis of the liver could potentially result in liver failure, jaundice or dehydration, although this is very rare.

The adverse effects associated with the method used to chemically induce liver cancer include tumour associated weight loss, liver failure or inactivity.

The resection of a portion of the liver by surgical methods is associated with the liver adverse effects above (liver failure and jaundice) alongside post surgical pain, bleeding or wound breakdown.

The adverse effects of ageing mice or determining how a new genetic mutation affects an animal include; arthritis, poor coat conditons, overgrown teeth or fur loss.

Protocols which induce tumours either from a mouse or human cell background have the potential adverse effects of tumour associated weightloss, hunched posture or inactivity.

Studies which test the properties of how well new or existing treatments are tolerated in animals could result in a drop in an animal's blood pressure, a drop in body temperature or making an animal feel drowsy.

Altering the diet of mice can have different effects depending on what type of modifications are made. For example, a high fat diet can result in obesity and an increased susceptibily to fatty liver disease. Whereas another diet used within this project can result in gradual weightloss, over grooming and poor coat conditions.

Two further two protocols on this licence are classed as 'mild' and these include taking of a small piece of ear tissue (akin to having an ear piercing in a human) in order to make cells, or stimulating the reproductive organs of the animals to assess function. Both could be associated with transient discomfort from an injection, for example. This discomfort can be minimized by ensuring staff are well trained in handling and restraint of the animals.

Animals will be monitored daily either by highly-trained animal technicians. This includes inspecting each individual cage and the animals to ensure they have a healthy body and coat condition, normal posture and that they are active and interacting with their cage mates. Alongside, this the technicians ensure the animals have sufficient access to food, water and warm bedding materials. In addition to this, animals that are used on protocols, will be additionally monitored by members of the research group at least three times each week. This will include the assessment of bodyweight, condition, and also food and water consumption. We have shown that, in the model of blood cancer, that mice tend to reduce their food and water consumption before any other overt signs of disease are apparent. If at any point an animal is found to cause a concern outside the expected range of adverse effects, advice from the Named Animal Care and Welfare Officer and Named Vetinary Surgeon will be sought, and appropriate treatment will be given. If required, and advised the animal may be humanely killed.

Furthermore,to ensure protocols involve the least suffering we will make maximum use of all information to minimize any potential adverse events. All studies will be in accordance with the guidelines set out in Workman P et al. (2010). Guidelines for the welfare and use of animals in cancer research. Br J Cancer. 102:1555-77
.

Animals will be humanely killed at the end of protocols within this project.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Due to the availability of animals with relevant genetic make-up combined with the fact that both humans and rodents have very similar NF-κB proteins, mice are the only suitable species of animal to perform these studies.

We are accumulating large banks of frozen and paraffin embedded tissue from previous experiments. These are used wherever possible to minimise the further use of animals.
Wherever possible we will use human tissue or cells. We have ethical approval to access and use human lymphoma tumour samples that were taken, and paraffin-embedded, at time of surgical resection. This also makes it much more likely that our findings will have direct applications to help treat patients in the future.

Reduction

Explain how you will assure the use of minimum numbers of animals.

To reduce animal use we will use power analysis or search the current literature to determine the minimum number of experimental animals.

We are able to grow tumours cells from our mouse models of blood cancer in tissue culture, hence reducing the number of animals we will need to use in some further studies to assess the role of NF-κB in blood cancer. These cells can also be transplanted into multiple recipients to reduce the numbers of genetically altered mice that we need to breed.

We are also developing a novel method of tracking chemically induced liver cancer using imaging techniques which has shown to give robust results using far less animals.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our mouse model of blood cancer is widely studied in the field and are genetically altered to model human disease in the best way possible. It has been consistently shown to reflect human disease onset and progression and provide a robust, sophisticated model for our proposed project of work.

The model of chemically induced liver cancer mice we have used is known to be less severe than other reported models that produce liver cancer more rapidly but have a higher mortality rate.

Any pain relief and supportive care will be administered as required for the species and model. For example, analgesics in order to minimise pain

NON-TECHNICAL SUMMARY

150. Noninvasive Ultrasound for Therapy and Diagnosis

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overarching aims of our research project are:

1. To understand the mechanisms of how ultrasound with or without acoustically active particles (e.g., microbubbles) interacts with biological tissue.

2. To design, create, optimise, and characterise novel ultrasound technologies, acoustic particles, therapeutic agents, diagnostic agents, and procedures for the treatment and diagnosis of diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The use of ultrasound and acoustic particles in the clinic has continued to increase over the last several decades both as diagnostic and therapeutic technologies. Ultrasound applications are expanding from their traditional use for imaging tissue structure towards high frame rate (>2 kHz) imaging, imaging tissue function and other capabilities. Meanwhile, therapeutic ultrasound is experiencing an even greater revolution of capabilities. Therapeutic ultrasound has been shown to dissolve clots to treat stroke, open capillaries to enhance drug delivery and a wide range of other therapeutic bioeffects, many of which we aim to understand and control here. A UK “Report of the Independent Advisory Group on Non-ionising Radiation” (Health Protection Agency, 2008) highlighted the necessity to address (1) the knowledge gap of how ultrasound with or without acoustic particles can produce different effects and (2) how these effects can be controlled so that the desired objective can be produced while avoiding adverse effects in patients. Our aims are to identify the mechanism of these interactions, to be able to predict and therefore control the beneficial biologic effect and to be able to use this technology to the development of basic research and the treatment of human diseases.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

5000 mice.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Animals inoculated with tumourigenic compounds are likely to develop tumours. We will not allow the tumour to reach a size that affects the overall health of the animal. As the tumour grows, potential adverse effects, such as tumour ulceration and a hindrance to ambulate, will be monitored closely. If signs of ill health are noticed a Named Animal Care & Welfare Officer (NACWO) and/or Named Veterinary Surgeon (NVS) will be notified and the animal will be monitored as appropriate. Palliative care may be provided as suitable.

We will follow standard guidelines (LASA) when collecting blood samples. The amount of blood sampled will not exceed an amount that will affect the overall health of the animal. Following the collection of blood samples, the puncture site will be cleaned and monitored in a manner similar to what we experience at the hospital.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The ultrasound technology developed here aims to perform non-invasive diagnostic and therapeutic procedures on biological tissue. One of the main challenges with studying these phenomena and methods is that ultrasound interactions occur at the micron-, and nano-scale 3-dimensionally. Current 3D tissue culture models are unable to model complex and clinically relevant microenvironments.

Also, ultrasound reflects strongly to material with a high acoustic impedance mismatch, such as glass and hard plastic materials, which are commonly used for tissue culture setups. These mismatches alter pressure waveforms in tissue culture setups that may never exist in vivo. Therefore, only a higher mammalian organism can be used to reproduce many of the important 3D tissue microenvironments.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will reduce the number of animals used in our experiments by using alternative methods:

- Theory, computer simulations, and experiments on tissue-mimicking material will be extensively used prior to in vivo experiments to select, validate and optimise the biological model and the ultrasound parameters.
- Long studies using the same mouse that do not significantly increase the severity of the protocol allow for overall reduced number of animals to be used.

During the experimental design stage of the studies, we will ensure that the data obtained throughout each stage will provide as clear of a conclusion as possible while using as low a number of animals as possible.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Mice were chosen because they are the lowest animals on the evolutionary tree for which many suitable models of diseases (e.g., cancer) are available.

Subcutaneous cancer tumours will be visualised by eye and measured by callipers. Tumour size will be monitored to ensure the animals do not experience any discomfort. The sizes of tumours used under this licence are unlikely to affect the health of the animals. Cancers not observable by the naked eye will be monitored by imaging when appropriate.

Adverse effects due to the administration of therapeutic or diagnostic agents will be monitored in accordance with NCRI guidelines for the Welfare and use of animals in cancer research. LASA Good Practice Guidelines on the Administration of Substances will also be followed.

When we want to use ultrasound in a way that does not affect the biological tissue, ultrasound exposure conditions will be selected to remain within clinically defined limits. However, the purpose of many of our applications is to understand and control how ultrasound alters the biological tissue structure and function to optimise beneficial effects while minimising adverse effects. As a result, some of our investigations will use exposure conditions that will alter the tissue. The following principles will be followed in order to refine our exposure conditions:

- Reduction of the region of ultrasound exposure by careful positioning of the ultrasound transducer(s) or by focussing ultrasound to a small target region.
- Limiting exposure parameters that are not contributing to the advancement of our understanding.

Home Office

NON-TECHNICAL SUMMARY

151. Novel therapies for childhood blood cell cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The purpose of this project is to develop new treatments for blood cell cancer and other blood diseases in children. Research is urgently needed to find new cures for children whose disease cannot be treated with current chemotherapy.

A retrospective assessment of these aims will be due by 13 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The potential benefits of this work will be the development of specific treatments for childhood blood diseases, such as leukaemia, which will be better at treating the disease and will have fewer toxic side-effects.

What outputs do you think you will see at the end of this project?

Blood cell cancer still accounts for just under a third of all childhood cancer deaths. New therapies are urgently required for children who cannot be successfully treated using current methods. This project aims to identify new therapies and to test how effective they are in blood cancer experimental models. Our aims in this project are to identify and test how effective different drugs are at killing cancerous blood cells. We will use drugs that we have shown are acting specifically on cancer genes. This research will generate a substantial amount of high quality data that will be submitted for publication in international scientific journals, and communicated to scientific and clinical colleagues, in scientific conferences, and to members of the public, in outreach events. We envisage this happening within the time-frame of this PPL (5 years). Furthermore, our research involves the use of a number of laboratory techniques which we use for identifying new treatments. A likely output is therefore the development of new specialised experimental techniques that can be used in the laboratory.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Communication of the research, through publication and presentation at scientific meetings, will benefit scientists and clinicians involved in leukaemia and cancer research. This will lead to greater understanding of the disease process in children and fostering international collaboration in efforts to develop new treatments for children who do not survive current treatment. In addition to these short-term benefits, in the long-term we envisage that this research will have a direct clinical impact within 5-10 years, resulting in improved therapy for children with poor prognosis blood cancer and decreasing the

burden of conventional chemotherapy in many others. By demonstrating the anti-blood cancer cell properties of the drugs, we will be able to develop clinical trials for their use in patients. If successful, this will result in the cure of children who fail blood cancer therapy at present and diminish the long-term side-effects of chemotherapy-related toxicity. Furthermore, some of the therapies may well benefit adult blood cancer patients, whose disease is similar to those studied in this project. Adoption of novel treatments in clinical trials (5-10 years) and eventually in clinical practice (10-20 years) will benefit patients with blood cancer that is difficult to treat. The development of new specialised laboratory techniques are likely to benefit scientists and clinicians involved in blood cancer research, within the time-frame of this project (5-10 years).

How will you maximise the outputs of your work?

We will ensure that the knowledge gained from this project is shared with the scientific and clinical community by publicising it as publications in international scientific journals and presentations at national and international scientific meetings and scientific and clinical workshops. The latter will also be particularly important in sharing experience of negative data, since this will inform future experiments and experiments on new treatments. In the event that negative data would potentially challenge current or future directions of research, we will aim to publish these in international scientific journals.

Species and numbers of animals expected to be used

- Mice: 5500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically mice will be transplanted with mouse and human blood cancer cells or normal blood cells.

Normal blood development or cancer will be analysed by sampling peripheral blood or through using imaging techniques that are non-invasive. No mouse will be bled more frequently than 4 times in any 28 day period and no more than 10 times in total. For imaging analysis, mice will be anaesthetised for a maximum of 2 hours and imaged for no more than 30 minutes

Mice may be treated with chemical substances and drugs to interfere with the development of blood cancer.

Mice will be kept for no more than 1 year following transplantation.

All animals will be killed by a Schedule 1 method at the end of the experiment.

In some cases, it may be necessary to house mice individually, where other mice in the cage have been sacrificed due to disease progression. This will be done in order to evaluate disease progression in all mice in a given group and/or evaluate the effectiveness of novel drugs. The duration of individual housing will be no longer than one year, and in most cases between 1-3 months.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some mice will show signs of clinical illness, resulting from development of blood cancer or the failure of normal blood cell development. Such clinical symptoms may be weight loss (up to 20%), abnormal coat, segmentation of vertebral column, readily palpable dorsal pelvic bones and subdued behaviour patterns. This will mostly be a result of blood cancer progression in transplantation recipients. Any animals showing one of these symptoms will be monitored daily and if there is no improvement after one week, they will either be sacrificed or the named veterinary surgeon will be consulted. Any animals showing more than one of these symptoms will be monitored daily and if there are no signs of improvement after two days, they will either be sacrificed by a schedule 1 method or the named veterinary surgeon will be consulted. In a small number of cases, some mice may die without showing any prior clinical adverse symptoms, despite close monitoring. Individual housing may result in stress and abnormal behaviour. This will be minimized by environmental enrichment and limiting the duration of individual housing to that essential for the experiment. Where possible, for example female mice, a companion untreated mouse may be added to the cage for company.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect that 10-40% of mice in this project to experience moderate clinical symptoms, and less than 2% to experience severe symptoms. We expect approximately 2-5% of mice will be individually housed at some point. The duration of such housing for most of these mice (>90%) mice will be 1-2 weeks, 1-3 months for <10%, and rarely for up to a year (<2%).

What will happen to the animals at the end of the study?

- Used in other projects

A retrospective assessment of these predicted harms will be due by 13 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to use mouse models in this project in order to accurately examine the anti-blood cancer efficacy of interfering with particular cellular pathways in the body of an animal. Furthermore, we require mice in order to determine whether the new treatments we are testing can eliminate blood cancer cells without killing normal blood cells.

What was your strategy for searching for non-animal alternatives?

We plan to make use of extensive laboratory models to investigate which genes and pathways are essential for blood cancer cells to survive, but are not required for normal blood cells to develop. This will involve using molecular tools to target particular genes and drugs to block specific cellular pathways. These experiments will be done in the laboratory. We will make use of recently developed ways of growing blood cancer cells in the laboratory that will enable us to test different new ways of blocking the growth of blood cancer cells and killing them. Only those treatments that are successful in the laboratory will be taken further for testing in mice.

Why were they not suitable?

Although these laboratory experiments are important and complement research in mice, they are limited in how closely they can reproduce disease occurring in patients and are not sufficient by themselves to justify starting clinical trials in children diagnosed with blood cancer. In order to be sure that our experiments are likely to succeed in human patients, we need to study how blood cancer cells respond to new treatments we develop in an organism, in this case the transplanted mouse. This is because the treatment may be less effective in an organism, for example because the drug does not last enough in the blood, or because the bone marrow cells protect the blood cancer cells from the drug.

A retrospective assessment of replacement will be due by 13 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the numbers of mice we will use in this project using mathematical calculations and experience from previous animal experiments. These numbers will be kept to a minimum while ensuring that the experiments are able to give us reliable information and results.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The number of mice used in this project will be kept to a minimum. Experiments in mice will only be performed if there is good evidence from laboratory experiments that the work in mice is likely to succeed. For example, new treatments will only be tested in mice once they have been shown to be effective at killing blood cancer cells in the laboratory. Wherever possible, we will use new techniques to minimize the numbers of mice used. For example, we routinely use a method to analyse the extent of blood cancer growth in mice that is based upon using a special camera that can detect the cancer cells inside the mice. The use of this camera allows us to determine which new treatment is effective at blocking the growth of cancer cells without having to sacrifice the mouse, and this technique will therefore reduce the number of mice necessary to identify an effective new treatment.

What other measures apart from good experimental design will you use to minimise numbers?

The estimated numbers will be reviewed following completion of particular experiments examining how effective particular treatments are at blocking blood cancer growth. If the treatments are very effective, we will need fewer mice in future experiments using these treatments, and new mathematical calculations will be used to determine how many mice we can reduce in these. Pilot studies will be used to confirm that appropriate amounts of drugs are being used in the treatment of blood cancers. This will optimize experiments designed to test how effective these drugs are.

A retrospective assessment of reduction will be due by 13 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project will only use mice as the experimental animal. These are the most suitable animal to use based on a large amount of evidence from previous experiments by scientists all over the world and our current knowledge regarding blood development and blood diseases in mice, which are similar to those in human beings in many ways. Significantly, a recent study has shown that mice transplanted with human blood cancer cells respond in a similar way to treatments used in people suffering from the same types of blood cancer. We will use the most sensitive and least invasive method to examine disease progression in experimental mice wherever possible. This will reduce distress and suffering, as well as provide more accurate information and allow us to end these experiments at earlier time-points, reducing the suffering and distress experienced by the mice used.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Normal blood cell development and blood cancer has been studied extensively in mice and mice represent the most accurate and least sentient species for this research. Adult mice and necessary to study these processes, because of the time-scales involved.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will examine and monitor mice regularly. Any mice showing any clinical signs of being unwell will be closely monitored by daily inspection. We will seek to use the most sensitive and least invasive method to examine disease progression. Any mice showing unacceptable signs of discomfort or disease will be humanely killed. We will keep up to date with new developments in animal experimentation in the UK and abroad that discover new ways of improving our experiments and minimising suffering of experimental animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The experiments will be designed, in accordance with ARRIVE guidelines, to detect differences between control and experimental groups in measurements of differences in blood cancer growth and normal blood cell development. For all experimental procedures, guidelines as published by Workman et al (Workman, P., et al., Guidelines for the welfare and use of animals in cancer research. British Journal of Cancer, 2010. 102: p. 1555-1577) and the LASA Good Practice Guidelines for Administration of Substances (October 1998) will be followed.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Attending external conferences and seminars on animal welfare and consulting the NC3Rs website - https://www.nc3rs.org.uk/

Explain the choice ofspecies and the related life stages

We will use mice in this project. Normal blood cell development and blood cancer has been studied in mice extensively and has been shown to be very similar to that in human beings. The information obtained by studying these biological processes in mice is therefore highly relevant to human blood development and disease, including blood cancer. Mice are required for certain experiments, because when these are performed in the laboratory, they do not reflect how cells behave inside the body. Mice can be used for these studies. For many experiments in this project we will use genetically altered (immunodeficient) mouse strains that can be used as hosts for the transplantation of human cells. This allows an even closer approximation to how normal blood development and blood cancer progression will be affected by future new treatments in patients.

Mice will be bred so that they are suitable for transplantation with normal or blood cancer cells, and exposed to new and existing treatments. Apart from breeding, our experiments will be limited to adult mice. Adult mice are the most appropriate stage for these experiments, which have been standardized previously in our laboratory.

A retrospective assessment of refinement will be due by 13 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

152. Nutrition of poultry

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims to establish nutritional strategies that promote growth, production and gut health in poultry, while reducing competition for resources for food and feed. To reduce nutrient excretion in the environment and its negative impacts on animal production, feedstuff's (including unconventional feedstuffs) will be tested for an accurate estimation of energy and nutrient utilisation. Non antibiotic feed additives will also be tested using different dietary interventions to address global food safety and public health issues linked with antibiotic resistance and ability of poultry species to resist infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The knowledge attained from this project will be used by poultry feed additive and feed manufacturing companies to alter the formulation of feed to meet the animal requirements and reduce nutrient excretion in the environment (for example the use of phytase to reduce phosphorus excretion to water bodies or in the manure). Feed costs account for nearly 70-80% of the total costs in poultry production. In many cases, this may be out of reach for smallholder poultry farmers who lack economies of scale and access to credit. Therefore, identifying the energy and nutrient profile of feedstuffs (conventional and unconventional) will help in long term to provide alternative feed resources and reduce competition between man and animal for food resources.

This work is of special interest to researchers (worldwide), food retail industry and poultry producers as it will increase our knowledge on the host response to diseases and will help to develop alternatives to antimicrobial growth promoters (feed additives) to reduce carriage of food borne diseases and identify interventions that can influence the ability of poultry species to resist infection and production of safe/healthy poultry products for human consumption.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Species to use are broilers and turkey. Nutrition and efficacy studies: 86,000 (13,440 layers, 63,560 broilers and 9,000 turkeys); Evaluation of feed ingredients – precision feeding: 900 (450 broilers or broiler breeder and 450 adult cockerels); Nutritional evaluation of diets: 11,000 (8,840 broilers and 2,160 turkeys); Standardised and true digestibility studies – 5,000 (4000 broilers, 1000 turkeys), Nutrition and gut health studies – 25,000 (20,000 broilers and 5,000 turkeys).

The calculation of approximate number of animals required in each protocol is based on the new larger poultry holding capacity of the institute and type of studies that may be required over next 5 years. The calculation also takes into account the number of studies conducted and the animals used in each study over last 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

In feeding studies, some of the birds in the project will receive diets that are not meeting nutrient requirement and such birds will be expected to have a 10 to 15% of body weight loss compared to aged matched control group.

In precision feeding, if any animal showed sign of resistance during gavaging the procedure will be immediately stopped for that specific bird and the amount yet to be fed will be noted and discarded.

In case of laying hens, if feather pecking becomes a problem we will consider beak trimming (if not already beak trimmed or badly trimmed). Veterinary advice will be sought if any bird showed gentle pecking injury. To prevent further pecking affected birds will be treated with anti-peck spray. If any bird shows signs of aggressive feather pecking (forceful pecking of featherless skin followed by bleeding) than appropriate action will be taken to minimise the suffering of the animal and if recovery is not expected within short time frame (24-48 hours) the animal will be culled. If 2 or more birds, or 10%, whichever is greater, have to be culled or die due to injurious pecking, then that entire replicate will be culled.

Any bird developing severe swelling, ulcers or scabs on footpad or hock lesions will be humanly killed.

In case of blood sampling, If any animal develops adverse effects, it will culled.

In establishing the standardised and true digestibility for nitrogen, amino acids and minerals using purified and semi-purified diets, some of the birds in the experiment will be provided with diets with very little or even no protein or mineral for a very short period, not exceeding 7 days. Any bird that exceeds 20% of weight loss compared to the starting weight will be humanly culled.

In case of *Campylobacter* challenge studies, birds will be screened for Campylobacter before recruitment onto the study and the trial will not commence if birds are found positive for Campylobacter. Birds exposed to *Emieria spp.* that develop clinical disease symptoms (high percentage of visibly sick birds, severe bloody diarrhoea etc.) will be removed from the experiment and culled . if more than 30% of birds in pen are unintentionally becoming clinical, then whole pen will be culled i.e 3 birds in pen of typical 10).

At the end of the experiments, some of the birds will be euthanised using humane methods. Some of the procedures do not require euthanasia of birds as part of the experiment and such birds may be rehomed to backyard flocks.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Studies that require effect of treatments on growth can’t be done in non-animal substitute. Digestibility studies are usually preceded by in vitro proof of concepts but ultimately because the feed additives will be incorporated to feed for actual animals, it is a requirement that such products are fed to animals.

A minimum of 3 independent in vivo studies showing significant effects are required by European Foods Standard Agency (EFSA) to demonstrate efficacy of the feed additive for the relevant target species/categories (Regulations (EC) No 429/2008.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The number of replications and animal per replications are determined based on statistical analyses and previous experience. Each experiment is individually set up to maximise ability to test for treatment effect combined with every effort to use the minimum number of animals. Experimental protocols are reviewed before each experiment to ensure that animals are not used unnecessarily. In addition, there are monitoring exercises after each experiment to see what lessons are learnt. The 3Rs is part of the monitoring exercises. Part of the review of the experiment include the input of expert statisticians.

Sample size calculations will be based on the magnitude of the the effect that the study is designed to test, its variability, an adequate statistical power and the confidence level as required by European Food Standard Authority (EFSA) for assessment of the efficacy of feed additives (EFSA Journal 2018: https://efsa.onlinelibrary.wiley.com/doi/epdf/10.2903/j.efsa.2018.5274) or safety of feed additives for target species (EFSA Journal 2017: https://efsa.onlinelibrary.wiley.com/doi/epdf/10.2903/j.efsa.2017.5021)

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The objective of this project is to provide information that is relevant to the poultry industry, and hence poultry species are the choice of animals for the project. There are instances where nutritional effects studied are applicable across species (i.e. what is studied in broilers may be applicable to turkey) and in such cases, studies are not repeated for all the poultry species. Most of the protocols in this project are mild in severity level except protocol 4 & 5 which are moderate. Birds used in this project will be monitored on a daily basis to ensure that bird’s well-being is not compromised. There is also on-site specialist (avian) veterinary support who helps ensure birds well-being is maintained. In disease challenge studies, only use sub-clinical infections models are used. All studies will be assesses pre and post conduct by the institute's AWERB whose primary function is to assess the ethical and scientific validity of the study proposed and , post study, the efficacy of the study and lessons learned. The evaluation of the study post conduct allows us to further refine our procedures from time to time.

NON-TECHNICAL SUMMARY

153. Opioid receptors in depression and anxiety

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Depression and related illnesses affect 1 in 6 people in the UK. Depression is the leading cause of disability worldwide, and is a major contributor to the overall global burden of disease. Almost twice as many women as men are diagnosed with depression. Stress is a major risk factor for developing depression. The medicines available for treating depression are limited because less than half of all

depressed people get completely well after taking them. These medicines are also slow to work (weeks to months), may have side effects and you can't just stop taking them suddenly as that can make the symptoms worse. We need new and better medicines for depression.

The aim of this project is to learn more about how opioid receptors in the brain may be involved in the response to stress and how we can use this information to design new medicines for depression. Opioids are chemicals found in brain cells that signal to other brain cells using different types of opioid receptor. The opioids are named endorphins, enkephalins and dynorphins which work through switching on mu-opioid receptors, delta-opioid receptors and kappa-opioid receptors, respectively. We're investigating how these different opioid receptors contribute to the brain's response to stress and how we can target them to make new antidepressant medicines
.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Understanding how the different opioids and their receptors help the brain respond to stress will allow us to design new medicines for depression. Using this knowledge we can design opioid medicines that target specific receptors and these may, in the long term, be useful in the treatment of depression.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We estimate that we will use 6,450 animals over the lifetime of the project (5 years): 1000 genetically altered mice, 5300 standard laboratory mice and 150 laboratory rats. Both adult and juvenile, male and female animals will be used.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Genetically altered mice will be used in this project (15% of animals used). Being able to interfere with opioid receptor signalling genetically will help us define the roles of individual receptors. The genetic alterations used for this project do not have a big effect on the mouse. For example, they don't change the way a mouse looks or moves or feeds so can be said to be 'not harmful'.

Around 7% of animals will be humanely killed, under general anaesthesia, to provide brain tissue for analysis after death. This results in no more harm than when a vet puts down an animal.
Another 7% of animals will undergo these same procedures but will have injections of drugs to interfere with the opioid receptor signalling pathway so we can identify the involvement of specific signalling molecules. Drugs will be used at doses that produce the desired effect, have no toxicity and injected in small volumes by trained and competent experimenters. Under these circumstances, the harms are expected to be minor stress and discomfort from the injections and the animals show a rapid return to normal behaviour.

Around 31% of animals will be used to investigate how the brain responds to stress. Chronic stress is a risk factor for the development of depression. In order to understand the role of opioids in response to stress, we need to study the adaptations to repeated stress. The stress procedure in mice has to be one that can produce significant physiological and behavioural change consistently. Repeated stress is likely to cause moderate impairment of the well-being of the animals. We will develop a paradigm that achieves our objectives while limiting the harms to the mice. Limits are placed on the duration, frequency and intensity of the stress to reduce the harms to animals. Monitoring of behaviour and appearance (body weight, coat appearance, movement, posture) on a daily basis ensures animal welfare is maintained and humane endpoints are in place.

The behavioural adaptation to repeated stress will be investigated using non-invasive mouse behaviours in a range of different tasks. Using multiple tests of different dimensions of behaviour increase confidence in the interpretation of the data. Typically, tests involve exploration of a novel environment such as a maze or self-grooming in response to sugar sprayed onto their coats. These behavioural tests cause only minor and transient discomfort induced by the test itself and also handling or drug injection. Animals are observed throughout the tasks and monitored on return to the homecage to ensure there is normal homecage behaviour. Limits are placed on the duration and frequency of testing to reduce the harms to the animals. However, when coupled with repeated stress procedures, the cumulative experience of each individual step is likely to cause moderate impairment of well-being.

Testing new potential opioid medicines in a mouse for the first time (4% of animals used) can cause unexpected effects and, very rarely, death. Before testing in a mouse, we do experiments with the new compound using cultured cells and isolated tissues to learn as much about the dosing and likely effects of the medicine before we use it in a mouse. When we test for the first time, we use only two mice and monitor their behaviour – posture, walking, coat state, breathing - carefully using a score sheet before proceeding to use further animals. If animals are showing abnormal behaviours they will be killed humanely and doses lowered before proceeding to test two further animals. We also need to demonstrate that the new opioid compound actually targets the opioid receptors in the predicted way (4% of animals used). This can be done by taking advantage of opioid pain-relief properties to assess the drug profile. Mice will have their tail tip dipped in warm water and experience mild and transient pain that they can escape from. This helps us work out how much of the new compound to use and what effects it is likely to have. Limits are placed on the intensity, duration and frequency of testing to reduce harms. We then use the fewest animals possible to find the right amount of the new compound to establish the potential antidepressant- and/or anxiolytic-like properties in a variety of non-invasive behavioural tasks (31% of animals).
Using multiple tests of different dimensions of behaviour increase confidence in the interpretation of the data.Typically, tests involve exploration of a novel environment such as a maze or self-grooming in

response to sugar sprayed onto their coats. Additionally, the forced swim test is used. In this test, mice are gently placed in a large cylinder of water for 6 minutes. Mice engage in active escape-related behaviours and periods of immobility. Mice are naturally bouyant and 'immobiliy' is a floating behaviour where minimal effort is used to keep their heads above water. The time spent immobile is reduced by antidepressant drug treatments and can therefore be used as a measure of antidepressant potential for new compounds. These behavioural tests cause only minor and transient discomfort induced by the test itself and also handling or drug injection. Animals are observed throughout the tasks and monitored on return to the homecage to ensure there is normal homecage behaviour. Limits are placed on the duration and frequency of testing to reduce the harms to the animals.

At the end of the experiments all animals are killed humanely. Brain tissues may then be removed for further investigation e.g. to see whether there are changes in gene expression in response to stress or drug treatment.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The way the brain responds to stress involves a complex network of different brain regions that can only be studied in a whole animal. Non-mammalian species do not have the same brain networks as mammals and so cannot be used. Human brain imaging studies could be used to study individual opioid receptors but there are no tools to be able to do this at present. New technologies using human stem cells to create ‘organ-on-a-chip’ and 3D cell cultures or ‘mini-brains’ are emerging but do not yet produce sufficient network connectivity to mimic an adult brain. It is also not possible to trial new potential opioid medicines in humans without first investigating their effects in an animal. Non-animal alternatives like cell cultures and isolated tissues are a vital part of this project. For new opioid compounds we can work out the likely effects and how much we need of these compounds before testing in animals.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The minimum number of animals is determined using statistical methods. We have extensive experience with these techniques to ensure the robustness of statistical analysis.

Good experimental design to reduce variability is essential to maximise the data obtained from the minimum number of animals.
Behavioural measures are carefully controlled including variables such as age, sex and strain; husbandry and handling; laboratory environment (light, noise) which also limits the stress to the animals.

We also try to get multiple different types of data from each mouse where this does not increase the harms. For example, we can study behaviour in the mouse, collect blood samples to tell us about

hormonal stress responses and then, at the end of the experiment, take brain tissues to look at gene expression.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Rodents are the lowest mammalian species that are appropriate for this work. There is extensive scientific literature on the brain circuits, nerve cell function and opioid receptors in mice and rats. Some studies, where urine is to be collected, are best performed in rats to obtain sufficient quantities of urine to have robust and reliable data.

The majority of procedures carried out in this project cause only transient and minor discomfort to the animals. Limits are placed on the duration, intensity and frequency of procedures to reduce the potential harms to the animals. Behavioural tests used are non-invasive. Typically, tests involve exploration of a novel environment such as a maze or self-grooming in response to sugar sprayed onto their coats. These behavioural tests cause only minor and transient discomfort induced by the test itself and also handling or drug injection. The impact of these is reduced by good technique, for example, handling by gentle cupping of mice and competent injection technique.
Animals are observed throughout the tasks and monitored on return to the homecage to ensure there is a rapid return to normal homecage behaviour. Limits are placed on the duration and frequency of testing to reduce the harms to the animals.

Repeated stress is likely to cause moderate impairment of the well-being of the animals. We will use a minimally effective paradigm that achieves our scientific objectives while limiting the harms to the mice. Limits are placed on the duration, frequency and intensity of the stress to reduce the harms to animals. Repeated stress can cause loss of body weight and hormonal stress responses. The harms to the animals are reduced by careful daily monitoring of home cage behaviours, and absolute limits set on the amount of weight loss, to define humane endpoints.

For blood sampling, we use a refined procedure that involves gentle cupping as a restraint, no anaesthesia and no needles where blood can be wasted. Limits are placed on the frequency and volume of blood that can be collected to avoid a significant drop in total blood volume that could affect blood pressure and circulation to the body. Repeated sampling from the same mouse within these limits minimizes the number of animals used overall, and improves the scientific variability of the data, as each mouse can be its own control.

For new opioid compounds, a small number of animals are used to establish a safe and effective dose

before screening for antidepressant or anxiolytic properties in a range of behavioural tasks. Data obtained from cell cultures and isolated tissues informs the choice of initial dosing and animals are carefully monitored to minimise harms
.

NON-TECHNICAL SUMMARY

154. Opportunistic pathogens

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall scientific objectives of the project are to determine the reasons for which opportunistic bacteria and fungi are able to cause infections in patients with chronic respiratory disease or immunosuppression/deficiency. For instance, there are around 10 million individuals globally with respiratoiry forms of aspergillosis. The main individuals at risk are those with chronic lung diseases

such as asthma or smoking-related lung damage, as well as individuals with weakened immune systems due to cancer treatments or because they have had organ transplants. This will enable identification of the primary deficiencies in patient immunity, and which immune cells are primarily affected. The altered immune response may also lead to the emergence of bacterial or fungal behaviours that enable infection to occur when host immune responses are suppressed. The development of new clinically-relevant animal models of infection will further enable the identification of the functional basis for any such factors. This will enable the development of novel diagnostic tests to identify at risk patient groups and enable the development of novel treatment to boost the immune system response when infection occurs

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The research seeks to understand the key factors within both the pathogen and the patients immune system that lead to an infection occuring. This will allow us to develop new diagnostic tests to identify that people who are at risk of or likely to have a serious infection. We will also seek to develop new targeted treatments of the immune system or new antibiotics that can improive the chances that a person will survive the infection or get rid of the infection.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Approximately 9000 mice (maximum) and approximately 10000 (maximum) zebrafish will be used over a 5 year period.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

We are breeding adult zebrafish to generate larvae (juvenile forms) to use in our research. Occasionally adults need to be humanely killed due to old age or illness. Where zebrafish adults are used for infection studies, the effects are moderate and at the end of the study they will be humanely killed. Expected adverse effects include: abnormal swimming behaviour, separation from the shoal, abnormal scale position, abdominal swelling, abnormal skin outgrowth. Fish will be regularly monitored for such effects and killed using a humane method if such effects are seen.

The mice may receive immunosuppressive drugs and will be infected with either bacteria or fungi. This will lead to establishment of infections, which may cause the animals to develop signs of infection. This may lead to increased breathing rate, fevers or hunched posture. This is not expected for the majority of infections. The level of severity is categorised as moderate. After infection animals may also undergo administration of pharmacological agents, which may cause the animals to become distressed. The level of severity is categorised as moderate. At the end of the experiments the animals will be humanely killed. Suffering will be minimised as all infections will be undertaken under general anaesthesia and in addition 20% weight loss has been established as a surrogate marker for death previously (and which point mice will be humanely killed).

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The immune response to an infection is controlled and influenced by multiple factors, including

how aggressive the microbe is and the the infected persons genetic make-up. Teasing out the multiple factors that contribute to infection in humans is extremely complex as many of the variables remain unknown.

Using animal models to study infection, the researcher can focus on individual variables during the infection process in order to establish their relative importance.

We use zebrafish in preference to mice for most experiments because

•They develop fast

•They are vertebrates and have a fully developed immune system (larvae have innate immunity only, adults can be used to study role of adaptive immunity)

•The eggs / larvae are clear and easily observed and manipulated at the microscope.

Where we use mice, this is generally to enable us to study the complicated immune responses that occur in the lung, as zebrafish do not have lungs. In addition, there are some parts of the immune system in humans that are not well represented in fish but are present in mice. Also for some of our therapeutic and diagnostic development murine experiementation is a requirement for subsequent use in humans. Therefore, the overall approach will be to use zebrafish for most experiments but only use mice where necessary because zebrafish lack the relevant biology, or when confirmation of findings is required in a mammalian system. I envisage this will lead to a substantial reduction in mouse usage.

Reduction

Explain how you will assure the use of minimum numbers of animals.

All experiments will be designed so that the minimum number of animals will be used. REDACTED This way the need for repeat experiments or increased animal numbers is minimised. Breeding strategies are carried out by qualified personnel and aimed to avoid unnecessary animal generation (animal surplus). In addition, we are developing novel imaging-based models of infection that will enable further reduction of the number of animals used by allowing longitudinal studies.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Zebrafish will be used where possible because they are easily genetically modified, fast breeders and the larvae are small and transparent which make it possible to follow individual cells and their behaviour using a microscope. We will mostly use larvae, where suffering is reduced compared to adults or mice as they are less able to sense pain.

Animal suffering will be minimised by regular checking of the animals for relevant symptoms that constitute the end point of the experiment. All breeding and husbandry procedures will be performed by trained staff, and the fish monitored regularly.

Mouse models of infection offer several distinct advantages for studying infections, including ease of use, reproducibility and availability of immunosuppression regimes which mimic patient factors of human disease. Additionally, mouse models offer the opportunity for a thorough investigation of immune responses and are amenable to novel diagnostics, which falls beyond the scope of this application but will become important in our future research and will facilitate standardisation across the present research community within the context of important novel findings. Suffering will be minimised as all infections will be undertaken under anaesthesia and in addition 20% weight loss has been established as a surrogate marker for death previously (and which point mice will be humanely killed).

NON-TECHNICAL SUMMARY

155. Organ dysfunction and survivorship following acute illness

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult
Rats	juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall objectives of the project are to (i) examine the response to disease processes encountered in critically ill patients, (ii) assess the impact of potential therapies and (iii) develop novel monitors/diagnostics.

A retrospective assessment of these aims will be due by 06 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Organ dysfunction following critical illness constitutes a continued major healthcare burden affecting both quality and duration of life. This work will assist in better understanding of the underlying biology of shock states, where the body cannot deliver enough oxygen to the tissues of vital organs, or the organs fail to use the oxygen appropriately. We place a particular emphasis on major body (metabolic, immune, circulatory, and hormonal) systems, their responses to specific insults, between-system interactions, and responses to therapeutic interventions. We will continue to explore similarities and differences in response between diverse acute illnesses, for example, haemorrhage, sepsis (a life-threatening condition that arises when the body’s response to infection injures its own tissues), heart attack and stroke. These studies will also be used to evaluate novel diagnostics, monitoring technologies, biomarkers (chemical warning signs in the bloodstream), and novel therapies that may either offer protection or enhance recovery.

What outputs do you think you will see at the end of this project?

We propose to continue our current line of investigation into the effects of shock and sepsis in critical illness to better understand how the progression to organ failure occurs. We will also further our knowledge of disease processes by exploring common biological mechanisms between shock, sepsis and organ-specific medical conditions such as heart attack and stroke. Armed with this knowledge, we

will attempt to repurpose existing drugs and develop new drugs that can potentially lead to protection, prevention or faster resolution of organ failure, and continue to develop new monitoring technologies and devices that can improve the care of patients in intensive care. We will present our research at national and international conferences and publish our work in high-impact journals. This aims to inform other clinicians and researchers of our progress, and often to enables a collaborative approach to achieving our common goals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Immediate scientific benefits likely to be gained from this programme of work (1+ years)

This work will assist in better understanding of the underlying biology of shock states, with particular emphasis on circulatory, immune and metabolic abnormalities seen in these conditions. We will explore common mechanisms in diverse conditions such as shock, sepsis, heart attack and stroke. These studies will also prove highly useful in the evaluation of novel diagnostics, including new monitoring technologies and biomarkers (chemical warning signs in the blood stream), and novel therapies that may either offer protection in shock states, or enhance recovery.

Longer term benefits related to how human patients may eventually benefit (3+ years)

Better appreciation of the processes underlying shock and acute critical illness states, and assessment of the responses to different therapies, will facilitate the design of clinical trials and the development of therapies and monitoring technologies that can improve patient outcomes. This could have significant ramifications for both improving quality and duration of life, and reducing the high financial cost of caring for these very sick patients.

How will you maximise the outputs of your work?

Over the last 20 years we have collaborated with >30 groups of diverse researchers from universities, biotechnology and pharmaceutical companies. This combined knowledge often led to scientific progress that neither us nor our collaborators could have achieved alone. We aim to continue this collaborative approach over the next 5 years with a view to better understanding disease processes and developing products that can improve patient outcomes. We inform others of our progress by presenting our work at national and international conferences, and writing up our results for publication in high impact journals. We will also aim to better inform the public and other researchers of our work by starting an online blog/twitter account. This could be very useful for disseminating knowledge of unsuccessful research (e.g. a novel therapy that did not work) that would otherwise be difficult to publish in high impact journals.

Species and numbers of animals expected to be used

Mice: 350
Rats: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In all of our protocols we have an optional pre-treatment phase where we may give drugs or alternative diets to see if they improve the response to a disease condition. Thereafter, we run three distinct protocols.

1) Short-term anaesthetised model. These experiments are performed over one day under terminal anaesthesia. This allows us to perform more complex surgical procedures than we could if the animal was to recover. This is important to be able to test specific organs to better understand how disease processes and responses to treatment(s) occur in different parts of the body, and how they interact with one another. We induce conditions similar to that encountered in an intensive care or emergency medicine setting, such as blood loss, heart attack and bacterial infection. The animals are euthanised at the end of the experiment with an anaesthetic overdose and do not wake up.

2) Long-term acute illness models (with or without metabolic monitoring). These are recovery experiments that we perform over 1-3 days, and under exceptional circumstances, up to 6 weeks. Typically, we perform a surgical procedure to insert special tubes into an artery and a vein. This allows us to be able to provide standard care that would be encountered on an intensive care unit, such as delivery of fluids and drugs, and blood pressure monitoring. These tubes are connected to a harness that, on recovery from anaesthesia, allows the animal unimpeded movement around its cage with free access to food, water, bedding and toys that enrich the environment. Sometimes we place the animals into 'metabolic' cages that allow us to measure their whole-body oxygen consumption. We typically induce a septic condition by administration of bacteria into the abdomen to model abdominal sepsis, a common condition in intensive care units. We frequently perform an echocardiogram after 6 hours (under brief anaesthesia) to assess the function of the heart, and this allows us to predict the severity of the disease course. We visually assess the animals at least 4 times a day and document their severity using our Clinical Scoring System. We monitor the animals more frequently in those that are predicted to be sicker. We sometimes give different drugs or fluids to assess their impact on the disease course. At pre-specified timepoints, usually 6 or 24 hours, the animals are re-anaesthetised. We then take blood and tissues from different organs for further study. The animals are euthanised at the end of the experiment with an anaesthetic overdose.

3) Survivorship model. These are recovery experiments performed over 14 days and exceptionally up to 7 weeks. Typically, a lower quantity of bacteria, fungus or inflammatory product is injected into the abdomen under anaesthesia to induce a less-severe disease course. The animals recover and are tested using methods to assess their survivorship, or quality of life. For example, this could include an assessment of their exercise capacity using a treadmill to see how well the heart and circulation can perform. It could also include tests to assess brain function such as interest in a new toy or exploratory behaviour in a new environment. At pre-specified timepoints, usually 14 days, the animals are re-

anaesthetised. We then take blood and tissues from different organs for further study. The animals are euthanised at the end of the experiment with an anaesthetic overdose.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Adverse effects during the pre-treatment phases of experiments (e.g. drug administration) are not generally anticipated. Pain relief is given to animals recovering from operations. Animals are always observed until full recovery from anaesthesia, and regularly monitored throughout the day and early evening. Our considerable experience with these experiments reveals no clear evidence of surgically related infection or other complications. Following the administration of e.g. bacteria, animals may show characteristic ‘shock’ symptoms within a few hours. These are documented regularly (minimum 4 times daily) with clear end points offered by the Clinical Scoring System that we use. Any animal that is deemed to be suffering unduly is promptly culled. As noted above, we also use biological measurements (e.g. heart rate) to predict outcomes. Those predicted to be sicker are monitored more closely and additional support provided (e.g. mashed food, extra bedding, pain relief) as needed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Our protocols have ‘moderate’ and ‘severe’ severity limits. The majority of experiments (>86%) will fall under the moderate category where severity limits are strictly imposed using our scoring system. A limited number of experiments (14%) will be performed under a severe severity limit although some of these will be controls (and are therefore unlikely to show a severe phenotype). The severe severity limit experiments are performed exclusively in rats for which we have developed a Clinical Scoring system to accurately monitor their health status, and act upon this accordingly. In human patients, the effectiveness of a treatment for a critical illness is measured by improved survival. Although we generally aim to terminate our studies at pre-specified times, we feel there is an important place for a protocol to provide firm verification of benefit. At experiment end all animals are culled humanely.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 06 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complexity of sepsis and other critical illnesses, involving multiple biological pathways (e.g. heart and circulation, immune and hormonal systems, and metabolism) means that we need to use whole animals to see the 'big picture'. This work will both complement and enhance concurrent studies on patients where the inability to sample vital organs such as liver, gut and kidney means we need to use comparable animal models to further our understanding of these conditions. Furthermore, potential new therapies need to be assessed in whole animal models to make sure they are safe and that they work before testing them in patients.

What was your strategy for searching for non-animal alternatives?

Where possible, we use cell cultures to address specific biological questions. In the future, we will also consider technologies such as "organ-on-a-chip" but they are still in their relative infancy.

Why were they not suitable?

Although some other researchers claim to have translated organ functions onto chips, this technology remains in its infancy. As such, they cannot currently replicate the complexity of a whole-body system, how organs interact in health and disease, and how they respond to treatments.

A retrospective assessment of replacement will be due by 06 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Each group of animals that receives an insult such as an infection, we typically study 6-8 animals within that group. Our previous work indicates this is usually sufficient to show statistically significant differences compared to controls. The limited number of survival studies that we perform usually requires group sizes of 12-18 individuals. This is required to demonstrate statistically significant differences between groups in terms of time to survival or, more usually, numbers surviving to a fixed

timepoint. We use power calculations for our survival studies, where we estimate the sample size we need using an online calculator.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We match in terms of age, weight and sex to minimise variation in our studies. We also perform control studies on the same day to minimise environmental variation. Our controls are as closely matched to the study group as we can make them. For example, if a new therapy is being assessed, the control animals will receive the insult (e.g. infection), an equivalent standard-of-care protocol (e.g. fluid resuscitation), but not the treatment under study. Where possible we also aim to combine groups. For example, if we are assessing more than one therapy or intervention at the same time, we would use only one control group, thus reducing the total number of animals we would otherwise need to use. We have statisticians based in our lab who help us with our experimental design.

What other measures apart from good experimental design will you use to minimise numbers?

At the end of all of our experiments, we take blood and tissues so that we can gain more information and make maximum use of each animal studied. We often combine non-treated tissue or blood samples which can be shared out. When we do survival studies we may include an interim analysis to see if a treatment looks like it may be working. If the interim result shows no difference in the treatment, or if it appears harmful, we would terminate the study early to prevent further animals being unnecessarily used.

A retrospective assessment of reduction will be due by 06 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Though rodent models do not exactly mimic human pathophysiology, the same intrinsic pathways exist. In human critical illnesses, continual monitoring and support of multiple organs are necessary to improve survival. In order to study the biology of organ failure in animal models, it is likewise usually necessary to monitor the animals and their organ function frequently, and to support them. This results

in models that are complex but more closely mimic a critically ill patient in an intensive care unit setting. Thus, the effects of novel therapies in our models are more likely to be relevant to the human condition.

The long-term awake animals do not appear to suffer unduly, either as a consequence of surgery and instrumentation (they are usually ambulatory and eating/drinking within 30 minutes of discontinuation of anaesthesia). Following the septic insult, the animals are usually not obviously distressed or in pain. Any that appear distressed are promptly culled. We created our Clinical Scoring System following consultation with REDACTED and our named veterinary surgeon to include more clinically relevant characteristics. A pilot study directly comparing the 'old' and 'new' scoring methodology was performed. The agreement (score awarded to each animal) between biological services and lab staff was improved using the new scoring system. This method awards the highest score from any category (rather than accumulation as previously performed), akin to actual severity assessment that we do for our animals. Scoring is performed at least four times per day and informal assessment is also performed regularly in between. Increasing clinical severity results in more frequent monitoring and additional support such as mashed food, more bedding and supplemental fluids.
Animals scoring three are deemed 'critical' resulting in euthanasia on moderate protocols. On severe protocols, we monitor the animals overnight or terminate experiments following three consecutive '3' scores, or two near the end of the working day. All animals that score 4 are promptly culled. The majority of experiments fall under the moderate category where severity limits are strictly imposed using our scoring system, as above. A limited number of experiments will be performed under a severe severity limit. For example, the effectiveness of a treatment for a shock condition is measured by improved survival. Although we generally aim to terminate the study at pre-specified times, we feel there is an important place for some protocols to provide firm verification of benefit. That notwithstanding, we are able to predict mortality resulting in closer, more effective monitoring of 'critical' animals.

We intend to perform a more extensive comparison of our clinical scoring methods and aim to publish our results. This could potentially allow further refinement of animal models of sepsis in other UK-based establishments and globally.

The use of circulatory monitoring also allows us to predict mortality through identifying persisting low blood pressure, allowing us to cull the animals electively before they die spontaneously. Monitoring for low blood pressure depends on whether the indwelling arterial line/tether system is being used (and remains patent). If so, during daytime hours the blood pressure is checked every 2 hours. Animals with a mean blood pressure <60 mmHg are culled as our experience shows that this precedes mortality by a few hours. Echocardiographic assessment of stroke volume (the volume of blood leaving the heart, per beat) at an early timepoint (6h) allows us to predict future mortality (with above 85% accuracy). Similar predictive values can be achieved using heart rate if echocardiography is not available. Predicted non-survivors are more closely monitored and experiments terminated before animals suffer unduly.

Animals lose fluid from their circulation into their tissues as part of the 'capillary leak syndrome' associated with sepsis. Loss of appetite and fluid intake is compensated by infusion of liberal amounts of fluid containing electrolytes and glucose. As noted above, this food can be mashed to aid feeding. Some studies assessing later endpoints in the disease progression are, we feel, justified, as the ultimate test of the efficacy of a treatment for a shock condition is improved survival. There are many examples in both animal models and clinical practice whereby improvements in the circulation, for example, do not necessarily translate into enhanced survival. Thus, while we generally aim to terminate

the study at pre-specified timepoints, we feel there is an important place for some protocols to provide firm verification of benefit.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The disease processes of organ dysfunction encountered in critical illness and response(s) to therapies can change with life stage and species. We propose mainly using 8-12 week old animals (opposed to younger animals) as responses observed in this age range more closely mimic the clinical scenario.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have a Clinical Scoring System developed in conjunction with Biological Services staff and our named veterinary surgeon. We intend to perform a more extensive comparison of our Clinical Scoring methods and aim to publish our results. This could potentially allow further refinement of animal models of sepsis in other UK-based establishments and globally.
Support for the animals increases in line with the Clinical Score we award. With higher scores we monitor the animals more frequently and provide additional support such as mashed food and pain relief, as required.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We recently took part in a round-table conference with other experts on animal models of sepsis. The outcome was a paper published in three journals informing on best practice. See 'Minimum quality threshold in pre-clinical sepsis studies (MQTiPSS): an international expert consensus initiative for improvement of animal modelling in sepsis'. We will continue to follow these guidelines and keep up to date with literature published during the course of the project.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We keep up to date with, and contribute to, published literature on the refinement of acute and critical illness animal models. We will additionally attend conferences and contribute to workshops set up to promote and inform on the 3RS.

Explain the choice of species and the related life stages

We will predominantly use rats as their metabolic response to infection and other conditions is similar to that seen in humans. Mice show a dissimilar metabolic response as they tend to hibernate, dropping their body temperature and metabolism, in response to some insults. However, we may use them for certain studies (such as mice that are born with an altered genetic background) to test specific biological pathways. The rats we use are typically 8-12 weeks old. Although animals (>1.5 years) rats may be more similar in age to the majority of patients we are ultimately aiming to treat (with additional

age-related conditions that can co-occur e.g. high blood pressure and cancer), younger rats show less variation and that means we need to use less of them to prove our biological findings are significant.

A retrospective assessment of refinement will be due by 06 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

Pancreatic Cancer - Exploring biology and options for therapy

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to investigate the importance of mutations and inflammatory pathways found in human pancreatic cancer in mouse models, and to characterize different subsets of pancreatic cancer caused by different mutations to understand the disease better and find specific targets for therapy. The models will then allow us to perform trials of new, potentially targeted therapies (which are specific to different mutations or pathways) in these clinically relevant mouse models of pancreatic cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pancreatic cancer is the 4th commonest cause of cancer deaths in the western world, and is predicted to be the second most common cause within the next decade. Current therapies are largely ineffective, meaning that the median survival is just 6 months, and only 6% of patients survive 5 years following diagnosis. This situation has remained virtually unchanged for the past 50 years making pancreatic cancer a huge unmet need.

A distinguishing feature of the disease is the dense microenvironment, almost like a healing wound, that surrounds and supports the tumour cells and can account for up to 90% of the tumour volume in human pancreatic cancer. This environment comprises fibroblasts (wound healing cells), pro-tumour immune cells, blood vessels, and structural proteins like collagen and fibronectin. All these components play an important role in disease progression, able to influence tumour cell proliferation, survival, metabolism, migration, immune surveillance, and response to chemotherapy. As such, it is essential to investigate these aspects of tumour biology in vivo, in spontaneous tumours with a physiological microenvironment and immune response.

What outputs do you think you will see at the end of this project?

We study the genes that go wrong in pancreatic cancer so that we can increase our understanding of how pancreatic cancer develops, progresses, and spreads to other sites in the body. We also aim to find new ways to target the disease therapeutically and understand how we might best treat patients. Our project concentrates on pancreatic cancer, but our work could apply to many cancer types. Outputs should include findings that can direct new clinical trials, and publications in peer reviewed journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Pancreatic cancer is the fourth commonest cause of cancer deaths in the UK. Studies from this project licence should provide insights into pancreatic cancer biology, and this will benefit the rest of the

pancreatic research community in the short term. Our studies will enable us to test novel targeted anti-cancer therapies in mouse models that mimic the human disease, so longer term, we hope that our work benefits patients and their families, and the medical professionals treating this disease. We will share what we learn with the rest of the scientific community by publishing our findings in scientific journals and giving presentations at scientific conferences both in the UK and internationally. We will also communicate our findings to the public through open evenings in our Institute, and meetings with supporters, patients and advocates in our Institute and around the country.

How will you maximise the outputs of your work?

We will continue to collaborate with other groups involved in cancer research, particularly pancreatic cancer, and disseminate our knowledge (both positive and negative) to the community. New findings arising from these studies will be submitted for publication in peer reviewed journals and presented at national and international meetings.

Species and numbers of animals expected to be used

- Mice: 50,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The majority of mice in the project will not suffer any adverse effects because they will not express all the right gene mutations to develop pancreatic cancer. With regard to the mice carrying the right gene mutations, most will develop pancreatic cancer as adults and be humanely killed without additional procedures when they show symptoms of pancreatic cancer (swollen belly, weight loss around haunches).

Some mice will be used in preclinical trials. That means that they will be monitored for tumour development by imaging (PET-MRI, fluorescent imaging, but most commonly ultrasound) under anaesthesia (typically for less than 10 minutes. Some of these mice will have their tumours biopsies by keyhole surgery under anaesthesia with pain relief in their drinking water pre- and post surgery. They will then be enrolled on a preclinical trial. The route and schedule of drug administration will depend on the drug, but they might be injected with anti-cancer agents from twice daily, to weekly). They will also be imaged weekly (again usually by ultrasound). They will be humanely killed when they shown symptoms of pancreatic cancer, which is usually ~3 weeks after being enrolled on trial, unless the therapy is effective, in which case time on treatment will not often be longer 2 months.

A small number of mice will have imaging windows surgically inserted into their skin to allow fluorescent imaging of the live interactions between tumour cells and their surroundings.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most mice will not experience any clinical signs, because they will not express all the right gene mutations to develop pancreatic cancer, however some mice will develop pancreatic cancer. Mice with pancreatic cancer appear to be a lot like humans with pancreatic cancer, in that they don't exhibit any discernible symptoms until very late in tumour progression. This means that they may exhibit mild symptoms for ~5 days, and moderate symptoms for up to 24 hours before being humanely killed. Symptoms are most often a swollen belly, and weight loss around the haunches and this could be apparent for 3-5 days. With late stage cancer, occasionally mice may develop jaundice (a yellowish hue to the skin) or may become less mobile, hunched and/or exhibit a scruffy coat (usually not more than 24 hours). At this point they will be humanely killed. When mice undergo surgical biopsy or surgical implant of tumours or imaging windows, there could be transient discomfort (~2 days), but this will be alleviated with pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All the animals used will be mice. The expected severities are as follows:

- ~80% mild (those mice that do not develop pancreatic cancer or are euthanised at early time-points before displaying any symptoms)
- ~20% moderate (predominantly mice that develop end-stage pancreatic cancer)

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Pancreatic cancer is a very complex cancer that involves a number of different cell types e.g. cancer cells, wound healing cells, immune cells, blood vessels, all within a particularly dense environment.

This environment, and all these different cell types, play a major role in tumour development, growth and spread, and stop drugs from working properly. Non-animal models cannot reproduce this situation and are not appropriate for studies to understand pancreatic cancer progression or for testing of new anti-cancer drugs.

What was your strategy for searching for non-animal alternatives?

We considered using cell line and (organoid) 3D cell culture experiments, and indeed we do use these where possible. We also examining human tissue samples where possible.

Why were they not suitable?

Cell line and organoid systems allow us to test the effects of drugs, or of deleting/activating cancer-causing genes in cells in plastic dishes but they invariably failed to deliver results in terms of predicting success in clinical trials in patients, and indeed can generate the opposite results. Indeed, many clinical trials based on results from these systems have failed, with the reasons for failure subsequently demonstrated in mouse models. (It's important to note that preventing negative clinical trials from being carried out in patients is as important as driving successful trials). On the other hand, immunotherapy, which has been a game-changer in cancer research was developed almost entirely from research in mouse models.

Cancer cells evolve and adapt to survive, and it is becoming increasingly clear that once removed from the supporting environment in which they normally grow, they 're-wire' many of their signalling pathways and no longer represent the tumour from which they came.

Archival human samples give us information about different mutations or altered signalling pathways, but they are not suitable for most work because any hypotheses are speculative without testing in animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Many of our strains have a predictable phenotype and this allows us to be quite accurate in the estimation of mouse numbers we need for each experiment. However, we use very complicated genetics in our models so that we need to breed a large number of mice to generate ones carrying all the genes necessary for each experiment. The numbers are based on these factors, as well as the number of genes and pathways that we plan to investigate.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The use of in vivo imaging e.g. ultrasound allows us to follow the same mouse during tumour progression and reduces the need to euthanize different mice at a number of different timepoints to assess tumour burden. Pre-treatment biopsies also allow us to reduce the number of mice used for timepoints. Thus, these approaches have been factored into experimental design.

The therapeutic agents that we will use in these studies will be screened in vitro for activity against the molecules that we want to target, and will be proven to have potential for development in the clinical setting (e.g. the target molecule is expressed in human and mouse pancreatic cancer), reducing the number of animals used in pre-clinical trials. We now have a dedicated bioinformatician within our lab who we continually consult to ensure best practice in experimental design.

What other measures apart from good experimental design will you use to minimise numbers?

Human pancreatic cancer occurs over a number of years and as a result of many mutations in cancer-related genes. To develop mouse models that mimic the disease, mice have to carry multiple mutations. In addition, some 'next generation' models allow us to target 2 different cell types (e.g. tumour cells and immune cells), or target only the tumour cells but in a sequential manner (for example to test the effects of deleting a gene from an established tumour). Thus, many of our cohorts involve breeding together of multiple genetically altered lines. Our breeding programmes are constantly optimised to generate the highest proportion of experimental mice possible, however, due to the complex genetics only a proportion of animals born will be of the desired genotype. We try to reduce the numbers of excess mice generated this way by maintaining stock animals carrying multiple mutations in a non-harmful combination, and where possible we minimize numbers of controls by extrapolating from different cohorts.

We collect tissue from all experimental mice which we share within the Institute and indeed throughout the UK. We also routinely prepare cell lines and organoids for use by our lab, but which are actually very often used by other labs in the Institute and around the UK, this reducing the number of mice used in pancreatic cancer research. In fact, we are involved in a project which brings together pre-clinical pancreatic cancer researchers from across the UK and prevents duplication of effort while maximising the benefit of our collective learnings.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice carrying the same mutations as human pancreatic cancer, specifically within their pancreas, will be bred to show predisposition to pancreatic cancer. We might also alter genes within 'normal' cells that can help drive cancer, for example, wound-healing cells, or we may induce inflammation in the pancreas, as this is a risk factor in humans. Some mice will receive a transplant of tumour tissue or cells from mouse or human cancer (occasionally via surgery).

Mice will develop pancreatic tumours or metastases (spread in other organs) that mimic the human disease. Pancreatic cancer is a very complex cancer involving a number of different cell types, so more refined models in cells or in less sentient animals don't mimic the disease well. Therefore to be able to effectively model human pancreatic cancer and metastasis, we need to observe metastatic pancreatic tumours in the mice. Mice with early stage pancreatic cancer do not actually exhibit signs of suffering or distress, and where possible mice will be humanely culled before showing any signs of suffering, however, mice with late-stage pancreatic cancer will exhibit some clinical signs (usually a slightly swollen belly and weight loss around the haunches), and unfortunately, it is necessary to allow some mice to develop established pancreatic tumours to accurately model the clinical situation. Mice showing these signs will be humanely culled.

In some cases, to mimic clinical trials, a biopsy will be taken and then mice enrolled onto a mouse 'clinical trial', using either clinically relevant treatments, or further genetic alterations where drugs do not yet exist, combined with imaging. Where any surgery is performed some pain or discomfort is expected so this will be kept to a minimum with analgesia. We expect mice to recover normally in 2-3 days. Once on therapy, mice will be given treatment by experienced staff using the most refined techniques (single use needles and asceptic).

For surgery or for imaging, anaesthesia will be used. The body temperature of the mice under anaesthetic will be maintained using heated platforms, and normal mouse food may be supplemented with gel diet or other treats after anaesthesia.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Pancreatic cancer, particularly, is a very complex cancer that involves a number of different cell types e.g. cancer cells, immune cells, wound-healing cells, and a particularly dense 'matrix'. All of these factors combine to play a major role in tumour development, growth and spread, and resistance to anti-cancer drugs. Mouse models of cancer are widely accepted to be the most closely representative of human cancers. We use state-of-the art genetic models to ensure that the cancer develops in the correct tissue (the pancreas), with the same mutations that are found in human pancreatic cancer. Tumours progress through the same stages of pre-cancer as in humans and also spread to the same organs. Other models cannot reproduce this situation.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Robust standard operating procedures for animal care, monitoring and minimal handling are in place. Social, environmental and behavioural enrichment are also provided. Lab members will ensure that all animals receive the highest standard of care. We have a vast amount of experience with mouse models

of pancreatic cancer, and close monitoring of tumour development allows us to recognize clinical signs before the animals exhibit signs of pain. Imaging, using small animal ultrasound, also allows us to detect internal tumours at much earlier stages, so in many cases we can monitor effects of chemotherapeutic drugs in tumours before mice develop symptoms. Where required, for example pre- and post surgery, preventative medicine (anaesthesia, pain relief, heated cages) will be used.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

For all of our studies we will abide by published guidelines (NC3Rs, Workman et al, 2010 *Br. J. Cancer*), as well as local guidelines, and ensure best working practice. We will also adhere to the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere). In our facility, compulsory monthly user forums are also in place for all personal licence holders, and 3Rs advances are introduced here and implemented across the facility.

Explain the choice ofspecies and the related life stages

We will be using mice that have been genetically engineered to be susceptible to developing pancreatic cancer as adults. Adult mice are excellent models in which to study pancreatic cancer for a number of reasons. We have a great deal of knowledge of the genetics of mice, and genetically altered mice carrying many of the gene mutations found in human pancreatic cancers already exist, meaning that we can combine these genetics quite easily. Further, the pancreatic tumours that develop in our mouse models go through the same stages of tumour progression that we see in patients, and spread to the same organs as in humans. Finally, pancreatic cancer is an incredibly complex disease that has a dense microenvironment, almost like a healing wound, which surrounds and supports the tumour cells and can account for up to 90% of the tumour volume in human pancreatic cancer. All the parts of this environment play an important role in disease progression and help tumours protect themselves from therapy. Importantly the pancreatic tumours in our mouse models also feature all of these components and are just as difficult to treat with drugs.

NON-TECHNICAL SUMMARY

157. Parkinson’s disease: understanding changes in the brain and testing new treatments

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to study the changes that occur in the brain of a rodent model of early stage Parkinson’s disease and to test possible treatments to prevent these changes and slow down the progression of the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Little is known about what causes some of the early signs of Parkinson’s disease, like the loss of smell and memory loss. However, it is crucial to understand the causes of these signs to be able to develop better treatments. These symptoms can happen more than 10 years before a diagnosis is made based on the start of the typical tremor and slowness of movements seen in Parkinson’s disease. Detection of the early changes in the brain may improve diagnostics and new treatments for the disease.

What outputs do you think you will see at the end of this project?

Parkinson's disease, like other age-related neurodegenerative diseases, is increasing within the population as the average age increases. The number of people diagnosed in the UK is about 145,000 (around 1 adult in every 350). Current Parkinson's disease treatments are only targeting the symptoms but fail to stop the progression of the disease. In order to find new treatments, we need to determine the early cause of the disease. In this project, we aim to collect new information on the changes that occur in the brains of appropriate rodent models of Parkinson's disease and test new treatments that will rely on stopping disease progression or using the capacity of the brain for self-repair. All data will be presented at national and international conferences and published in scientific journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

- Scientists/doctors studying the origin of Parkinson’s disease- The most effective clinical advance outside an outright cure for the disease may be an early diagnosis. Detection of early symptoms, like the loss of smell for example, in early-stage Parkinson's patients may greatly help such a diagnosis and allow treatments to prevent the death of nerve cells and stop the appearance of the more severe symptoms. To this end, appropriate rodent models that display symptoms and pathologies actually seen in patients will be a benefit to scientists and doctors who are trying to understand the origin of the disease.

- Patients suffering from Parkinson's disease- The study of models of early stage Parkinson's disease that present symptoms similar to those displayed by Parkinson's disease patients may play a vital role in understanding the origin of the disease and determining promising treatments. Furthermore, it is vital to determine if some of the new drugs to be tested can also be effective in decreasing the symptoms observed in patients long before the typical shaking and slowed movements. The clear rescue effect of some new treatments in rodent models represents a very promising avenue for a new and long-overdue effective therapy for Parkinson's disease.

- Scientists/doctors studying other diseases caused by death of brain cells- Patients suffering from these diseases- Information from this project could also prove very useful to scientists studying the causes and treatments of other serious disorders that affect brain function such as Alzheimer's disease or multiple sclerosis that share loss of smell as a common early symptom with Parkinson's disease.

In the lifetime of the project (5 years), we expect to build the knowledge base on the aetiology of the early stage of Parkinson's disease, to determine the effects of dopamine agonists and probiotics on non-motor symptoms observed in the early stage PD model and to compare these to those observed following EX-4 treatment. All data will be disseminated and presented in international conferences and published in peer-reviewed journals.

The EX-4 gene therapy, considered as drug development, is expected to have medium term benefits. Although the benefit of the drug itself has been previously shown, the project may lead to a novel method of administration that will carry less adverse effects than the drug treatments available for PD at present. This project, if successful, will see our involvement in a future clinical trial as a medium term benefit. Long term benefit for this study will be the translation of this research into practice.

How will you maximise the outputs of your work?

All data will be presented in national and international conferences, discussed with experts in the Parkinson's disease field and published in scientific journals. Follow-up funding based on the data collected will be sought.

Species and numbers of animals expected to be used

- Mice: 300
- Rats: 470

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be subjected to injections and surgical procedures via injection of a placebo solution, a toxin or a virus directly into the brain to induce the model of early stage Parkinson's disease (PD). Behavioural experiments will then be carried out at different relevant time points of the project to study both the effect of the injections and surgery (early stage PD model) and the effects of EX-4 that will be either injected or surgically administered as a gene therapy. The effect of conventional early stage PD treatments will also be tested and compared with that of EX-4.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

It is important to consider that our intention is to look at early stage Parkinson's disease. As such, the changes that are likely to be introduced will almost certainly be mild. To this end, we will be looking to use minimally-effective doses of toxins that give a cumulative but still subtle effect in the animals tested. Animals may suffer from weight loss for a few days after the surgery. We do not expect abnormal behaviours from rodents during the 4 week experiments. However, animals may start moving slowly and experiencing some motor disruptions in longer experiments.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

This study will be of moderate severity due to the surgical procedures. We expect some variability in the speed of recovery between animals. However, based on past experience, we do not expect animals to show any adverse effects 3 days after surgery.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals will be used in this project to answer important scientific questions related to human health. The lack of a cure for Parkinson's disease or even the lack of treatments aiming to slow down the progression of the disease have meant that the study of animal models mimicking the early stage of the disease may bring new therapeutic targets to light and therefore new drug treatments for the condition.

What was your strategy for searching for non-animal alternatives?

Full or partial replacement would not be possible to mimic Parkinson's disease with a view to test new therapies.

Why were they not suitable?

The mammalian brain is almost certainly the most complex biological system that exists. Parkinson's disease is the result of disruption of several chemicals that have a unique but interlinked distribution in the brain. Replicating this in a dish would not be possible. Furthermore, the interaction between genetic mutations and toxins are also difficult to reproduce in non-animal alternatives.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals needed for this project was estimated using power calculations based on previous experiments carried out in our laboratory. Typically, each animal used will provide a large amount of data towards more than one objective.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice taken from local statisticians and the use of the results from preliminary experiments obtained on a previous licence, helped in the design of future experiments. The amount of data/information gathered per animal in one single experiment will be maximised in order to reduce the number of animals to be used in this project and answer all the questions set in each of the objectives. Negative results will also be reported to prevent unnecessary studies to be conducted by other laboratories.

What other measures apart from good experimental design will you use to minimise numbers?

Training of personnel will be compulsory for all the techniques used in this project to ensure good practice and reproducibility of the results. Tissues (i.e. brains from all experimental groups) will be shared, increasing the amount of data collected from each experiment. Pilot studies with a few animals will be carried out for each new drug to be tested to ensure that the best dose regimen is used and animal welfare is appropriately addressed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Our intention is to induce an early stage model of Parkinson's disease in both rats and mice to study the early causes of the disease in the brain and to test new or established early-stage treatments. These models will therefore not suffer from the more severe side effects associated with later stages of the disease as they will be culled either before the appearance of the motor symptoms or when these symptoms are just starting to show. We have extensive experience in the method used for the induction of the models and staff will follow appropriate guidelines to perform the surgeries on these animals. Daily monitoring after the surgery will be carried out to assess the behaviour of the animals and minimise pain, discomfort and stress during the experiments.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Most patients suffering from Parkinson's disease start developing symptoms at the age of 50 or over and it is rare that patients are diagnosed with the disease when they are under 40. We cannot therefore use animals at a more immature stage of life if we are to study the aetiology of the disease. The induction of an appropriate model of Parkinson's disease requires the use of adult rodents in which the loss of the nerve cells and appearance of relevant symptoms mimic what is seen in patients.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We consider the welfare of the animals of paramount importance. The post-operative surgical care will help prevent and minimise complications related to anaesthesia and surgical procedures. We do not expect complications following the procedures in this project. However, animals will be given recovery gel (DietGel recovery), a nutritionally fortified water that aids with post-surgical recovery, and the use of analgesics will be considered pre-emptively and/or as needed after the surgery to minimise pain following close monitoring of the animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will ensure that experiments are conducted in the most refined way by following standard operating procedures from the Home Office, the LASA 2017 Guiding Principles for Preparing for and Undertaking Aseptic Surgery (E Lilleyand M. Berdoy eds.) and the guidelines for the use of animals [Animal Behaviour (2018)].

How will you ensure you continue to use the most refined methods during the lifetime of this project?

My link to the NC3Rs through the newsletter and social media allows me to keep up-to-date with any advances in this domain. Any new development of new 3Rs technologies related to this project will be srutinised and implemented if possible.

Explain the choice ofspecies and the related life stages

Previous scientific studies have shown that it is possible to produce models of Parkinson's disease (PD) in rats and mice that display similar symptoms to those observed in patients suffering from the disease. Young adult rodents will be used for this study to avoid undesirable side effects of the injected toxins in younger animals. Rats are the most commonly used animal in PD research and are a reference point to help compare results with previously published data. We will also establish the early stage model in mice to allow comparison with available genetically-modified mouse models.

The duration of the experiments will depend on the different objectives of the project. The majority of the experiments will be terminated after 4 weeks. However, some will be continued until the rodents start experiencing some motor symptoms. A close monitoring will confirm the beginning of the symptoms and will dictate the end of the study.

NON-TECHNICAL SUMMARY

158. Pathogenesis of Respiratory and Persistent Virus Infections

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Virology, Immunology, Pathogenesis, Vaccines, Anti-viral therapies

Animal types	Life stages
Mice	adult
Hamsters	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This programme of work aims to study the how the body responds to virus infections and use this information to investigate the potential new vaccinations and drug treatments. The viruses that we are studying are Influenza A virus (IAV), SARS-CoV2, human respiratory syncytial virus (HRSV) and gammaherpesviruses (γHV).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The viruses we are studying cause significant disease and death worldwide. SARS-CoV-2 is causing significant morbidity and mortality worldwide and may become a persistent problem. Influenza causes seasonal outbreaks of disease and deaths in the elderly with occasional worldwide outbreaks that cause thousands of deaths each year. HRSV causes seasonal colds but is a major problem in newly born children, causes lung inflammation and can lead to death. Gammaherpesviruses cause cancers.

There are still large gaps in our knowledge of how these viruses cause disease and even where available, vaccines and antiviral drugs are not 100% effective due to virus evolution. This project will advance this knowledge and help us to design and test new drugs and vaccines. This will lead to reduced disease and deaths due to virus disease.

What outputs do you think you will see at the end of this project?

The viruses we are studying cause significant disease and death worldwide. SARS-CoV-2 causes significant morbidity and mortality worldwide. Influenza causes seasonal outbreaks of disease and deaths in the elderly with occasional worldwide outbreaks that cause thousands of deaths each year. HRSV causes seasonal colds but is a major problem in newly born children, causes lung inflammation and can lead to death. Gammaherpesviruses cause cancers.

There are still large gaps in our knowledge of how these viruses cause disease and even where available, vaccines and antiviral drugs are not 100% effective due to virus evolution. This project will advance this knowledge and help us to design and test new drugs and vaccines.

The data from this programme will directly generate primary research publications from this work as well as presentation at scientific conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short-term, it is mainly the scientific, medical and veterinary community working in basic research who will gain new knowledge.

During the life-time of the programme we aim to engage with clinicians and commercial entities to work towards translating knowledge obtained on anti-viral drugs and vaccines into the clinic. We also aim to use knowledge to inform policy and the public through the media.

In the long-term, our work might end up in the development of new therapies and vaccines in the clinic

How will you maximise the outputs of your work?

Most of this programme of work and the funding to perform it is already undertaken in collaboration with other scientists. We will present our findings as posters or oral presentations at international conferences, we will publish pre-print manuscripts on open-access servers like BioRxiv, which allows public scrutiny and feedback on our results by anybody interested in the work and we will publish all data, positive or negative in open-access formats to widen dissemination.

Species and numbers of animals expected to be used

- Mice: 4300
- Hamsters: 1000
- Rats: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice, genetically modified mice and hamsters will be infected with viruses and these will cause disease in the lungs and sometimes cells of the immune system. We will also in some experiments test anti-viral compounds and potential vaccines. They will usually be maintained over a period of 2 weeks. The general condition of animals and their weight will be regularly monitored. Many of the animals will lose weight and then recover. About half of the mice will show no apparent sign of infection whereas the other half may show a mild flu-like illness.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The general condition of animals and their weight will be regularly monitored. Many of the animals will lose weight and then recover after about seven days. About 90% of animals may show a mild flu-like illness the rest will show no apparent sign of infection.

In a small number of mice we will alter the immune response. In these mice a more profound or rapid disease could develop after virus infection. In this case, the general condition of animals and their weight will be regularly checked. About 90% of animals may show a mild flu-like illness the rest will show no apparent sign of infection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

About 90% of animals may show a mild flu-like illness which would be classified as moderate severity the rest will show no apparent sign of infection.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed programme looks at how viruses cause disease in mammals. The interactions of multiple types of cells that form the lining of the lung, with cells of the immune system are needed to for our studies. These interactions are currently not possible in cell culture experiments in the laboratory. The lungs and immune systems of the animals we will be using are similar enough to recapitulate disease and it's mechanisms for us to study.

What was your strategy for searching for non-animal alternatives?

We already use cells in culture, 3D cultures that attempt to mirror airways of the lung and slices of lung to study aspects of how viruses cause disease in the lung.

Why were they not suitable?

Whilst we use cells cultured in the laboratory to study viruses and these experiments are informative, they are not currently able to mirror the complex environment found in the lungs and in particular how

cells of the immune system interact with lung cells to defend against infection.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated these numbers of animals in two ways. First, based on previous experience from maintaining and investigating genetically modified mouse models that are similar to what is proposed in this project. The number of animals necessary has also been determined by statistical analysis, consulting with a professional statistician. This will ensure that we use the minimum number of animals necessary for our experiments to be statistically significant.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will use a use a number of measures to reduce the number of animals used

First, we will use statistical and design software e.g. the NC3Rs Experimental Design Assistant (EDA) and power-calculation software to design animal experiments, maximise the data readout from a minimal n-number of animals and obtain estimates of how many mice might be needed for a specific experiment.

For experiments where we cannot use formal software in advance to estimate sample size, for example in novel experiments where we do not have an estimate of the expected standard deviation, we will utilise a block design or the similar ‘variable-criteria sequential stopping rule’ (SSR) and in consultation with a professional statistician

This will ensure that we use the minimum number of animals necessary for our experiments to be statistically significant.

What other measures apart from good experimental design will you use to minimise numbers?

We will employ careful long-term project management to ensure that only the required numbers of animals are obtained at the appropriate time for experiments to be performed.

Wherever possible, we will use and offer tissues that we do not need for our own research to other parties in order to share resources and maximise the usage of the animals for multiple aims.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will be using conventional mice, hamsters and genetically modified mouse strains that are deficient in components of the host response to virus infection. The structure and function of the lungs of mice and hamsters is similar to that of the human. They are therefore excellent animal models, which reproduce the complex human disease characteristics.

Data from our previous and future experiments will be used to determine the minimum doses of substances required to work but avoid side effects. The shortest possible time of treatment will also be used to obtain experimental data

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Other species such as zebra fish and drosophila (flies) are increasingly being used instead of mice. However, neither of these alternative models have a respiratory tract or lungs and thus are unsuitable for our studies.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We already through experience from previous and others' work that have enabled current 'best practice' protocols. Where new techniques are developed to refine procedures (as above) we will aim to adopt them to improve our methods.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All workers involved will use a range of best-practice guidance

Protocols, training resources and guidelines on best practices in animal experiments are available through the NC3Rs website. We will also follow the NC3Rs ARRIVE guidelines, and make use if the NC3Rs Experimental Design Assistant for new experiments.

There are also a number of training and resources published by the RSPCA and available on their website that will be used to guide our practice.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We regularly attend workshops and seminars, including those run by the NC3Rs that keep us up to date on latest developments. We also receive NC3Rs newsletters and check the NC3Rs websites for novel developments. We will adopt novel techniques and equipment as appropriate during the project.

Explain the choice ofspecies and the related life stages

The proposed programme looks at how viruses cause disease in mammals and how we can develop new interventions. We therefore need to be able to use an animal model system that enables us to perform these studies. The lungs and immune systems of the animals we will be using are similar enough to recapitulate disease and it's mechanisms for us to study.

NON-TECHNICAL SUMMARY

159. Pathophysiological Mechanisms of Cardiovascular Diseases: A Proteomics Approach

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to further our understanding of the processes that underlie cardiovascular diseases. We do this by using advanced techniques for protein analysis (proteomics). Proteomics allows us to understand the function of proteins that are produced by the body, and are the main building blocks of our blood vessels. In particular, we are interested in proteins constituting the structural scaffold of our vessels.

Starting from observations in patients, we will take advantage of genetically modified mice. These genetic modifications affect the building blocks that constitute the scaffold of our blood vessels, and the way these building blocks get modified over time and in disease. By doing this, we can investigate molecular targets towards which new potential drugs should be directed. These modifications do not only affect the structure of the vessels, but also the signals that are presented to the cells that populate the blood vessels (and that in turn, produce the building blocks), allowing us to expand the potential repertory of drugs and therapies aimed to prevent the changes in our vessels that lead to cardiovascular disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ischemic heart disease and stroke are the two leading causes of death worldwide. Both conditions are mainly caused by atherosclerosis, a disease in which the inside of an artery narrows due to the build-up of plaques. The plaques are predominantly composed of fat and can rupture leading to the formation of a thrombus. Narrowing of the artery and subsequent thrombus formation limits the flow of oxygen-rich blood to parts of the body.

Besides acute mortality following these ischemic events, survival often goes hand in hand with severely diminished quality of life. While ischemic heart disease can lead to heart failure, strokes can cause lifelong morbidity. This research programme will provide basic knowledge useful for both scientific research and clinical practice. We aim to achieve this by discovering new drug targets or better methods of disease diagnosis that will benefit patients both in the UK and worldwide.

What outputs do you think you will see at the end of this project?

The proposed project will advance our knowledge on the remodelling process taking place in our vessels during cardiovascular disease. Other processes such as inflammation are also associated with cardiovascular disease and will also be studied to better understand the link between inflammation and remodelling of the vessels. Together, our research will potentially lead to a change of the clinical practice in the future in the form of improved diagnosis and novel therapies that will positively impact on the survival and the quality of life of patients. As per our previous work, all relevant data emerging from this project will be published at the highest possible level in the most appropriate scientific journals.

This will ensure not only the sustainability of our line of research and success in future funding, but also a maximal outreach for our research, so it is useful for others and paves the ground for new research, ultimately leading to a change of the clinical practice in the future.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The primary aim of our research is to decipher basic processes occurring during the remodelling of our vessels during cardiovascular disease. The processes by which the scaffold of our vessels gets modified during cardiovascular disease have not been fully studied. In the short term (i.e. <5 years), our research aims for the development of strategies that control remodelling and degradation of the scaffold of our vessels during cardiovascular disease. We will only use mice under this license. At a later stage, models, i.e. involving the use of gene therapy, will need to be expanded to large animals (i.e. 3-5 years) before research can be translated into patients. These studies will be performed by collaborators at other centres under other licenses. Ultimately, we hope that our research will be applicable to patients suffering from cardiovascular disease (i.e. up to 10-20 years), possibly in the form of better diagnostics or combined therapies that improve the efficacy of current therapeutic approaches, and that will have a positive impact in the quality of life and outcomes of patients.

How will you maximise the outputs of your work?

1) Our protocols have been adapted to our research questions based on previous experience from other research groups in our Centre. This is a strategy that we will continue to use in the future.

2) Hearts obtained from previous experiments focussing on vessels only have been used to generate preliminary data that secured a fellowship. This demonstrates the level of synergy that can be achieved in REDACTED, and our commitment to maximize the outputs obtained from our research whilst minimising the use of animals.

3) Our group has an extensive track record of collaborative research, demonstrating that data from our experiments can be complemented by research in other internationally recognised institutions in order to maximize the impact of our outputs.

4) As a general policy in our group, we publish our results and disseminate them at scientific conferences, including negative findings or unsuccessful approaches, so our research is helpful for others, and we ensure that we do not duplicate unnecessarily the research already done by others.

5) Whenever relevant, we do not only publish clinically relevant work, but also technical papers that make our protocols available for other groups.

6) The data are deposited in public data repositories. Together, these strategies ensure that our research contributes to maximal dissemination of knowledge.

7) We will engage with clinical partners to seek for feedback, ensure that our research is applicable to human disease, and that it covers actual clinical needs, so it can ultimately benefit patients and be implemented into the clinical practice in the future. When appropriate, we will get involved in the

development of any potential clinical therapy emerging from the data obtained from (or part of) our research.

Species and numbers of animals expected to be used

- Mice: 6,150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, mice under our license will be bred and maintained in order to provide a stock for our experiments. In most cases, animals will be kept for about a maximum of 20 weeks. This is sufficient time to perform most of the procedures described in our license. An exception to this will be animals used to investigate ageing, and animals used as breeders. The former will be kept for a maximum of 24 months, while the latter will be kept for a maximum of 12 months (males) or about 6 months (females).

Animals undergoing experimental procedures will typically enter experiments between the 6th and the 10th week of age and are generally culled before the 20th week of age, once the experimental purpose has been achieved, avoiding any unnecessary suffering. Again, an exception to this is represented by animals used to study ageing (i.e. about 6% of the mice included in this license), on which similar experiments will be performed on a later time point in life.

We anticipate two standard routes our animals will typically follow:

1) The animal will first undergo an evaluation using echocardiography under anaesthesia, after which a surgery will be performed to induce the relevant vascular disease. After that, cardiovascular functions are monitored using echocardiography (once or twice) until the experiment is finished, usually within the first month after surgery, after which the animal is humanely culled.

2) The animal will first undergo an evaluation using echocardiography under anaesthesia, after which the animal will be, for example, fed a cholesterol-enriched diet to induce vascular disease. Animals are then maintained on this diet for about 12 weeks, after which a final monitoring is done using echocardiography, before the animal is humanely culled.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most animals in our protocols are not expected to experience an impact to their wellbeing beyond that required for the experimental purpose. However, a risk of observing side effects is associated to each experiment, as described in our protocols. Any potential side effects will be closely monitored, and remedies provided to ensure that animals do not experience unnecessary or long-lasting suffering.

Typical examples of side-effects are as follows:

For experiments involving surgery: Complications can include bleeding, wound infection or breakdown of wounds.

For experiments involving diet manipulation: Complications can include weight loss, or excessive weight gain.

For experiments involving ageing of mice: The mice will experience symptoms of senescence like skin conditions (e.g. dermatitis and eczema), reduced activity levels, and weight loss. Other age-related side-effects may include tumours, heart failure or the presence of seizures, but these are only anticipated to affect a very small proportion of all aged animals.

For genetically modified animals: We will be using a mouse model of obesity. These mice eat more than normal mice, become obese, and therefore they may display conditions commonly associated to obesity. These include impaired mobility, and occasionally the development of wounds that take longer than normal to heal. Other animals with genetic modifications are not expected to show side effects different to those appearing in normal mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Examples and definitions of severity levels are provided at the end of this section. We will only use mice in our protocols. Estimates of expected severity levels under this license are as follows:

We will use an estimated total of 6,150 mice.

These animals will be breed and/or maintained at our facilities. The vast majority of these animals (6,000, i.e. 97.5%) will experience only mild suffering related to breeding and maintenance. Only 150 (2.5%) animals will suffer a moderate level of suffering related to breeding and maintenance.

Of animals entering protocols other than breeding and maintenance (4,350), 75% will experience a mild severity level, while 25% will experience a moderate severity level.

Mild severity is defined as that in which animals are likely to experience short-term mild pain, suffering or distress, or not significant impairment of the well-being or general condition of the animals. An equivalent example of this level of severity is an echocardiography or the administration of an anaesthetic.

A moderate severity level is defined as that on which the animals are likely to experience short-term moderate pain, suffering or distress, or long-lasting mild pain, suffering or distress as well as any procedure causing moderate impairment of the well-being or general condition of the animals. An equivalent example of this level of severity is a surgery under general anaesthesia and appropriate analgesia or frequent withdrawal of blood samples.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal models are essential. Whenever possible, strategies not involving the direct use of animals have been implemented (tissue engineering, cell cultures). Unfortunately, the animal models proposed for this project cannot be replaced by other methods, since the complex process of atherosclerotic lesion formation and blood vessel remodelling cannot be accurately reproduced, and there is no suitable alternative to animal models for studying this complex and chronically developing condition.

What was your strategy for searching for non-animal alternatives?

Alternatives considered for our research include the development of tissue engineered scaffolds (e.g. artificial tissues) for experiments looking into the effect of stretch on blood vessels (similar to what happens during hypertension). For experiments looking into processes at the molecular level, we use commercially-available cell lines when possible, or cells obtained from relevant mice. When feasible, we obtain clinical samples and data rather than using animals. We have collaborators and staff in our group dedicated to the development of biostatistical and computational models. All these alternatives will be used whenever feasible.

Why were they not suitable?

Certain processes that will be studied in this project using animals cannot be studied in cell culture studies nor can they be mimicked by computational modelling due to the numerous uncertainties/unknowns regarding these complicated diseases. The scaffold of our vessels is exposed to continuous forces, e.g. by high blood pressure, and this scaffold is formed over long time periods. These conditions can only be produced in vivo (i.e. in a living animal and not in cells). We will complement our studies in animals with in vitro studies (i.e. in a test tube, culture dish or elsewhere outside a living animal) to obtain greater detail. However, such studies in isolated cells/organs cannot model chronic changes and interactions among multiple body systems in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used in the present project has been carefully estimated based on the funded research projects currently active in our lab and a reasonable estimation of future projects to be obtained during the duration of this project.

All our experiments are performed after careful statistical estimations based on preliminary experiments or relevant literature. All our current grants involving animal work have been only accepted after providing appropriate calculations regarding animal numbers, ensuring that funding is only available for the required animals. Importantly, when estimating total numbers, we have taken into account the fact that some animals might serve multiple purposes (for example, tissues used for different objectives). The majority of measurements we aim to obtain are suitable for statistical analysis. Dropout for the different models has also been taken into account in order to estimate final numbers.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have implemented methods like echo imaging that allow non-invasive serial assessment during the experiment in the same animal, which significantly reduces the numbers required, as otherwise animals would have to be killed at each relevant time point to collect data. Serial assessments also reduce experimental variability by allowing comparisons at different time points in the same animal, thereby providing more statistically robust data. At the end of the experimental period, animals are humanely killed. Our protocols ensure that once samples are taken, the maximum possible data can be obtained from each animal. This also significantly reduces the total numbers of animals required.

Experimental study plans will be written for each experiment as part of good laboratory practice, to include: objective(s); description of the experiment including experimental treatments; the number of groups and number of animals/group; data to be obtained; and an outline of the planned method of analysis of the results. For genetically modified animals, where suitable mice already exist, they will be obtained from the relevant supplier. In cases where we generate the required genetically modified mice ourselves, we will measure production and breeding performance and ensure that the minimum numbers of animals required are bred.

What other measures apart from good experimental design will you use to minimise numbers?

All experiments proposed for this project will be designed based on pilot experiments that provide important data to help us to estimate the number of animals required on each individual experiment. We

will keep records of breeding efficiency and survival, to help us to estimate the number of animals produced on each breeding cycle. All female breeders will be identified and tracked for the number of pregnancies and age, so only efficient breeders are used. When feasible, we will ensure that mixed animals will not be bred. This occurs when the parent animals have different genetic backgrounds; this will be avoided whenever possible. Whenever possible, tissues from the same animals will be used for multiple purposes and can be shared with other groups from which we might also obtain tissues (i.e. hearts from the same mice can be used for projects by other lab members), overall reducing the number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Only mice will be used. Mice have a well-defined genetic map and are sufficiently similar to humans to obtain clinically relevant conclusions. Mice require small quantities of reagents yet there is a wide availability of specific reagents that can be used for this species. Examples of these are antibodies and inhibitors that have been developed for mice, but would not be available for research in other models. These reagents are more specific and can be used in smaller doses, considerably reducing side effects and pain caused to the animals.

Atherosclerosis-prone mice (i.e. mice that are prone to present fatty deposits in their arteries leading to hardening of these blood vessels) develop mild disease even when on normal diet. When on Western diet, these animals require shorter times than control mice develop vascular disease. Therefore, our protocol ensures that mice are on protocols for minimal time periods. The scaffold of our vessels is critical for the binding of lipids to the vessel wall, and for the structure and stability of the vessel. Genetic modification of specific components of the scaffold of blood vessels allows us to study the effects on the structure and remodelling during the development of cardiovascular disease.

This project intends to use mainly mice which are prone to develop atherosclerosis or have defects on the scaffold of their blood vessel. The vast majority of mentioned genetically altered mice develop and grow normally and have normal fertility.

All methods used for the present project use the least invasive and least painful techniques of those available. Our group has adopted techniques that reduce operation time and chance of bleeding and increase success rate. These surgical techniques include the implantation of minipumps (it avoids repeated animal dosing by injection), telemetry probes are the gold standard in mice to measure blood pressure, and a simplified model of vessel grafting. These models have been reproduced by other laboratories and are well described in the literature.

Whenever possible, we choose to induce disease by methods not involving vascular surgery, as in the case of inducing high blood pressure. Several of the methods rely on the administration of agents with the diet or with drinking water (e.g. agents that cause high blood lipid levels and high blood pressure) avoiding the use of injections and reducing considerably the stress caused to the animals.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Our main goal is to study disease progression. Therefore, animals terminally anaesthetised are not appropriate. Species that are less sentient do not share sufficient common characteristics with humans, nor are they sufficiently characterised to be reliably used as models of human disease. Animals are used at the earliest possible life stage, but the composition of the scaffold of blood vessels changes and builds up over life, and we can only use mice in which a fully mature blood vessels have developed (i.e. after 8 weeks of age).

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All surgical procedures under all Protocols will be conducted under sterile conditions to avoid infections, with appropriate pain relief, the highest levels of post-operative care and appropriate veterinary consultation. As the major component of mortality or expected side-effects is during surgery and in the first 24 hours after surgery, animals will be closely monitored at frequent intervals during this period. Animals will be reviewed at the end of the working day on the day of surgery and any considered likely to die overnight will be humanely killed. Careful attention will be paid to heating, pain relief, body weight, surgical wound-sites, hydration, and signs of pain or distress.

We periodically revise all medications administered to our mice; e.g. we have recently changed from an injectable to an oral pain medication. We periodically re-assess all methods with the help of other members of our department.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

- LASA guidelines

- Guidelines and training materials provided by NC3R

How will you ensure you continue to use the most refined methods during the lifetime of this project?

- Websites e.g. https://www.nc3rs.org.uk, https://www.lasa.co.uk

- Webinars e.g. hosted by Charles River
- Advice of NVS, NACWO, NTCO and NIO
- Attendance of scientific conferences
- Publications in cardiovascular journals

Explain the choice of species and the related life stages

Only mice will be used. Mice have a well-defined genetic map and are sufficiently similar to humans to obtain clinically relevant conclusions. Mice require small quantities of reagents yet there is a wide availability of specific reagents that can be used for this species. Examples of these are antibodies and inhibitors that have been developed for mice, but would not be available for research in other models. These reagents are more specific and can be used in smaller doses, considerably reducing side effects and pain caused to the animals.
Atherosclerosis-prone mice (i.e. mice that are prone to present fatty deposits in their arteries leading to hardening of these blood vessels) develop mild disease even when on normal diet. When on Western diet, these animals require shorter times than control mice develop vascular disease. Therefore, mice are on protocols for minimal time periods. The scaffold of our vessels is critical for the binding of lipids to the vessel wall, and for the structure and stability of the vessel. Genetic modification of specific components of the scaffold of blood vessels allows us to study the effects on the structure and remodelling during the development of cardiovascular disease.

The Figure below compares the life phases and maturational rates of mice and humans. Mature adult mice range in age from 3 - 6 months, which is the life phase equivalent for human ranges from 20-30 years. For experiments not involving ageing, we generally choose
to use animals up to the 6th month of life. While these are young adults, they are mature animals, and this prevents the introduction of co-founding factors related to age that are often not relevant for our projects and might mask our results. Animals of older ages also tend to present with higher variability (e.g. broader weight ranges), and often require the use of larger amounts of reagents. Ageing will be a specific matter of study in some of our projects. For these projects, mice will be kept up to the age of 24 months. Noteworthy, the age range 18-24 months in mice is equivalent to the 6th and 7th decades of life in humans, at which most cardiovascular events occur. This age range is therefore highly relevant for studies looking at the changes in blood vessels occurring upon ageing.

NON-TECHNICAL SUMMARY

160. PATHOPHYSIOLOGY AND TREATMENT OF NEUROLOGICAL DISORDERS

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims to advance our understanding of the underlying mechanisms involved in the pathogenesis and chronicity of neurological disorders in the eye or the central nervous system (CNS) and develop potential therapies for patients.

A retrospective assessment of these aims will be due by 04 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Worldwide neurological disorders have become the leading cause of disability, and the second leading cause of death. The absolute numbers of deaths and people with disabilities caused by neurological diseases have risen substantially in the past 30 years, and it is expected to increase further as a result of population growth and ageing. The social and financial burdens imposed by these chronic, debilitating diseases include poor quality of life, high health care costs, and substantial loss of productivity. Thus, there is an urgent need to understand the disease mechanisms of these neurological disorders, and develop strategies in disease prevention and treatment for patients.

This project focuses on three of the main neurological diseases: multiple sclerosis (MS), uveoretinitis (this work may be undertaken in the future) and Alzheimer disease (AD). MS is a chronic disease in which repeated episodes of inflammatory demyelination result in irreversible axonal injury in the central nervous system (CNS). MS is a disease of all ages but commonly diagnosed between the ages of 20 and 40. It affects more than two million people worldwide, and the UK has higher MS prevalence than many other countries with around 100,000 people in this country suffering from the condition. MS is the major cause of non-traumatic neurological disability among working adults, it can substantially and adversely affect an individual’s quality of life and is associated with high costs for MS patients, their families, and society as a whole. Posterior uveoretinitis (inflammation of the uvea layer, which can involve the retina tissue, thus also called uveoretinitis) often leads to retinal tissue damage and is a potentially blinding condition (10% of blindness in the developed countries) with a significant economic and social impact. In the UK, it is estimated that two to five in every 10,000 people will be affected by uveitis every year.
The number of individuals living with dementia is increasing (more than doubled globally from 1990 to

2016), negatively affecting families, communities, and health-care systems around the world. AD is the most common form of dementia which causes progressive cognitive deterioration and is characterized by beta-amyloid deposits and neurofibrillary tangles in the cerebral cortex and subcortical grey matter.

The direct cause of many neurological disorders is often not known. Currently, there is no cure for MS, uveoretinitis or AD, and the efficacy of the available treatments is limited by many side effects. Thus, better understanding of the underlying molecular mechanisms of these diseases will help develop better strategies to treat the patients and delay disease progression, thus help the patients and families, and reducing the economic burden too.

Experimental autoimmune encephalomyelitis (EAE) and experimental autoimmune uveoretinitis (EAU) are animal models commonly used in research because their pathological features closely resemble human MS and uveoretinitis. EAE provides a valuable tool for obtaining insights into the immunobiology of MS disease and has led to the development of three clinically approved therapies: glatiramer acetate, mitoxantrone and natalizumab. For its part, EAU has contributed enormously to our understanding of uveoretinitis disease and drug development.

Although EAE and EAU are pathologically separate disease models, there is tremendous overlap as both CNS and eye are considered to be the immune privileged sites, and they share similar mechanisms of immunopathogenesis. Furthermore, this has been exemplified by the use of similar, if not the same, biologicals for the treatment of MS and uveoretinitis in the clinic. It should therefore be appreciated that the lessons we can learn from these two separate diseases will very likely benefit sufferers of either and possibly of other autoimmune diseases.

For AD research, genetically modified animals such as 5XFAD mice have been successfully used to explore the disease pathogenesis, immunomechanisms, and potential therapies. For example, accumulating research evidence has confirmed that AD pathology includes amyloid plaques, neurofibrillary tangles and inflammation in the CNS. In addition, CNS resident microglia cells and immune cells in the peripheral immune system are now known to play important roles in the development of AD. Our studies here aim to improve our understanding of AD pathologies and the interaction between the CNS and the immune cells, which is the key for the development of novel therapeutic strategies for patients.

Research from decades of studies suggests that the dynamic balance of effector and regulatory immune cells, together with their related cytokines/chemokine, control the immune response towards immunity or tolerance respectively, and has a major influence on the pathogenesis of immune mediated diseases including neurological diseases. Thus, factors that regulate the balance of effector and regulatory T cells in the development of MS, uveoretinitis and AD are of particular interest and may represent potential therapeutic targets. However, immune response is a complex manifestation of multi-factorial dysfunction of an array of genes and molecules. Although impressive progress has been achieved in recent decades both in the fundamental understanding of, and therapeutic approaches to these diseases, much still remains to be learnt. The limitations encountered with new therapies would suggest the existence of unrecognised pathways operating in the development of these neurological disorders.

Therefore, it is essential that we understand better the underlying mechanisms of neurological disorders, and better therapeutic control of these diseases, since this will result in huge economic, social and health care benefits.

What outputs do you think you will see at the end of this project?

The project will further our understanding of the underlying mechanisms involved in the pathogenesis and chronicity of neurological disorders, thus informing rational design of novel therapeutic strategies for patients with these diseases, all of which have enormous impact on the economy and the health care of humans.

For example, we are investigating the underlying action mechanisms of immune cytokines in multiples sclerosis, the findings will provide novel insights into the effect of immune molecules on the important immune cell function during the neurological disease development.

The outputs of research using this PPL will include novel knowledge in understanding the underlying immunomechanisms of multiple sclerosis (MS), uveoretinitis, and other autoimmune diseases. The findings will be published in peer-reviewed research journals and presented in national and international conferences (oral and post presentation).

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Neurological disorders are one of the most challenging health problems with global economic and societal impact. The new knowledge we learn from these studies will help us to understand the initiation and development of MS, Alzheimer's disease and uveoretinitis. In the long term the findings will also lead to the possibility of identifying new molecular targets for autoimmune diseases, for which new pharmaceutical products could be developed for clinical intervention of these diseases.

The information is likely to be of interest to pre-clinical scientists interested in immunobiology. The secondary potential benefit relates to the value of the results to clinicians (ophthalmologist, neurologists) and patients. Furthermore, new molecular targets may be identified, for which new pharmaceutical products could be developed for clinical intervention of these diseases, thus benefiting patients, patient families and the society.

How will you maximise the outputs of your work?

I collaborate with colleagues within the REDACTED, in UK and internationally to promote the research in understanding the immune mechanisms of MS and other neurological diseases. The findings our studies will be published in peer-reviewed journals for other researchers in the field, in addition we will disseminate our findings through presentations at national and international conferences, and thus there are ample opportunities to share data and results with the international community. We also aim to promote public understanding of research in immune mediated neurological diseases via our outreach activities.

Species and numbers of animals expected to be used

- Mice: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Experimental autoimmune encephalomyelitis (EAE) is induced by one subcutaneous immunisation of protein or peptide of central nervous system (CNS) emulsified with complete adjuvant, together with two intraperitoneal injection of pertussis toxin. Experimental autoimmune uveoretinitis (EAU) is induced by one subcutaneous immunisation of protein or peptide of retina emulsified with complete adjuvant, together with two intraperitoneal injection of pertussis toxin. These mice receive prophylactic or therapeutic regimes of treatment (e.g. injection of reagents/cells/biocompatible materials). Mice will then be monitored closely for clinical symptoms (EAE clinical symptoms will be recorded by observation, EAU symptoms will be monitored using fundus imaging). Experiments often last 4 to 8 weeks, and mice are humanely killed at the end of the experiments, and tissues are analysed.

AD models, such as 5XFAD mice, are genetically altered mice; animals start to develop pathology of AD at about 2/3 months' of age. These mice receive regimes of treatment (e.g. injection of reagents/cells/biocompatible materials) before 2 months, or after developing cognitive deficits at around 9 months. Mice will then be monitored closely and weight will be recorded. Depending on the specific research aims, experiments often last 3 to 6 months, at the end of which mice will be culled and tissues analysed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The adverse effect for each genetic modified mouse colony will be dependent on specific genetic modification of the mice. The majority of mice have no gross phenotypic abnormalities, reproduce normally and mature to full age as wild type mice. Some strains have mild phenotypes involving altered behaviour or activity, or susceptibility to disease due to immunomodulation. The information for the adverse effect for each colony will be obtained from the suppliers and/or from literature if published already. Other potential minor adverse effect: Ear notching should involve only slight and transient pain, and no healing problems. Haemorrhage after blood sampling will be controlled by local pressure.

Immunisation protocols for EAE and EAU induction in mice may lead to small skin ulcers at the injection site. However, the small ulcers should heal without the need for treatment and generally cause no discomfort to the animal. Granuloma formation may develop at site of injection when using complete adjuvant and although this is common, it does not appear to cause any health issues in the animal.

Clinically, EAE animals can display a monophasic bout of EAE, a relapsing-remitting form, or chronic EAE. In the monophasic form, disease develops as an acute clinical course followed by complete clinical recovery. Alternatively, animals may develop a stable chronic neurological deficit, or even develop a relapsing/remitting clinical course during which episodes of clinical disease are separated by periods of clinical remission at intervals of 7 to 20 days. Initial recovery is often complete but the disease progression may be associated with the development of irreversible deficits (such as loss of tail tone or hind limb weakness) due to failure of tissue repair. In all cases, after disease onset, animals will be scored on a daily basis and humane end-pionts applied as described above. By contrast, EAU-induced mice do develop retinal inflammation but show no clinical signs.

Animals may also experience transient stress due to anaesthesia used during immunisation or imaging, this is minimised by good technique and the use of short-acting agents.

Normally the adverse effects associated with imaging are not expected to result in any lasting harm. Possible adverse effects include: transient stress/discomfort associated with anaesthesia, dehydration and hypothermia. Repeated anaesthetic sessions may have a detrimental effect on the animals, but this will be minimized by using short-acting inhalation anaesthetics and making the imaging sessions as short as possible. Fluid support will be provided where appropriate. Mice will be kept warm throughout imaging sessions.

Potential adverse effects associated with dosing regimes (e.g. different routes of injection) are not expected to cause any lasting harm, but may include distress or discomfort due to restraint as well as transient, momentary pain during injections. Some signs of illness, e.g. listness, hunching, maybe observed after injection of some of the agents to be used. This is normally transitory (2-48h). Animals will be monitored regularly after injection and if any of the mentioned symptoms persist or deteriorate, humane end-points will be applied as described previously.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The adverse effect for each genetic modified mouse colony will be dependent on specific genetic modification of the mice. The majority of mice have no gross phenotypic abnormalities, reproduce normally and mature to full age as wild type mice. The expected severity is Mild (>95%).

EAE immunised mice are expected to develop clinical symptoms resembling human MS, thus may reach a Severe severity (about 60%). However, control animals without EAE immunisation or animals with EAE immunisation but sacrificed before disease onset will not reach such a level of severity.

While EAU mice develop local inflammation in the eye, this seems to cause little discomfort and animals continue to behave normally. Because a significant proportion of animals in this model will also undergo dosing regimens and repeated anaesthesia for fundus imaging, we assign a Moderate severity to about 60%. Control animals without EAU immunisation or animals with EAU immunisation killed before full disease onset will likely score a Mild severity.

AD mice develop amyloid protein accumulation in the CNS around 2/3 months, then rapidly develop AD pathology. These animals are expected to develop moderate severity with cognitive impairments. Experiments using WT littermates as controls or AD mice completed experiments before clinical

symptoms will only experience Mild severity. Therefore 80% of mice are expected to be in Moderate category.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 04 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed studies investigate the underlying immunopathogenetic mechanisms of neurological diseases (MS, uveoretinitis or AD) and effect of proteins/compounds/cells or other novel treatments on the development of these diseases in normal and pathogenic conditions of the neuron system and determine the cellular and molecular mechanisms involved. These studies require an animal with an intact immune system and nervous (or eye) system. The complex interplay of cells and cytokine interactions between the eye or the central nervous system and immune organs *in vivo* simply cannot be replicated or replaced by any available *in vitro* models. It is absolutely critical the functional studies are analysed *in vivo*. Mice are the best animals for this work because of their structural and physiological similarities to the human immune system. There is no good alternative model than the use of mice that can answer the specific questions of the proposed project.

What was your strategy for searching for non-animal alternatives?

Whenever possible we will use non-animal alternatives in this project. For example, *in vitro* culture experiments will be used to study the effect of interested reagents on cell toxicity, immune cell activation and neuron myelination etc. Previously we used a myelinating culture system to reproduce myelination *in vivo* and study the role of IL-33 in CNS myelination.

Why were they not suitable?

These *in vitro* experiment systems do not have the complex interplay of cells and molecule interactions between the organs CNS/eye and the immune organs, thus not suitable for research to determine how immune system and CNS/eye system interact with each other during the development of many neurological diseases.

A retrospective assessment of replacement will be due by 04 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from yourexperience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals will be used in each protocols below are based on the current funding obrained and potential research interests through collaborations.

Protocol 1: breeding of genetically modified mice, 1500;

Protocol 2: EAE induction, 1500;

Protocol 3: Animal models for AD, 1500.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will take the following measures to ensure that minimum number of animals used in this project:

- Use of minimum numbers in each experiment: The experimental designs and methods of analysis of the results have been discussed with the Statistical Services Unit at the REDACTED. Experiments will be designed to use the minimum number of animals per group consistent with obtaining data that can be tested statistically. These numbers are based on our considerable collective previous experience of the numbers required and power projection of numbers required for our future needs. For the qualitative experiments, the amount of material required is the minimum necessary to provide an adequate description. We have also planned to reduce the animal numbers by harvesting multiple organs for analysing.
We will continually review our results to adjust the number of animals used in experimental groups so that we use the minimum number of animals to have statistically valid data.

- Use of clinical scoring: Clinical score of EAE is commonly used. For EAU model which may be undertaken in the future, we will use the recently developed non-invasive *in vivo* fundus imaging techniques for clinical scoring of retinal inflammation. This approach enables the evaluation of disease severity in live mice thus reduces the overall numbers of animals required to screen new reagents and to assess their potential and safety for human use.

What other measures apart from good experimental design will you use to minimise numbers?

We will use other measures to optimise the number of animals used in this project:

- We will work closely with staff at the animal unit for efficient breeding of mice in protocol 1.

- Small pilot studies will be performed for any new project to ensure the success of following *in vivo* experiments and reduce any unnecessary waste of animals. Following that power calculations will be performed to calculate the animal group size for subsequent experiments.

- We also plan to reduce the animal numbers by harvesting multiple organs for analysing.

A retrospective assessment of reduction will be due by 04 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This project will use EAE and AD models.

Depending on the antigen used and the genetic make-up of the animal, rodents can display a monophasic bout of EAE, a relapsing-remitting form, or chronic EAE). Most commonly, EAE induced with MOG peptide emulsified in complete adjuvant will used. The model is easy and quick to induce and is a monophasic EAE model, mice recovers from the symptoms after peak stage and thus less suffering.

We use a well established 5xFAD mice for AD disease study. Mice live a normal life for several months then develop pathology of AD, which is important for the studies.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The project aims to investigate the underlying pathogenesis of neurological diseases in the CNS and the eye, and develop potential therapies for patients. The animal models used require the intact complex the complicated immune and neuronal interactions between molecules, cells, tissues and organs *in vivo* which are important in the initiation, development and resolution stages of various neurological diseases. Therefore, *in vivo* work using the proposed animal models is required.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We use the following steps to refine our experimental procedures:

- The experiments (all using mice) of EAE often last 4 weeks from immunisation day to finish, some will be up to 8 weeks or more to study the long term symptoms of disease.
AD models will be kept for longer period because of the nature of the disease. However all experiments will be kept to the minimum length needed for the experiment to acquire the necessary data.

- We use our improved immunisation EAE protocol (cleaning the injection site and needles, prior to immunisation & carefully avoiding the leakage of injection reagents) to reduce adverse effects such as skin ulceration caused by the use of Freund's complete adjuvant (CFA). In the last 5 years, severe skin ulceration has been rare (<5%). EAE mice develop will be provided with soft food and extra bedding when they develop EAE, and will be monitored closely.

- We have developed non-invasive *in vivo* clinical scoring methods that allow early stage disease to be investigated and changes in disease severity to be quantitatively analysed, which in turn can helps us refine our end-points.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Guidance from the NC3Rs of animals in research, and advice from RSPCA for laboratory animals.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will learn advances in the 3Rs through various opportunities such as the REDACTED annual 3Rs symposium, and information from NC3Rs.

We aim to implement advances in the 3Rs in our research whenever we can. For example, the new recommendation of using one needle per animal, we had a discussion with our NVS and revised our protocol two years ago.

Explain the choice ofspecies and the related life stages

Normal naive mice or mice with genetic modification of specific genes of research interest will be used in this study. The animal models for multiple sclerosis (MS), uveoretinitis and Alzheimer's disease (AD) have been the essential tools used in research in our understanding of the underlying pathogenesis of disease development, and in the recent development of therapies for patients because of their pathological features closely resemble the disease in human.

For research in MS and uveoretinitis, young adult mice are best in developing disease models. For AD model, adult and old mice (up to 9 months) will be used as symptoms resembling AD patients develop at old age mice.

A retrospective assessment of refinement will be due by 04 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

161. Pharmacological characterisation of novel therapies

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Antigenic Challenge, Pharmacokinetic, Breeding, Mutants, Tolerability

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to test and develop novel therapies to ensure they are safe for use and observe how they behave in the body prior to being used in animal models of human disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

By contributing to the development of new candidate drugs, our project will accelerate the discovery of new treatments, for the benefit of patients and improving their quality of life and reducing symptoms. Understanding the safety profile of novel therapies and the targets they act on will allow for a smoother transition to other studies looking at the efficacy of these drugs on different diseases.
By providing high quality services and scientific expertise, we make the testing of such drugs quick and reliable, ensuring that effective treatments are identified at the earliest opportunity. This means benefits to patients are realised in a timely manner and potentially harmful or ineffective therapies are identified long before they get to the stage of being given to people.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

This project will use rats and mice. The estimated number of animals to be used over the duration of the project is 6500.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

What happens to the animals? You should describe briefly what happens to them. Animals may experience mild distress as a result of the procedures. Animals will be closely monitored and any animals experiencing more than mild effects will be humanely killed.
At the end of an experiment, all animals will be humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

These studies are required to understand how drugs behave in an animal prior to moving into clinical trials.

The complexity of the pharmacological response cannot be wholly reproduced *in vitro. In vitro* experiments on cell lines and ex vivo experiments on cell cultures will be performed. However, the limitations of these methods do not allow them to replace the use of experimental animals: there is no alternative to the use of a living animal that would allow the objectives to be met.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The number of animals used will be the minimum required to ensure meaningful data is acquired. Experiments will be carefully designed to make sure that valid results can be obtained using the smallest number of animals.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Animal suffering will be limited by ensuring the most appropriate, robust and well-defined models are used in order to achieve the objective. Mice and rats will be used for the projects in this licence. Mice with changes in their genes may be used to mimic some human diseases.

Animal suffering will be limited by ensuring that the models used cause the least amount of harm to the animals. The mildest dose will be used, and studies will be kept as short as possible. Animals are monitored frequently for signs of discomfort, and appropriate action taken promptly. We will monitor animals closely throughout the studies, and they will be treated or humanely killed if they develop signs of excessive suffering.

Animals are housed in groups and kept in an appropriate environment with plentiful bedding and nesting material and suitable object that allow them to express normal behaviour. All staff are trained in good animal handling procedures. Animals are always handled gently and humanely, especially animals which may be in pain. Animals may be acclimatised to being handled prior to the experiment starting so that they are less stressed once the study begins.

NON-TECHNICAL SUMMARY

162. Physiology of the extracellular space of the brain and its role in neurodegeneration

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Rats	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to understand:

1) how protein aggregates are removed from the space in between brain cells during wake and sleep

2) how individual protein aggregates may interact with receptors on neurones inducing toxic effects

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodegenerative diseases are a heavy burden for individuals and society as a whole. By 2016, the global number of people with dementia was estimated at 43.8 millions (Lancet Neurology 2019; 18: 88–106), and this number is clearly on the rise. It is estimated that there are over 850,000 people living with dementia in the UK and that this costs the UK £26 billion a year. My project will address key aspects of dementia in a highly interdisciplinary way, aiming to clarify how the (suspected) main toxic agents which induce neurodegeneration are cleared out of the brain.

What outputs do you think you will see at the end of this project?

The main output will be in form of scientific publications. We will present this work in national and international meetings as well.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

To animals:

The project aims to understand how cerebrospinal fluid (or interstitial fluid, i.e. the liquid in between cells in the brain) flows inside the brain and how this affects the clearance of toxic protein aggregates (or protein particles) from the extracellular space of the brain. This has been a matter of debate for the past 50 years, and it is currently becoming an important topic in the field of neurodegeneration. The clearance of protein aggregates is an issue that affects animals in general, not only humans. Mounting evidence suggests that there are a variety of species that suffer different forms of amyloid and/or tau pathologies, including domestic dogs, domestic cats, a variety of non-human primates, REDACTED, black bears etc. Furthermore, we'll study how protein aggregates circulate this convoluted space and how does the complexity of the extracellular space of the brain affect the clearance of these aggregates and the likelihood of interactions between aggregates and receptors in neurons. Understanding the role of sleep in clearing toxic metabolites from the brain might also provide valuable insights into welfare of animals whose natural sleep patterns are disturbed by artificial light.

To humans:

We will provide novel experimental evidence in order to clarify the current controversies on the mechanisms by which the brain clears protein aggregates present in the spaces between cells. This is a fundamental issue in the field of neurodegeneration, and in particular in the field of Alzheimer's disease research. The results will also help to understand the risks that modern society faces with bad quality sleep due to the abundance of electronic devices that have been reported to interfere with good sleep habits in a large fraction of society, particularly among children. We will also study what is the direct toxic mechanism of protein aggregates when they interact with receptors in neurones, in particular the interactions of alpha-synuclein aggregates (relevant to Parkinson's disease) and amyloid-beta aggregates (relevant to Alzheimers disease) with a selected subset of their putative receptors. These interactions have been reported to impair memory formation and learning among other deleterious effects.

To scientific knowledge:

This project addresses both physiological and pathological issues of the brain that could not be studied until now due to the lack of suitable biophysical techniques. We aim to provide a better understanding of the (almost unexplored) physiological characteristics of 20% of the mammalian brain, and how is this regulated in wake and sleep. The consequences of this study have the potential of opening new avenues in Alzheimer's disease research.

How will you maximise the outputs of your work?

Our work is highly collaborative. We will collaborate and share results with top leaders in the field, including my established collaborators REDACTED, USA and the UK. Funded by the European Commission, I have opted into a Pilot project to share data online in a public way, so many other research groups can also benefit from this study.

Species and numbers of animals expected to be used

- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

The project requires the injection of tracers (small fluorescent particles, fluorescent dyes or proteins) to follow the flow of cerebrospinal fluid in the brain, as well as tracers to describe the behaviour of relevant actors in the mechanism under study. Once the tracers are in the brain, we need to study the trafficking of the tracers, the state of the extracellular space and the dynamic behaviour of related molecules. For this purpose we need to analyse the brain and cerebrospinal fluid using a variety of microscopy techniques, which require the preparation of brain and cerebrospinal fluid samples as well as the direct observation of the brain in a living (anaesthetised) animal through a cranial window.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

All procedures in the project will be done under anaesthesia, and in most cases this anaesthesia will be terminal. In one out of the three procedures needed, the animal will be injected with the necessary substances in the brain and then it will be allowed to recover. In this case, the animal will be given the necessary anaglesic doses and will be closely monitored. As all the substances that we need to inject are biocompatible (within the timeframe of the experiments) we do not expect any abnormal behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Two of the protocols are done under terminal anaesthesia, so animals will not recover. One protocol (injection of substances to the brain under anaesthesia) will allow the animal to recover, so we clasify the severity as moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To study the organisation and function of the space in between cells of the brain we cannot use cultured cells, as the native architecture of the brain is needed. We do not have an in vitro model to replicate the complexity of the brain’s extracellular space. Furthermore, in order to address the differences between the physiology of the extracellular space of the brain during wake and sleep we need to work with living animals. Nonetheless, whenever possible, we will replace the experiments in vivo by using primary or organotypic cultures.

What was your strategy for searching for non-animal alternatives?

I considered using cultured neurons, mixed cell cultures and organoids.

Why were they not suitable?

Although cultured neurons (or even cultured brain slices) are useful systems to investigate some neural mechanisms, they unequivocally differ in many aspects from cell networks in intact brain preparations (acute brain slices). For instance, the architecture of the cellular assemblies is strongly altered, causing changes in the extracellular environment and intercellular communication.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in the proposed project has been estimated from experiments I conducted during 4 years of work in REDACTED. There, REDACTED the tools to do single-nanoparticle tracking in brain slices and settled the experimental basis for the project I propose to do. The experiments proposed here have not been done before (the experimental techniques needed are not available elsewhere), so we are not able to predict a precise number of animals through statistical calculations. Nevertheless, based on the experiments I have done, I am confident that I can predict an upper limit to the number of animals that we will use.

To reduce the number of animals in the study we will work with cultured brain slices to obtain information about the organisation of the extracellular space of the brain, the abundance of cul-de-sac structures in the brain, the variation in complexity across different parts of the brain, and the regulation of the extracellular space volume. In vivo experiments will be necessary to take into account the effect of cerebrospinal fluid flow and blood pressure in extracellular trafficking, as well as the dynamical changes of the volume of the extracellular space of the brain between wake and sleep. In the case of the interactions between receptors and protein aggregates, every receptor under study will be first characterised in cell lines, subsequently in primary cell cultures and brain slices, and only once these experiments are done the overall model will be validated in vivo.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To estimate the numbers of anuimals needed we have extrapolated from similar studies previously carried out and made some educated guesses.

What other measures apart from good experimental design will you use to minimise numbers?

I will do computer modelling to explore the behaviour of the system and have more accurate experimental result. As I have done in the past, simulations of receptor mobility can help us to predict behaviour and narrow down the experimental parameters to be explored.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The model organisms to be used will be Sprague-Dawley rats, since they have a suitably advanced nervous system for investigating the mechanisms we want to address. This is the only species in which the extracellular space of the brain has been characterised in acute brain slices at the scale in which events addressed in this proposal are regulated (i.e. with a spatial resolution below 100nm). Furthermore, it is the only species in which the mobility of receptors has been characterised in brain slices at the single-molecule level. The proposed project will remain in the same animal model in order to maximise impact in the field by being able to compare results with the work of other research groups. Furthermore, this choice will decrease risk, workload and number of animals needed.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Two out of the three protocols needed are done under terminal anaesthesia. It is not possible to do the three protocols in this condition because we need time for the injected substances to diffusion along the brain. We cannot use more immature animals because the barriers in the brain are not fully formed and the physiological effects under study will not be fully functional.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To minimise the suffering, experiments have been designed in such a way that all stereotaxic surgeries are done under general anaesthesia. Out of these surgeries, 75% will be terminal and the other 25% will allow the animals to recover while they are treated with analgesics. All experiments encompassing cranial windows will be under terminal anaesthesia. In all cases we will use appropriate peri operative care measures as advised by the NVS and surgeries will be carried out under aseptic conditions.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The studies will be done in different levels of complexity: cerebrospinal fluid analysis, experiments in cultured cells, in cultured slices, in acute slices, and finally in vivo. These systems are routinely used worldwide in neuroscience laboratories, with well-established protocols that guarantee reproducibility of preparations and are robust enough to be compared across different laboratories. Protocols for dissociated primary cell cultures are commonly used for imaging purposes. Protocols for brain slices are commonly used when connectivity matters, as it is the case in electrophysiology studies and imaging studies that lack meaning in dissociated cells. The protocols for in vivo imaging experiments are equivalent to the well established in vivo 2-photon microscopy experiments performed in many laboratories worldwide. Additionally, we will use the ARRIVE guidelines to design, perform and report our in vivo experiments.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Discussing possible improvements to experimental conditions with technical staff and obtaining new ideas for improvement in forums such as LASA and NC3R.

Explain the choice ofspecies and the related life stages

The main goal of this project is to study the mechanisms by which the brain clears out small protein aggregates from the brain, in particular the aggregates that are located outside cells. Among these protein aggregates we will focus on the ones that are thought to be the cause of neurodegenerative diseases such as Alzheimer's or Parkinson's. In order to study how the brain naturally clears out these toxic agents, we need a model of study that has the physiological mechanisms relevant to this process. This can only be achieved using living animals, at ages in which the barriers between compartments in the brain are already formed and fully functional. The model organisms to be used will be Sprague-Dawley rats, since they have a suitably advanced nervous system for investigating the mechanisms we want to address. This is the only animal in which we have a detailed characterisation of the space in

between cells, which is very complex and dynamic. The proposed project will remain in the same animal model in order to maximise impact in the field by being able to compare results with what has been published about the extracellular space in the living brain. This choice will decrease the risk of the project.

NON-TECHNICAL SUMMARY

163. Platelets in haemolytic diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to understand the role of platelet's adhesion receptors in sickle cell disease and their contribution to inflammation and thrombosis. Platelet receptors involved in platelet activation also regulate immune cell activation and inflammation.

A retrospective assessment of these aims will be due by 27 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Classically, platelet are known for their role in haemostasis and thrombosis. However, recent work have shown their contribution to the inflammatory response, organ damage and wound repair. We have identified key receptors on platelets in particular CLEC-2, GPVI, CLEC-2 and TLR4 as key regulator for these activities using mouse model of lipopolysaccharide-induced endotoxemia and bacterial infection. These studies were performed in wild-type mice with no specific alteration or susceptibility to infection. In this licence, we will investigate the role of these receptors in a humanized mouse model of sickle cell disease, a haemolytic disease associated with increased susceptibility to infection. Therefore, targeting platelet receptors in this model might represent a unique pathway to decrease the severity to infection in sickle cell disease.

What outputs do you think you will see at the end of this project?

The aim of the work is to investigate the potential of targeting platelet adhesion receptors in inflammation and thrombosis in haemolytic diseases. The use of clinically relevant mouse models are critical to assess to role of platelets, identify targets and validate in vitro observations for selected drugs. The information generated will be published in peer reviewed scientific journals and can be used to inform clinical trials with the selected drug(s) in patients with haemolytic diseases. This would be undertaken in collaboration with clinicians at local teaching hospitals. It is hoped that if effective as the drugs to be tested in are already approved and used for other diseases such as Leukaemia and Malaria they could rapidly progress to human trials.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term, the data generated in this project will establish the role of platelets adhesion receptors in sickle cell disease. In the absence of key data on the role of platelets in sickle cell disease, it is currently not possible to assess the role of anti-platelet drugs. Therefore, using a humanized mouse

model of sickle cell mice will clearly define the role of these receptors in thrombosis and inflammation in sickle cell disease. This will inform the direction of future research that we disseminate to scientists and medical doctors through conference presentations, and publication of the data in scientific journals using the ARRIVE guidelines on animal experiment reporting.

On the long term, based on the results, selective drugs targeting platelets can be administrated, in particular drugs available on the market that can be re purposed to use in haemolytic patients.

Sickle cell disease patients develop pain crisis, with no available treatment. Identifying a target that can reduce thrombosis and inflammation is crucial to justify a clinical trial that can reduce pain in patients, decrease organ damage and increase survival in these patients.

How will you maximise the outputs of your work?

The information generated in this work will be published in peer reviewed journal. Even in the absence of beneficial effect of anti-platelet drugs or immunomodulatory molecules on thrombosis and inflammation, this information is needed to increase the knowledge about the cause of thrombosis and potential targets. Moreover, I collaborate with many experts in the field in haemolytic diseases, who will give advice on possible changes that will be required to study these diseases in mice and compared to patients.

Species and numbers of animals expected to be used

- Mice: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Terminal procedures will be undertaken under non recovery anesthesia where the animals will only be aware of the anaesthetic being administered and may experience mild distress and no pain. Procedures using infectious and inflammatory agents will also be undertaken under non-recovery anaesthesia.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Substances will be delivered under terminal anesthesia.

As sickle mice have progressive organ damage, they will show increase in the clinical disease over time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Sickle mice show impaired organ function.

Around 50% of mice used on the licence will develop the disease (Sickle mice) and 50% of mice have normal phenotype (Non-sickle mice).

Non sickled and sickled mice will be injected with substances under terminal anesthesia and will not experience pain or suffering from the procedure.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 27 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are not able to monitor inflammation and thrombosis leading to organ damage under haemolytic conditions in the laboratory. Our main output is assessing organ injury and thrombosis in multiple organs, which cannot be replicated in vitro because of the complicated nature of the interrelationships involved in these processess.

What was your strategy for searching for non-animal alternatives?

The fundamental reason why the use of animals is required to understand these processes is that at present no methods in the laboratory exist to model hemolytic diseases. Therefore, many experiments will be performed in vitro but the use of animal work of crucial to assess the relevance.

We are currently working on developing organoids to mimic the complex environments in different organs. If we are successful, many of the animal work will be tested using organoids and the use of animals will be further reduced.

Why were they not suitable?

As mentioned above, sickle cell disease are highly complex multifactorial diseases that cannot be mimicked in vitro. Although some studies can be done in vitro, the clinical relevance cannot be observed in vitro or ex vivo. Therefore using animals of hemolytic dieases are crucial to understand the underlying mechanisms.

A retrospective assessment of replacement will be due by 27 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The approximation of the sample size for in vivo experiments was done by the G*Power 3.1.3 software. In HUS, the major read out is kidney function assessed by blood urea nitrogen (BUN). Based on my preliminary data and the literature, a sample size of 8 per group would provide 80% power to demonstrate a difference of at least 50% in one of the major parameters of interests (BUN). A similar sample size will be applied for SCD. For intravital microscopy, based on published data and our previous experience, the sample size for the intravital microscopy experiments, based on 70% effect size, α error probability taken as 0.1 and desired power value of 0.80, gave a value of 6 mice per group. For platelet functional assay, based on our previous experience, 5 mice are required to assess platelet aggregation and protein phosphorylation. For microfluidic assay, 4 mice are required per experiment to test the inhibitory effect of drugs. Two-way ANOVA with Bonferroni's multiple comparison test will be used to compare the effect of platelet receptor deficiency or drugs on kidney and lung function. Mean differences in other parameters will be analysed by either Student's t-test (two groups comparison) or one-way ANOVA with Bonferroni post-hoc test (more than two groups) using GraphPad Prism software.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

As mentioned above, the numbers were calculated based on our previous experience and based on power calculation.

Reduction will be achieved by first performing experiments on human platelets and immune cells through the use of pharmacological inhibitors to identify proteins of interest. All inhibitory will be first tested in vitro using ex vivo flow assay to perfuse blood on endothelial cells before injecting in mice. Only receptors that show clear role in flow assay will be tested in mice.

We have refined our techniques for use of small amounts of blood from mice. This has involved development of new tests that require very small numbers of platelets, such as flow cytometry and static adhesion assays. Thus, through the combination of this experience and allocation of people, we are able to keep the numbers of mice to the minimum required to answer a particular question.

What other measures apart from good experimental design will you use to minimise numbers?

Statistical analysis to ensure that we use the minimum number of mice per group that will be informative will be performed.

We are using a staged approach, involving pilot studies to ensure that an appropriate number of animals are to be used.

To maximize the information gained from a single animal we aim to take samples from the blood under terminal anaesthesia and then from multiple body sites post mortem.

A retrospective assessment of reduction will be due by 27 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The vascular and immune system of mammals is highly conserved with cell types and mechanisms well-maintained. The mouse has been selected because of established and reliable transgene technology and extensive literature on sickle cell disease and haemolytic uremic syndrome (a collection of diseases that involve destruction of red blood cells and inappropriate clotting which leads to kidney damage) models in murine strains with established and reproducible protocols due to the reliable reagents available.

In SCD mice, we will use a behavioural clinical score indicative of the extent pain and distress that each animal is experiencing to help ensure humane endpoints are maintained. In addition, pain relief and hydration will be maintained throughout the protocol to reduced pain and suffering.
Blood count will be a good marker for VOC development.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The aim of this study is to assess the role of platelet and immune cell interaction in disease development and progression. It is therefore not possible to perform this on terminal anaesthetised mice. However, their response to inflammatory response in the presence of anti-platelet drug, which is the most severe protocol, will be performed under non-recovery protocol.

We cannot use non-mammalian species for this work, as mammals are the only animals to have platelets. In mice there is established and reliable genetic alteration technology, and established tests of platelet function. There are a large number of genetically modified mutant mice available and there is extensive amount of work that has already been performed and published using mouse models

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Our procedures will be performed under terminal anesthesia.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment.

Experiments will be conducted in accordance with the guidelines published by the Laboratory Animal Science Association (LASA).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will stay informed by advances in the 3Rs through attendance of seminars and conferences, as well as discussions with the NVS and NACWOs.

We will review each experiment on completion to determine any refinements that can be applied to future experiments.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially used to replace animal use.

We will use SyRF the free online platform for researchers to perform a systematic review and meta-analysis of animal studies. https://www.nc3rs.org.uk/camarades-nc3rs-systematic-review-facility-syrf

We will also stay up to date with guidance published by the International Society for Thrombosis and Haemostasis (ISTH) Scientific and Standardisation Committee on the most refined experimental methods for haemostasis and thrombosis research.

Explain the choice ofspecies and the related life stages

Mice are the animal of choice as there are a large number of genetically altered mice available and because of the knowledge built up over 20 years of research. We will use adult mice, usually between 6 – 16 weeks of age.

There is no other model of sickle cell disease that can be used. The major problem in SCD is progressive organ damage. This cannot be monitored in vitro. Moreover, the use of humanized SCD mice are the closer model to the human disease.

A retrospective assessment of refinement will be due by 27 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

164. Polyclonal Antibody and Normal Serum Production

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Sheep	adult
Goats	adult
Alpaca	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The Aim of this Licence is to provide a high quality antibody and normal serum production service to the Scientific
Community throughout the World.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antibodies and normal serum is used by Medical Diagnostic Companies worldwide for the manufacture of Test Kits for the detection of disease in both The Human and Veterinary markets.

Diagnostic kits and reagents are used by Blood Banks and Hospitals throughout the world for the detection of common bacterial and viral diseases that include but are not limited to Hepatitis, MRSA, Salmonella, Yellow Fever, Shigella and Streptococcus infections.

It is a legal requirement to test donated blood for a range of diseases.

Antibodies are also used to better understand disease and dysfunction to further knowledge in a wide range of health conditions in man.

What outputs do you think you will see at the end of this project?

The Project will deliver outputs in the form of high quality antibodies throughout the life of the Licence. These outputs will be used immediately in products many of which are gold standard tests used in the ongoing testing in Hospitals and Blood banks on a daily basis throughout the World.

Where the project is delivering antibodies for research or vaccine development the outputs may take a longer to deliver benefit, these outputs may take the form of publications and new information.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The Business manufacture high quality IgG antibodies for use in diagnostic test systems that are used for the

identification of infective agents and physiological disorders.

Prompt and effective treatment is required in some diseases where a severe infection or fatal outcome is likely.

E.g. Bacterial Meningitis infection in children, where rapid detection is required so that appropriate treatment can
be administered without delay.

Early identification of an infectious agent can be of considerable value in providing the patient with appropriate
antimicrobial treatment and minimising the risk of spread of infection to susceptible individuals.

How will you maximise the outputs of your work?

The Business will work closely with clients to record data on antibody response, initially to ensure that minimum severity is used to achieve objectives but secondly to maximise outputs.

Objectives can be measured as titre level of response and volume of antisera generated.

This plan of work will be progressed by strong data gathering and regular discussions with clients, ERP meetings will used to drive the initiatives.

Species and numbers of animals expected to be used

- Sheep: 950
- Goats: 450
- Camelids: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be injected with a set of antigens a minimum of 14 days apart to evoke an immune response.

In the short term 6-9 injections will be carried out over 3-6 months.

Adjuvants will be used in conjunction with the antigens to improve response.

Antibodies will be produced in the animals blood system, these will be harvested by the removal of blood from the animal on a monthly basis or by terminal harvest.

Depending on the type of work animals will either be humanly ended where all blood will be harvested.

Where the work is on a longer term basis animals will be kept as donors to supply up to 10 blood samples per year.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals may experience mild reactions at injection sites, these are rare, during the blood harvesting phase animals may suffer anemia.

There are set procedures to monitor all potential side affects which include monitoring the blood of each individual to ensure that animals are fit and healthy, individuals may be rested and supplemented with vitamins to ensure health is maintained. Each animal is monitored for early signs of reaction to the antigen.

Animals kept for long term supply of blood will be given two rest periods per year.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All animals are classified as Mild severity

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Sheep, Goats & Camelids have been historically used for antibody production, they were originally chosen for their ease of use (blood sampling & antigen dosing), plentiful supply and ability to produce high quality antibodies.

Currently there are no methods available for the production of specific polyclonal antibodies using non animal alternatives.

What was your strategy for searching for non-animal alternatives?

Production of polyclonal antibodies is not achievable without a living mammalian host.

Why were they not suitable?

No answer provided

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals stated are based on historical use.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Reductions of 30% have been achieved in the last 12 months by maximising techniques for the recovery of blood and processing in the Laboratory, this initiative will be continued.

What other measures apart from good experimental design will you use to minimise numbers?

Purpose bred animals that produce larger volumes of serum due to their size and weight (purpose bred strains) will be used where possible, these animals will be bred on site.

A further 25% reduction of animal use has been achieved in the last 2 years with this approach.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Sheep and Goats have been historically used for antibody production, they were originally chosen for their ease of use (blood sampling & antigen dosing), plentiful supply and ability to produce high quality antibodies.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Adult, mammalian animals are required for the the generation of antibodies used in medical diagnosis of disease in Humans.

Sheep, Goats and Camelids are well suited for this role.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinement is achieved in many ways including; use of disease free stock, an ongoing training / coaching system of staff to ensure good welfare, environmental enrichment, objective health monitoring, and regular assessment of individual staff and their procedural techniques.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

NC3R's

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Regular meeting attendances and effective ERP meetings.

Explain the choice ofspecies and the related life stages

Sheep and Goats are commonly used for the production of polyclonal antisera.

Alpacas and Llamas are used to provide a unique type of antibody
.

Adult animals are used as they have well developed immune systems and peak weights which ensures good antibody production and larger volumes of harvested blood.

NON-TECHNICAL SUMMARY

165. Preclinical safety, efficacy, and pharmacokinetics of antimicrobial peptides and antibiotics for corneal infection

Project duration

2 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overarching aim is to assess the safety, efficacy, and key biological measurements (pharmacokinetics parameters) of our newly identified antimicrobial peptides alone and/or in combination with antibiotics in mouse model of wound healing and corneal infection

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Clinical need: Cornea is a transparent window in the front of the eye. Corneal diseases are the 5th leading cause of blindness globally[1]. In addition it accounts for 2 million new cases of single-eye blindness every year[1]. Corneal infection represents a major cause for corneal blindness worldwide, with contact lens wear and trauma being the main risk factors[2]. *Pseudomonas aeruginosa* (PA), a bug, is the commonest cause of corneal infection with worst outcomes of disease. Lack of effective therapy and constant rise of multi-drug resistant (MDR) bugs have increased the prevalence of blindness[2]. One of the strategies of the World Health Organization (WHO) is to improve the effectiveness of existing antimicrobial agents and/or development of alternative drugs[3]. Vancomycin (VCN) is a last resort antibiotic used for treatment of difficult to treat infections caused by a bug known as methicillin-resistant *Staphylococcus aureus* (MRSA) [4]. However, it does not cross through the surface (outer membrane) of another bug (Gram-negative bacteria including PA) and therefore less preferred for clinical treatment[5].

Solution: Antimicrobial peptides are naturally occurring host defense molecules with killing activity against a wide range of disease causing bugs[6]. FK13 and FK16, the small size peptides, have previously shown greater killing effectiveness against a variety of bugs such as bacteria and fungi[7]. We have successfully showed that FK16 *has* specialised abilities (creates hole on the surface of bacteria), which helped improving the bug-killing capability of antibiotic [8].

However, thus far, it is unknown whether the peptide/antibiotic combination therapy is ready for the management of corneal infections. It is anticipated that the proposed animal studies will confirm the safety and efficacy of this new therapy and provide a platform to undertake more advanced studies and early clinical trial for the treatment of corneal infections in humans.

REDACTED

What outputs do you think you will see at the end of this project?

The key output will be the preclinical safety, efficacy, and key biological data (pharmacokinetic parameters) for the proposed peptide/antibiotic combination drug. These outcomes will be protected as

intellectual property and lay a strong platform to test our new drug therapy in human-based clinical trials.

The results of this study will also form the basis for high-quality publications and impact the research excellence framework (REF) outputs of our REDACTED.

Pseudomonas aeruginosa is an opportunistic bug (a bacteria) that also affects other bodily organs such as kidney and lungs. Thus, outputs of this proposed study will be utilised to gain translational REDACTED to test this new combination therapy in the animal models of renal and lung infections.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Who will benefit?

1. Patients and the health services

2. Industries and policymakers

How it will benefit?

Benefits topatients and the health services: Eye infection caused by bacteria is one of the leading causes of single-eye blindness and other life-threatening bodily infections. The proposed new drug treatment could considerably improve patient's quality-of-life, ultimately reducing overall burden on the UK's national health services and global healthcare systems.

Benefits to industry and the policy makers: The discovery arising from this study will be commercially protected as an intellectual property (also known as a 'patent'). With an added advantage to utilise this drug therapy for other bodily infections, pharmaceutical manufacturing firms will be benefited. This will improve their economic output and eventually their budget for translational research. The research outcomes will impact the policy makers/regulatory bodies, promoting fast-track approvals for patient-based studies and implementation of our drug therapy for the treatment of infections.

Timescales of impact:

With the successful outcomes from this research, we have plans to initiate advanced animal and early clinical safety trials (Phase I) within 12-18 months. These studies will be complete in 2-3 years. Next, a larger phase II/III trials will be conducted to assess the efficacy of therapy in patients with corneal infection. The culmination of phase II/III trial studies (up to 3-5 years) will provide necessary clinical data to seek for the fast-track MHRA (Medicines and Healthcare products Regulatory Agency) and FDA (Food and Drug Administration) regulatory approvals for using our new therapy combination for treatment of infection.

How will you maximise the outputs of your work?

This study is now funded through the institutional support by the UK Medical Research Council under the Confidence in Concept scheme. It is anticipated that the outputs will include meaningful preclinical efficacy and safety data, which will form the basis for advanced studies through translational funding from the MRC Developmental Pathway Funding Scheme (DPFS), National Institute of Health Research (NIHR) i4i scheme or UKRI (Innovate UK scheme) within 18-24 months of completion of this project.

Dissemination Plans:

Corneal infection is an avoidable blindness condition. Within 6-12 months of completion of study, my group will engage in educational activities targeted at young people and adults to promote awareness of hygiene and proper use of contact-lens and their implications to blindness. Additionally, we will also involve societies/charities such as Fight for Sight (FFS), National Eye Research Centre (NERC) and Sight Savers International (SSI) and Royal National Institute of Blind People (RNIB) to disseminate research findings, receive lay-man reviews and building capacity for future research. To disseminate our findings, we will ensure timely publication of our research in high impact peer review journals and through conference attendance/presentation (national and international). Providing there is no copyright

infringement we will also deposit published papers on professional social media sites such as ResearchGate and LinkedIn to archive publications, providing easy access for interested parties.

Species and numbers of animals expected to be used

- Mice: 1) Corneal wound-healing model=60 mice; and 2) Corneal-infection model=360 mice

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Protocol-1: Corneal wound-healing model. BalB/C mouse is a widely used strain of animal for testing drugs for eye diseases as these animals have an excellent ability to heal corneal ulcers naturally.[1-6] For the treatment of corneal infection in humans, antibiotics are frequently applied as drops on the surface of eye at a wide range of concentration (0.1 to 5% w/v) at repeated intervals. Here, we will test the safety of peptide/antibiotic combination only on one eye of 8-10 weeks old adult mice in a similar fashion.

Under anaesthesia (both local and general), we will create the superficial wound on corneal surface (removal of central epithelial layers) using an appropriate published technique (e.g. ocular burr).[3] Peptide (e.g. 0.01, 0.05, and 0.1% w/v) in combination with antibiotic (e.g. 1, 2, and 4% w/v) will be applied as drops on the surface of eye at an interval of 4 times/day (3 hours apart) for 3 days. Animals treated with clinical-grade antibiotic drops and sterile buffered saline will be used as control groups.

Healing of corneal wound will be checked every day up to 4 days using a clinical technique under mild anaesthesia (staining with a sterile sodium fluorescein dye). Images of stained cornea will be analysed using a specialised software (e.g. ImageJ) for measurement of corneal wound. At the end of day 4, animal will be killed to retrieve cornea tissue for laboratory-based analysis (assessment of inflammation).

Protocol-2: Corneal infection model. In humans, corneal infections are often regarded as emergency conditions and their treatment involves use of antibiotics as drops on the surface of eye at high concentrations in a repeated manner (*one-drop per hour for first 48 hours and then four times/day for next 3-7 days or until clearance of infection*). Corneal infection mouse model has been widely used to test the effectiveness of antibiotics and antibiotic-like drugs. [7, 8] Our aim here is to utilise this model to test whether our peptide/antibiotic combination therapy is capable of clearing infection in the eye. Also,

we will ascertain the key drug indices (pharmacokinetic parameters - important for designing future clinical studies)
of peptide/antibiotic combination in this model. We have propose to use C57BL/6 strain of mouse for infection studies because they develop progressive infection similar to humans. We will set-up the corneal infection model using a well-characterised bug (*Pseudomonas aeruginosa*) as described in the literature. [7, 8]

Under anaesthesia (general and topical), corneal surface will be wounded using a sterile 26-gauge needle (three parallel, 1-mm long superficial scratches). Bacteria (one million in 5 micro litre suspension) will be applied directly onto wounded cornea. Another drop of anaesthetic drug will be applied after the animal is awake. A single injection of pain killer (analgesic) will be given to alleviate any pain at day 0. *However, continuous and regular use of analgesic or topical anaesthetic is contradicted and will interfere with the outcomes of our proposed combination therapy.*

Six different combinations of peptide and antibiotic will be tested as eye-drops (starting 6 hours p.i.; 4 times/day (3-hours apart) for 4 days) in mouse with infected cornea. Levofloxacin and sterile buffered saline will be used as control drugs. Animals will be monitored every 24 hours (**2-4 times/day**) for five days for clinical assessment of infection and general signs of well-being. All experiments will be performed in two groups in a staged manner: 1) Bacterial killing and 2) Advanced pharmacological assessment.

Group-1: As a first step, we will test the effectiveness of drugs in infection model. Mice will be killed at different days (day 1, 3, and 5) of treatment duration to assess how quickly the infection is cleared. We will specifically measure the amount of bacteria remaining (titer quantitation (CFU per gram)) in the cornea tissue, which will be retrieved from killed animals.

Group-2: For advanced pharmacological assessments, mice will be killed at different durations of treatment to retrieve bodily tissues. Cornea and serum will be analysed for measurement of free concentration of peptide and antibiotic using a specialised technique [e.g. Liquid chromatography-tandem mass spectrometry (LC-MS/MS) methodology (at the National Mass Spectrometry Facility, Swansea)]. Other bodily tissues from killed animal will also be collected and stored in deep freezers (-80C) for future analysis.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Protocol-1:

- Mice with wounded cornea should only experience a mild level of discomfort (e.g. saline treatment group). Corneal wounds are naturally healed within 2-3 days.
- If application of drops containing high concentration of peptide/antibiotic combination delays normal wound healing or show dense cloudiness (i.e., within 2 days), the mice is expected to experience a moderate level of discomfort (include hunched back, subdued and unresponsive behaviour, and greater than 15% bodyweight loss).
- Non-healing or highly irritant cornea will show dense cloudiness covering the entire surface and this can be visualised cage-side without fluorescein staining. These animals will be taken off the study and culled as per Schedule 1 procedure.
- The humane endpoint includes delayed healing of corneal wound leading to moderate discomfort, which includes hunched back, subdued and unresponsive behaviour, and greater than 15% bodyweight loss.

Protocol-2:

- Corneal infection caused by bacteria are rapidly progressive, therefore, it is expected that corneal surface will start to show mild cloudiness starting as early as 12 hours post infection.
  Mouse with a specific genetic features (C57BL/6 background) develops corneal infection similar to humans.
- In this study, we will be using moderate infection protocol to set up a clinically-relevant pharmacological mouse model. The treatment will be stopped on day 5 and animals will be killed

as per Schedule 1 procedure.

- There is a possibility that up to 10% of mice (e.g. in saline control and low drug treatment groups) may develop corneal perforation (tiny hole) at day 5 post infection. Therefore, to minimise this incidence, we will monitor the animals every day (**2-4 times/day**).
- Humane endpoint includes earliest clinical signs of corneal perforation and general signs of moderate discomfort.
    - *Early clinical signs of corneal perforation include focal thinning of cornea without or with discharge (white to off-white).*
    - *General signs of reduced animal well-being include hunched back, subdued and unresponsive behaviour, and greater than 15% bodyweight loss.*

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol-1:

- The corneal wound-healing is rapid and normally the superficial wound is repaired within 2-3 days.
- Based on our *in-vitro* safety results, it is anticipated that about **10-15%** of experimental mice that were treated with higher concentrations of peptide/antibiotic will show the signs of moderate discomfort by day 4.

Protocol-2:

- In group of experimental animals such as those treated with sterile saline solution (control group) and/or with low amounts of peptide/antibiotic, the infection will be progressive with mild cloudiness of cornea will be seen starting as early as 12 hours post-infection. In these group of mice, we expect to see common features of progressive infection such as cloudy cornea (covering entire corneal surface) with or without swelling/crater formation.
- Based on previous experiences of our collaborator's laboratory, mouse with one eye infected with bacteria will experience moderate discomfort (at day 5 post-infection) with progressive infection. There is a possibility that **between 5-10% of mice in control group** may develop corneal perforation at day 5 post infection.

*Note: We will monitor our mice every day (**2-4 times per day**) to minimise the incidences of corneal perforation. Animals showing early signs of worsening infection or corneal perforation such as focal thinning of cornea without or with discharge (white to off-white) will be immediately killed as per Schedule 1 procedure.*

- Similar to clinical cases, in group of mice that are responding to treatment, we do not expect to see any significant signs of discomfort and/or clinical signs of progressive infection.
- Based on plate-based bacterial killing data, the infection is expected to be cleared within 48-to-72 hours post-treatment with alleviation of the complete or most disease symptoms within 5 days.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Wound-healing model: Our recent non-animal, laboratory-based study showed that the new peptide/antibiotic are safe and have ability to kill bugs. However, full testing requires a bodily (physiological) system, including a functional blood vessel support network. It is not feasible to produce an adequate model of this complex system using *non-living plate-based model*. Isolated *ex vivo* eye tests (using cadaver donor tissues) account for a degree of multicellular interplay and can provide limited biological data. Still these cadaver model unable to mimic the response of the complex biological (physiological and systemic) milieu, which are responsible for mediating wound healing. *In vitro* assays (plate-based) cannot adequately model the complete array of physiological healing responses to a wound important in ocular surface injuries. Therefore, proposed *animal* work is required to ascertain the safety of therapeutic compounds.

Corneal infection model: *In-vitro* and *ex-vivo* models of corneal infection are available. However, they do not recapitulate the *in-vivo* host responses to infection. Bacterial corneal infection is a progressive disease that triggers typical host responses such as inflammation, infiltration of defence cells through limbal region of cornea, and reduction of corneal nerves function and wound-healing processes. Therefore, testing of our proposed therapeutics in an *in-vivo* diseased environment will provide essential data and proof-of-principle for subsequent human-based clinical studies

What was your strategy for searching for non-animal alternatives?

In-vitro cell based infection model

Ex-vivo cadaver corneal tissue infection model

In-vitro cell-scratch model

Why were they not suitable?

The above-mentioned models may not recapitulate complete *living tissue* disease events (Infiltrating immune cells and bacteria interaction and the resultant tissue inflammation) and bodily environment (tears, blinking, and their impact on drug adsorption and availability).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- Estimated number of animals (sample size) was calculated based on published studies and our previous experiences.
- Additionally, we have consulted a statistician based in our REDACTED to help with designing our animal studies.
- All animals in proposed studies will be coded with a random number and studied in a masked fashion (where investigator performing experiments and those that are analysing data do not know about the treatment each animal have received). At the end of each experiment, the code will be revealed to perform statistical analysis between groups. This will allow us to reduce biased errors.
- This is in accordance to human-based clinical studies and the ARRIVE guidelines for animal research.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Our published *in-vitro* results have demonstrated the superior safety and efficacy of test compounds and these results have formed the basis for the planned animal studies.

Proposed animal studies have been successfully funded by the Medical Research Council (MRC). This is a highly competitive award and undergo rigorous peer-review filtering.

All statistical analysis was prepared in consultation with a statistician based within the School of Medicine and these have been approved by the MRC peer-reviewers.

What other measures apart from good experimental design will you use to minimise numbers?

- Our non-animal laboratory based results have successfully showed that the peptide/antibiotic combination is safe and effective. Having this key data have considerably helped us to reduce the total number of animals required for planned experiments in protocol 1 and 2.
- As a first step, we will conduct pilot experiment using a small group of animals. This will optimise the key experimental procedures, ascertain the maximum amount of peptide/antibiotic that can be used safely, and will enable us to gather essential knowledge of disease progression in animals.
- The results from experiments in protocol 1 is anticipated to provide essential clues to avoid application of drops (containing high amounts of peptide/antibiotic) that may cause corneal irritation in animals that will be used in protocol 2. This will also reduce the number of animals required in protocol 2.
- Due to the costs of advanced analysis (e.g. quantification of free drug using LC-MS/MS methodology) and funding limits, we have only proposed to test the biological characteristics (e.g. pharmacokinetic parameters) of peptide/antibiotic in cornea and serum. We will also collect other bodily tissues from killed animals, which will prevent any duplication of studies and reduction of animal use for research in future. Tissues will be stored at deep freezers up to 2 years after completion of proposed study.

Table depicting the template of planned experiments under protocol 1. A similar plan will be followed for the protocol 2:

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Protocol 1 - Corneal wound-healing model: Mouse with superficially wounded cornea (corneal wound-healing model) naturally get healed within 2-3 days, therefore, should only experience a minimum level of discomfort. For animal welfare, we will be only wounding one eye for experimentation. All procedures will be performed under appropriate anaesthesia. To refine an ideal concentration, we will be testing a range of different amounts of peptide/antibiotics. Pilot experiment in a small group will establish the model system, standardise the key procedures, and refine the maximum amount of peptide/antibiotic that the animal could tolerate. The proposed concentrations was based on our *non-animal laboratory-based* safety and efficacy results. If the application of maximum concentration of combination therapeutics on wounded cornea delays normal wound healing then mice is expected to experience a moderate level of discomfort. However, the animals in experimental group that will show any signs of significant discomfort (at any time during study) will be immediately killed as per Schedule 1 killing procedure. Results from this model will provide us the information on the concentration of test combination therapy that is safe and do not delay wound-healing. This is to ascertain that the undue and significant discomfort to animals is prevented in subsequent planned studies in protocol 2.

Protocol 2 - Corneal infection model:

Mouse with one eye infected with bugs (optimised number of bacteria) is expected to experience a moderate level of discomfort at the peak of disease (at day 5 post-infection). Appropriate anaesthesia (general and topical) will be administered before wounding or infecting the animals' eyes to reduce the discomfort induced by the procedure. Another drop of anaesthetic drug will be applied when the animal is awake. A single dose of pain-killer can be provided to reduce any pain associated with the procedure. Animals treated with different concentration of drugs will be killed as per schedule 1 procedure for collection of eyes and blood.

Note: Continuous or regular use of anaesthetic/pain-killer are contraindicated for the management of corneal wound and infections because these have shown to worsen the healing process. *It is also noteworthy to mention that this same principle applies to patients who present with corneal infection in the clinical practice where anaesthetic drops are only used once during the initial corneal scraping for microbiological sampling and no further topical anaesthesia is continued based on the same reason.* Additionally, regular systemic analgesia may interfere with the biological outputs of planned studies.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice at mature age (8-10 weeks old) will provide us data needed for subsequent clinical studies in adult humans.

Body's defence system plays an important role in wound-healing and fight against infection therefore mice at immature life stage may not capitulate the clinical corneal disease.

Corneal infection is a progressive and active disease; therefore, it will be difficult to derive therapy data from terminally anaesthetised animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Only one eye of each animal will be wounded or infected and the other eye will remain untouched so that the impact on the general well-being of the animals is minimised to the best possible level. Corneal abrasion and infection will be performed under appropriate anaesthesia. Once the animal is awake after the procedure, one-drop of topical anaesthetic will be applied for post-procedure care. A single dose of pain-killer can be administered to manage post-injury pain at day 0 of the study. However, regular pain-killer or anaesthesia are contradicted and will interfere with the outcome of our therapeutics. We will utilise the appropriate clinical scoring and the NC3Rs mouse grimace scoring

systems for post-infection or post-wounding assessment of animals for any significant discomfort. We will assess the mice daily (under the supervision of NVS) and if any study animal showing significant signs of discomfort will be killed as per ASPA Schedule 1 and tissues will be collected as appropriate.

The mice will be housed socially during maintenance, but will be housed individually or maximum two/cage (for those in protocol 2 - corneal infection model) in view of the risk of cross-infection. For animals in protocol 1, they will be housed in group of 2 as per block design.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Corneal wound-healing model:

How will you ensure you continue to use the most refined methods during the lifetime of this project?

NC3Rs website (nc3rs.org.uk) will provide us the updates on the advances made in the 3Rs. Moreover, we will stay in regular contact with NACWO, NTO, and NC3Rs regional programme manager to receive any new updates related to 3Rs and implement them during the project.

We have access to the REDACTED-subscribed journal in the ophthalmology field, which will also keep us informed of new advances in studying preclinical models *i.e.*, experimental tools for studying how therapeutics kills bacteria in cornea of live animals. This will allow us to reduce the number of animals requested in this project.

Explain the choice ofspecies and the related life stages

Mouse as a model system is key for drug discovery process and it is central to transitioning of potential drugs from laboratory-to-clinic. Planned studies to assess the safety, efficacy, and key biological factors (pharmacological parameters) in the proposed mouse model systems will inform whether drug concentration in cornea during disease condition is at safe levels and will be sufficient to clear infection. Additionally, outputs from mouse models will enable us to refine the dosages of drugs for advanced studies and reduce the costs that will incur for extensive human-based clinical trials.

Home Office

NON-TECHNICAL SUMMARY

166. Preventing Neonatal Infectious Arthritis in REDACTEDs: Sources, Transmission and Characterisation of Streptococcus dysgalactiae

Project duration

4 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
REDACTED	neonate, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to identify methods to prevent a severe and common joint disease of new born REDACTEDs. We will study the bacteria which cause the disease, *Streptococcus dysgalactiae*, in order to identify sources and routes of transmission of infection from the mother and farm environment to the REDACTED. We will examine animal and farm level risk factors for disease. Our study will also contribute to separate project work to develop a vaccine against the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Streptococcus dysgalcatiae infectious arthritis (joint-ill) is a common condition of new born REDACTEDs that causes chronic pain and suffering to many REDACTEDs in the UK each year; as well as significant economic loss to the farming industry through REDACTED deaths and reduced growth rates. The disease will often occur despite farmers best efforts to prevent it. Therefore, to prevent "joint ill" and help improve REDACTED welfare this study will try to identify where the infections arise from, and how the bacteria reach the REDACTED in order to provide farmers with effective advice on how to prevent it. The study will also contribute to work on developing a vaccine against *Streptococcus dysgalactiae*.

What outputs do you think you will see at the end of this project?

Through a better understanding of *Streptococcus dysgalactiae* joint disease, transfer of new information and guidance to farmers and contributing to the development of a new vaccine, the project aims to benefit REDACTED welfare and contribute to a more sustainable and efficient REDACTED farming industry.

1. We plan to publish our work in publications in peer reviewed scientific journals. We plan to produce at least three scientific publications.

2. The findings of the study will be directly communicated to farmers in the form of updated guidance on prevention of *Streptococcus dysgalactiae* joint infections in REDACTEDs. This will be done through guidance documents, webinars, articles in farming press and on-line resources.

3. The outputs of the study will inform the development of a vaccine against *Streptococcus dysgalactiae* joint infections.

4. *Streptococcus dysgalactiae* bacteria are closely related to bacteria which cause human disease, and therefore knowledge of the bacteria gained here could also benefit human research.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

The beneficiaries of the work are therefore animal welfare, the farming industry, the veterinary profession, and the scientific community. The outputs of the project are planned when the project is complete.

How will you maximise the outputs of your work?

The project is collaborating with the UK REDACTED industry to ensure maximum dissemination of the knowledge gained from the project to farmers and veterinarians.

The project is collaborating with existing work on vaccine development against *Streptococcus dysgalactiae.* An effective vaccine would be a substantial benefit in our ability to prevent *Streptococcus dysgalactiae* infection in REDACTEDs.

We will also create a biobank of samples and bacterial isolates obtained in the study for use in other research projects. Anonymised data will be archived for use in other studies.

Species and numbers of animals expected to be used

- REDACTED: 200 REDACTEDs and 700 REDACTED

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

There are two studies:-

In the first we will collect faecal, vaginal and skin swab samples and blood samples from REDACTED from farms affected by *Streptococcus dysgalactiae* joint infections to identify REDACTED that maybe carrying the infection and passing it onto their REDACTEDs. Any REDACTED that are positive for the infection and equal number of healthy animals will be resampled for the next two years in order to find out where the infection is harbouring and how long they carry it for.

In the second study we will collect blood, faeces and joint samples from REDACTEDs naturally affected by this *Streptococcus dysgalactiae* joint infection, after which we will give the REDACTEDs an appropriate treatment for the disease. We will collect blood and faeces samples from healthy REDACTEDs of the same age on the same farm for comparison. We will also collect environmental samples, as well as faeces, milk and

vaginal samples from the mothers of diseased REDACTEDs and healthy control REDACTEDs so we may see whether the mothers are the source of infection to the REDACTED.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The REDACTEDs and REDACTED will experience brief pain or discomfort during the sampling which will last 10-20 minutes. They will remain on their own farms at all times, and diseased REDACTEDs will be provided with correct treatment for their condition.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Severity is mild for all animals in the study.

What will happen to the animals at the end of the study?

- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We require to study Streptococcus dysgalactiae joint infections in REDACTEDs already naturally affected by the disease, their mothers and control animals for comparison.

What was your strategy for searching for non-animal alternatives?

There are no non-animal alternatives models for *Streptococcus dysgalactiae* joint infections in REDACTEDs. However, we have used a questionnaire of farmers to gather as much data as possible on disease prevalence and risk factors without using animal sampling.

Why were they not suitable?

There are no non-animal alternatives models for *Streptococcus dysgalactiae* joint infections in REDACTEDs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used power calculations, estimates from previous studies and advice from other researchers in the field to calculate the sample sizes.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice from local statisticians, on line tools (Open Epi https://www.openepi.com/Menu/OE_Menu.htm) and advice from other researchers working in the field has been used.

What other measures apart from good experimental design will you use to minimise numbers?

The project sampling phase will run over three years so we will use data gathered in year one to determine if our calculations are accurate and if we are able to reduce our sample size. Furthermore in the longitudinal study all REDACTED on the farm will be sampled in year one but we are using a case control study design in years two and three to minimise animal numbers

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will study *Streptococcus dysgalactiae* joint disease in naturally occurring affected REDACTEDs. We will collect the minimum number of samples and minimally invasive samples from these REDACTEDs and healthy control REDACTEDs and REDACTED from the same farms. Sampling will be brief (10-20 minutes). Local anaesthetic will be used where appropriate. All diseased animals will receive appropriate treatment for the disease. All animals will remain on the farm of origin.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There are no animal models for this disease.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Local anaesthetic will be used for sampling from infected joints.

All animals will be monitored for at least 1 hour post sampling for any adverse effects, should these occur veterinary attention will be sought.

All diseased REDACTEDs will be treated appropriately with antibiotics.

Results of the study will be continuously monitored to ensure only the required number of animals will be sampled.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The study will be supervised at all times by an experienced farm animal veterinary surgeon.

All staff involved in farm sampling will be experienced in handling animals and trained personal licence holders.

ARRIVE guidelines will be used for study design and reporting.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The project licence holder will stay informed about advances in 3R's through engagement with the National Centre for Replacement Reduction and Refinement of Animals in Research Website and through seminars and information disseminated through the research institution where the project licence is held.

Explain the choice ofspecies and the related life stages

The project will study the disease of young REDACTEDs *Streptococcus dysgalactiae* joint infections. We wish to collect samples from REDACTEDs already affected by the disease, their mothers and healthy control animals in order to understand the bacteria causing the disease; where the infection comes from; how it spreads to the REDACTED; and what farm management practices contribute to its occurrence.

Home Office

NON-TECHNICAL SUMMARY

167. Preventing SARS Coronavirus 2 infection and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, aged
Hamsters	juvenile, adult, aged
Ferrets	juvenile, aged, adult
Marmosets	juvenile, adult, aged

Animal types	Life stages
Rhesus macaques	juvenile, adult, aged
Cynomolgus macaques	juvenile, adult, aged
Tamarins - red bellied (Saguinus labiatus)	juvenile, adult, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To establish appropriate models of infection with SARS Coronavirus 2, so that the mechanism of preventing infection or disease may be established and effectiveness of potential treatments evaluated.

A retrospective assessment of these aims will be due by 02 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immediate global threat of Covid-19 caused by SARS Coronavirus 2 cannot be underestimated. More than 20,000 deaths have been recorded in the UK to date and worldwide, it is possible that many millions may die as a result of SARS Coronavirus 2. It is critical that suitable animal models of SARS Coronavirus 2 infection and/or disease are identified and developed very quickly, so that candidate vaccines may be evaluated at the earliest opportunity. This will ensure that the most promising

candidates are selected rapidly for further development. Previous studies trying to develop vaccines for other Coronavirus infections of man or cats have found that immunisation with some candidates may not prevent infection, but may make the disease worse. We must identify whether this is the case for SARS Coronavirus 2 and identify the mechanism of how to prevent infection and avoid making the disease worse.

What outputs do you think you will see at the end of this project?

We expect to publish scientific papers that will be published in open access journals describing the studies that have been undertaken and the ensuing results.

We anticipate that these data will guide the development of documents that provide medicines manufacturers and regulators with a framework for performing safety and efficacy tests for products designed to prevent or treat infection with SARS CoV 2 which causes Covid-19

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

It is anticipated that the attainment of intermediate Objectives 1 and 2 will generate data that will establish the most appropriate model for evaluation of infection and or disease. This will impact on medicines manufacturers and regulators within a year of initiation of the project by providing information on the appropriate laboratory animal model that they should apply to ensure that candidate medicines are both safe and effective.

The completion of Objective 3 will provide a go/no-go decision on the progression of a candidate antibody-based medicine into clinical trials in the UK

In the longer term the attainment of Objective 4 will provide a robust framework for developing superior assays that apply the principles of the 3 R's in achieving the same safety and efficacy data.

How will you maximise the outputs of your work?

We shall collaborate with scientists at other establishments in the UK and elsewhere. In some cases we shall receive candidate materials from others for pre-clinical evaluation in the model systems established at this site. In other cases we shall share information at an early stage on our planned studies and also early results with other establishments with equivalent facilities to ensure that each programme of work does not duplicate but complement each other.

We anticipate that engaging with appropriate international teams dealing with Coronavirus outbreak and under the auspices of WHO will enable our data to have early global impact, whether it is positive or negative.

We will work closely with national regulators and medicines/vaccine developers to share our knowledge and information at the earliest opportunity.

We shall publish our work, initially in pre-print on line platforms and then in peer reviewed open access journals to share our data at the earliest opportunity.

Species and numbers of animals expected to be used

- Mice: 250
- Hamsters: 125
- Ferrets: 80
- Marmosets: 40
- Rhesus macaques: 80
- Cynomolgus macaques: 80
- Other non human primates: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In initial studies, animals will be administered a specific amount of virus onto the nose, into the trachea or onto the surface of the eyes to mimic the routes of transmission of SARS CoV 2 between humans. Blood and oral and nasal swabs will be collected before and after administration of the virus. These will be analysed for the presence of the virus and/or antibody or other responses made by the animal to the virus. Once the most suitable species is identified for further study and the timetable of virus detection and control is determined, then animals will be treated with a candidate treatment such as a vaccine or an antibody-based medicine before being administered with the virus. These studies will last no more than 4 months with the virus infection part lasting just over a month.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some animals may get coronavirus disease, but the evidence from studying related corona viruses is that the disease in most animal species is relatively mild. Treating animals prior to infection will be

similar to people being vaccinated - a short pain for the duration of injection. There is a small risk that some vaccines and treatments may make the subsequent SARS CoV 2 infection worse. If so then there may be fever and weight loss - weight loss may be controlled/slowed by providing supporting husbandry measures eg easily consumed food. These would normally be expected to last a couple of days and then recovery observed. If this is not the case then animals will be killed humanely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most studies will be classed as Moderate Severity. In most cases this will be because of the needs for animals to undergo surgery to allow implant of a remote telemetry device that allows continuous monitoring of body temperature and movement. This device, which is about the size of two kidney beans stuck together will be implanted under the loose skin in the scruff of the neck/back, where they are well tolerated by ferrets and non-human primates. A much smaller device is used in mice and hamsters.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 02 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to understand the basic cellular and molecular pathology of infection and complex multi-organ host responses, it is necessary to use laboratory animals. Furthermore, the complexity of host immune responses to experimental treatments including candidate vaccines or antibody-based medicines, cannot be fully reproduced in in vitro systems. The urgency for identifying safe treatments or vaccines requires rapid action. Waiting for results from other groups to be shared in order to establish whether it may be possible to model aspects of this programme of work in vitro or in silico would introduce delays in development of safe effective treatments. This would lead to people dying from Covid-19, perhaps unnecessarily.

What was your strategy for searching for non-animal alternatives?

In vitro recapitulation of susceptibility of different cell types to virus infection. In vitro methods of recapitulating induction of immune responses.

Why were they not suitable?

Neither methods provide the appropriate combination of cell types in the 3D structure found in the broad range of organs to either fully mimic the situation in vivo

A retrospective assessment of replacement will be due by 02 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on each species being suitable as a model for SARS-CoV 2. However, as described previously, it is not envisaged that all species will be taken forward but the most appropriate for the scientific questions that are being addressed.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Initially the concept of performing a pilot study rather than large group study will enable an indication of the species which are susceptible, and the comparative course of disease resulted in a significant reduction in the number of animals or all species. Subsequently, the selection of only up to 3 specific laboratory animal species for more detailed analyses, based on similarity of infection kinetics and host responses to those of humans (including expression of disease symptoms) will reduce the total number of laboratory animals required. It is not anticipated that experimental treatment studies will need to be performed in more than one species, unless there is a likelihood that they may yield markedly different outcome (for example a vaccine or treatment that might protect in one species but not in another). The group will use the regular flow of pre-published reports from other groups around the world to guide

experimental design, prioritise studies and prevent duplication. This information will be gathered from regular telecoms coordinated by international organisations such as WHO and CEPI.

What other measures apart from good experimental design will you use to minimise numbers?

If fewer than 3 species prove to yield robust models of infection and disease with SARS CoV 2, then the 1 or 2 suitable models only will be studied. In addition, to good experimental design for a single experiment, where a series of challenge studies are planned then committing to the use of a common challenge stock of virus or a positive control treatment, will enable positive and negative controls to be combined from each stand alone study increasing the statistical robustness of the studies.

A retrospective assessment of reduction will be due by 02 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

At a time when we are responding to a new infectious agent causing large numbers of deaths worldwide, we need to identify the most appropriate models for studying disease and establishing the risks and benefits of treatments quickly. Therefore, it is proposed that Mouse (normal and human receptor expressing) hamsters, ferrets, New World and Old World monkey models should be compared and provide head to head analysis of infection and disease. Using the data generated then selected models will be developed further.

The use of remote measurement of body temperature and movement will minimise the amount of animal handling required and yet important and frequent measurements of key disease markers.

It will not be possible to administer analgesics during the first 7 days after Step 5 of the protocol as fever is recognised as a key disease symptom which we would wish to recapitulate in a laboratory animal model. However, if fever lasts more than 48 hours or increases throughout this time, then analgesics will be permitted.

All subjects will be killed humanely at the end of the experimental protocol

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

A range of laboratory animal species will be compared and selected species taken forward. There will be an endeavour to include less sentient species for more detailed studies (particularly when larger number of experimental animals are required to evaluate potential medicines or vaccines). However as most studies last more than 2 weeks it is not possible to use terminally anaesthetised subjects.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Small animals are habituated into groups for 1+ weeks prior to entry onto study. Non-human primates are grouped according to information supplied by breeding organisation and habituated at our establishment for 2+ weeks prior to entry onto study. The application of remote telemetry to this study (for ferrets and non-human primates) is based upon experience gained from another PPL, where improved methods for surgery of implantation have been evaluated and applied. Early studies will establish the time-course of disease symptoms following infection. Once these are established, then the optimal timetable of treatment with analgesics that minimise suffering without interfering with scientific purpose of the study will be determined and applied going forward. Furthermore the timetable when more frequent monitoring of experimental subjects will also be identified and applied in future studies.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

FELASA guidelines will be applied to guide dose volume/route per laboratory animal subject. NC3R's documents on husbandry and housing and procedural work will be met or exceeded.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Within the field of Coronavirus work, I am linked into WHO and other scientific groups to hear of their scientific progress on the development of models. Through our network within our organisation, internally and externally developed improvements in 3R's are routinely shared to all PPL holders and these will be incorporated into the Coronavirus work as appropriate.

Explain the choice ofspecies and the related life stages

At this present time, when there is an urgent need to develop safe and effective treatments, we need to evaluate the widest range of species of laboratory animal for which there is evidence, from other

Corona viruses, that they may prove useful as a model of SARS CoV 2. Because there is clinical evidence that older people are at greater risk of severe disease, it is prudent that, for each laboratory animal species, old animals are compared with juvenile/adults of the same species. This may result in specific factors, that co-associate with age, being identified as risk factors for severe clinical Covid-19.

A retrospective assessment of refinement will be due by 02 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

168. Prevention of post-surgical adhesions

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Post-operative adhesions are abnormal bonds formed between organs or tissues after surgical procedures, which is one of the most prevalent complications after surgery. This project aims to investigate the cellular and molecular mechanism by which post-operative peritoneal (intra-abdominal) and pericardial adhesions are formed and furthermore develop new treatments to prevent adhesion formation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Post-operative adhesions occur in more than 90% patients after surgical procedures. This can cause critical issues, including bowel obstruction, pain and female infertility. Currently, millions of patients suffer this complication all over the world. As the only effective treatment, once developed, is invasive corrective surgery, prevention of this disorder is vital. However, current preventative treatments have limitations in the efficacy or availability. To develop innovative approaches, it is essential to further understand the mechanism underpinning the post-operative adhesion formation.

What outputs do you think you will see at the end of this project?

This project will develop pre-clinical evidence to validate new treatments to prevent post-operative adhesions, enabling further development of the innovative approaches forward to clinical application. In addition, this project will provide important new biomedical and scientific knowledge to understand the mechanism for adhesion formation and shed light on new biological insights, which will pave the way to future medical and scientific research. These pieces of new information will be presented at international conferences and published in academic journals.

There are also commercial opportunities associated with the innovative therapy for post-surgical adhesions (i.e. development of new drugs or new biomaterials). Therefore, this project potentially has a great impact on patients, doctors, scientists, the NHS and society. Thus, this project has great potential to help patients who have risks to develop post-surgical adhesions and save the cost to treat such patients.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Various people and sections will receive benefits from the outputs of this project.

Researchers (immediate): This basic and translational research project will provide a range of novel biological information regarding a mechanism by which post-operative adhesions are formed. This new scientific information will provide impact and benefits to researchers in a wide range of areas, including inflammation and immunology research. Also, through this research we will be able to provide high-standard training for the research staff and students involved in this project.

Patients, Clinicians and National Health Service (future): Post-surgical adhesions are one of the most important causes of complications following abdominal as well as heart surgery. This project will propose novel approaches for prevention of post-surgical adhesions, which will be further developed by subsequent pre-clinical and clinical studies. The new treatment proposed in this project is expected to effectively prevent such post-surgical adhesions, improving the outcome of surgeries, enhancing post-surgical quality of life of patients, and reducing labor and cost to maintain these patients. Thus, successful development of this treatment will offer great benefits on patients, clinicians and the National Health Service in the future.

Business and Society (immediate and future): Scientific success of this project will improve opportunities for advanced life science research training in cutting-edge technologies in the UK and attract international postgraduate and undergraduate students to our Institute as well as to the UK. Successful pre-clinical information obtained from this project will attract interest from commercial companies in progressing development of this innovative treatment towards clinical application, as this therapy possibly has a huge market. Through the effective dissemination of our results, the general public will be more aware of the benefits of developing and using a novel drug to treat human diseases. This will allow the full potential of such drug development to be recognized and will also attract large numbers of younger generations to enter scientific disciplines as a career opportunity. These aspects will support the UK in maintaining its reputation in medical research.

How will you maximise the outputs of your work?

To achieve the maximum impact from this project, we will fulfill all aspects of communications, in cooperation with the College's departments for Research & Development, Intellectual Property, and Public Engagement, according to our dissemination and engagement strategies as follows.

1. Publication and presentation: As soon as sufficient data is obtained in the proposed project, it will be published in high-quality peer-reviewed academic journals subject to consideration of protection of their potential for intellectual property and commercial exploitation. Our publication strategy will be taken in accordance with the College policy on "open access" publishing. The obtained results will also be presented and discussed at scientific meetings/seminars (institutional, national and international). This will help to disseminate the obtained results to academics, clinicians, and companies in the relevant field. In addition, to raise awareness of the potential of our new therapeutic approach in the hospital, we will introduce our project to clinicians, nurses, and other hospital staff at clinical seminars/lectures and via hospital newsletters.

2. Data sharing: Data produced in the proposed project will be preserved within our Institute for sharing among the researchers according to our institutional policy on data sharing and preservation. Raw data will be retained and available for possible review/audit, in digital format and as original materials. We will encourage collaborations (internal, external and international) via our website with a link to this project and through communications during the conferences.

3. Exploitation: Obtained results may include patentable intellectual property. Intellectual Property Department in our institute will help handle intellectual property issues, licensing, and commercialization of the exploitable results produced in this project.

4. Public engagement: Our REDACTED, School and Institute all have active public engagement programmes. Results produced are open to the public on their homepages and will be published in the Bulletin/Newsletter and REDACTED publications. Our publications contain special lay sections to make data accessible to public. If appropriate, the results of this project will be disseminated by media broadcast and newspapers. These engagements will collectively enhance public awareness of the importance of this project. In addition, our institute, particularly the Public Engagement Department, runs a number of outreach projects, including annual science festival, designed to reach local school pupils to raise their career aspirations through activities that include science experiments, work experience placements, visits to the College and talks from international leaders in medical research. Our project will be introduced during such public activities.

5. Business: This project will pre-clinically develop an innovative therapy for prevention of post-surgical adhesions. Thus, there is a good opportunity for business development, potentially attracting the interest of biomedical ventures or mega-pharm. Through our dissemination strategy above, we will maximize such an opportunity. I will be responsible for identifying additional intellectual properties and establishing appropriate protection of the data from this project before public dissemination.

6. Clinical medicine: Although the knowledge obtained in this project cannot be directly applied to the bedside, this project is one of the major steps to reach the ultimate goal of the establishment of a novel therapy for prevention of post-surgical adhesions. To raise awareness of the potential of our new therapeutic approach in hospitals, we will disseminate the progress of the project among doctors and other hospital staff through clinical seminars/lectures/conferences and hospital newsletters.

Species and numbers of animals expected to be used

- Mice: 2000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The adult animal will receive a peritoneal or pericardial adhesion-inducing surgery with one of the treatments to regulate adhesion formation (either prior to or at the time of the operation). Subsequently, animals will be followed up for adhesion formation for up to 90 days (commonly within 4 weeks). Then,

animals will be humanely sacrificed so that the degree of adhesion formation can be assessed and tissues/organs are collected for histological and biochemical investigations.

We will produce genetically altered animals, which do not exhibit any harmful phenotype. We will also produce bone marrow chimera mice through irradiation and bone marrow transplantation.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals are expected to recover uneventfully from any procedures in our project. No death is predicted by the protocols, and animals are likely to experience discomfort and pain of the mild-moderate severity temporarily during the immediate post-procedure period when the adverse effects will be limited with our countermeasures.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Up to the moderate severity in all animal types used.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The proposed project aims to develop a new treatment to prevent post-operative adhesions. In order to evaluate therapeutic effects of the treatment, measurements of the degree of post-surgical adhesions after the treatment are essential. The process to form post-surgical adhesions is extremely complicated, involving multiple cell types (both locally resident and recruited) as well as many molecules and signalling pathways, which cannot be mimicked without the use of animals.

What was your strategy for searching for non-animal alternatives?

We have considered a potential use of computer-based systems, lower organisms and embryo stages, 2-dimensional and 3-dimentional culture of cells relevant to adhesion formation including peritoneal

and pericardial cells. We have also considered the possible use of culture of peritoneal/pericardial tissue and organs.

Why were they not suitable?

Because any non-animal alternatives cannot appropriately represent complex in vivo processes associated with post-surgical peritoneal or pericardial adhesions, which include multiple cell types and cytokines/chemokines/growth factors. In addition, inflammation and fibrin formation/lysis, both of which are regulated by multiple cell types and factors, are tightly related in the mechanism of adhesion formation post-surgery. These work together, mutually affecting each other, toward adhesion formation as a whole. Only living mammals can be meaningful models that mimic the clinical scenario of post-operative adhesion formation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The proposed methods, experimental designs, and methods for analysis of the results have been discussed with the Statistical Service Unit in our Institute. The design of individual experiments generally involves factorial designs, which maximizes the information obtained from the minimum resource. Some of measures are essentially qualitative; others are quantitative, for which statistical analysis may be appropriate.

For the quantitative experiments, sample sizes are set using power analysis. Generally, the significance level will be 5%, and the power 80%. For example, in a four-group experiment, if the least practicable difference between groups is chosen to be 25% and if the coefficient of variation is estimated to be 15%, then about 7 animals per group would be able to give a solid conclusion.

Having said this, the exact numbers of animals required will vary according to the particular experimental model/treatment and the estimate of the coefficient of variation, etc. Such estimation may be difficult from only in vitro studies. In this case, we will conduct an in vivo pilot study to estimate the degree and variation of the effect, using which the accurate group size in each study will be determined.

For the qualitative experiments, the number of animals required will be the minimum necessary to provide an adequate description.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experiments were in principal designed by referencing to the NC3Rs Experimental Design Assistant. It is known that the degree of post-surgical adhesions is affected by surgical procedures. Good Practice should prevent, or at least minimise the introduction of bias into the experiments. This will, in turn, help significant reduction of the animal numbers used in this project. Accordingly, individual experiments will include:

- Randomisation of treatment or control
- Allocation concealment
- Blinded assessment of outcome
- Explicit inclusion and exclusion criteria
- Sample size calculations done before the experiment
- Monitoring and controlling of blood pressure and temperature during surgery
- Stable depth of anaesthesia

For each and every experiment, as part of good laboratory practice, we write an experimental protocol which includes:

- Astatement of the objective(s)
- A description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animal/group), and the experimental material.
- An outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated).

What other measures apart from good experimental design will you use to minimise numbers?

In principal, we will refer to the NC3Rs Experimental Design Assistant. Animals will be bred efficiently using a Standard Operational Protocol in our Biological Sciences Unit. In vitro pilot studies will be carried out to exclude less-promising approaches to regulate post-operative adhesions. All useful tissues/organs will be collected from each animal to reduce the number of animals required. Tissues/organs collected will be used to assess as many biochemical parameters as possible, which will also help to minimize the number of animals required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use rats and mice, which are the most suitable for this basic/pre-clinical investigation; basic pathophysiology on post-surgical adhesions is sufficiently compatible between human and rodents. In addition, the rodent models allowed the use of genetically altered animals or bone marrow chimera model.

Adhesion-inducing operation, which is used in this project, is the only appropriate experimental model to represent the clinical process of post-surgical adhesion formation. As the proposed project requires evaluation of post-surgical adhesions in clinically relevant settings, this model is needed. It is a fact that all previous reports have used this model to produce post-surgical peritoneal or pericardial adhesions.

The adhesion-inducing operations, either peritoneal or pericardial, are recovery surgeries and are classified to be “moderate severity”. Following this surgery, animals usually behave normally without any symptom. Appropriate analgesic regimes will be used during the surgery and also prolonged as necessary in order to minimise the pain, suffering and distress to the animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

There is no established model of post-surgical adhesions in less sentient animals due to technical difficulty. In addition, the basic pathophysiology on post-surgical adhesions is likely to be different between human and less sentiment animals. It is needed to study living animals in order to mimic the complex, long-term process of post-surgical adhesion formation. Having a similar anatomy of intra-abdominal organs and heart/lungs is essential, while this is not available in less sentient animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have used the procedures for the last 5 years, which have been well established and refined. However, we will continue our effort to further refine the procedures to minimize the animal suffering. This may be achieved by:

- the use of newly-introduced, more effective analgesic regimen and/or antibiotics. This will be regularly discussed with the NVS.
- less-invasive surgery, including minimizing the incision and reducing the surgical time.

- improved post-operative observation procedures.
- minimally invasive ways to assess the progression of adhesions, including advanced imaging.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

I will regularly refer to the Home Office homepage and documents, NC3R homepage and documents, and ARRIVE or PREPARE guidelines. This ensures full transparency in reporting all the in vivo experimental data.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will stay informed about the latest advances in the 3Rs through information/newsletters from the Home office and NC3Rs, attendance at relevant academic conferences and regular literature search. Identified new methods/protocols will be discussed with our Biological Sciences Unit staff, NVS and Home Office Inspector for the implementation.

Explain the choice ofspecies and the related life stages

The proposed project requires evaluation of post-surgical adhesions in clinically relevant settings. Adhesion-inducing surgery is the only appropriate experimental model to represent such a clinical process. We will use adult rats and mice, which are the most suitable for this basic/pre-clinical investigation; basic pathophysiology on post-surgical adhesions is sufficiently compatible between human and rodents. Lower species are not suitable to this aim. In the rodent models, we will be able to use genetically altered animals and bone marrow chimera animals (animals whose bone marrow is replaced with other animal's bone marrow that has specific features). The use of these animals enable in-depth investigation of molecular and cellular mechanism for post-surgical adhesions.

Home Office

NON-TECHNICAL SUMMARY

169. REDACTED

Project duration

5 years 0 months

Project purpose

- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Cattle	juvenile

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to generate larvae REDACTED. This is done by working with a natural host (cattle) in whom many larvae can be cultivated and harvested from the faeces of very few animals. The larvae are later attenuated and used to produce a vaccine which protects cattle against REDACTED. Generation of larvae for the vaccine is known as 'primary production'. The resulting vaccine is well established and widely distributed.

A retrospective assessment of these aims will be due by 27 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

REDACTED is a common disease of cattle in temperate regions of Europe. Clinical symptoms usually begin with coughing and raised respiratory rate and effort. In extreme cases, severe respiratory distress and death can occur. As sexually mature worms develop in the bronchi and trachea, animals suffer bronchopneumonia and acute obstructive pulmonary disease of varying severity depending on infective dose, general condition, climate and opportunistic secondary infections. Clinical signs may abate as active immunity develops but lasting and irreversible damage may have occurred to the respiratory system. During infection, wellbeing and productivity of infected animals are significantly compromised.

Husk outbreaks are not predictable from year to year. Build-up of infective larvae on pasture can occur very rapidly in optimal conditions and severe disease can occur rapidly in the absence of immunity. Although modern anthelmintics can control, treat and suppress REDACTED, they only act while the active ingredient is present within the body and offer no immunity. There is also increasing concern over anthelmintic resistance and their usage should be minimised. There is demand for vaccination. The vaccine is the most logical and environmentally friendly method of controlling this disease and offers benefits for the health and welfare of cattle and calves at a time when (out at pasture) they may be exposed to the parasite and be clinically monitored infrequently. Enough larvae to satisfy the entire global demand for vaccination is produced from approximately 30-40 calves per annum. Therefore the cost:benefit analysis is highly favourable.

What outputs do you think you will see at the end of this project?

It is expected that for each year this project remains active, the global demand for REDACTED shall be met.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Vaccination with this product is extremely effective. Therefore, given the predicted demand during the life of the project, approximately 2 million cattle shall directly benefit from protection. This helps to preserve their wellbeing, optimise milk and beef yields on farm and reduce reliance on anthelmintics in response to REDACTED outbreaks.

How will you maximise the outputs of your work?

Close collaboration with colleagues within the organisation has identified potential ways to increase recovery of larvae from raw harvest. This may mean more vaccine can be made, and/or fewer calves can be worked with. There are concepts to be able to extend the shelf-life or get the product to market with more shelf-life remaining. This creates the potential to look to new markets and increase the sales and protect more animals. It is entirely feasible that the above are achieved with no increase in animal usage.

Species and numbers of animals expected to be used

- Cattle: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Calves are appraised and possibly blood sampled on farm from one day of age onwards, and not commonly sampled on farm beyond two weeks of age. This sample may be screened for acceptance criteria to bring to site.

Suitable calves are brought to site whereupon occasional samples including faeces and blood are taken to assess presence of certain pathogens. Calves are enrolled on a comprehensive vaccination programme for good herd management which is outside of the scope of the Act. Vaccinations are commonly a combination of injectable or intranasal administrations.

Calves may also be subject to a bTB comparative intradermal test for regulatory bTB testing. Currently a similar test may also be conducted for Johnes disease.

The above procedures occur during the rearing phase i.e. before infection with REDACTED larvae. During the rearing phase it is unlikely that animals will be singly housed. Single housing shall only be applied for husbandry purposes e.g. to monitor an ailing animal, allow recovery from injury or disease, or where mixing delivery cohorts to avoid single housing could be more aversive than remaining singly.

Shortly prior to infection, calves are appraised by a vet for suitability to undergo larvae production. Suitable calves are infected with a small aqueous oral dose of a known number of viable infective REDACTED larvae. Approximately 7 days later, calves are rehoused to closely monitor and treat animals as necessary. Preliminary appraisal of larval output via faecal sample and (modified) Baermann test begins at patency (approximately 21 days post infection) and continues frequently throughout production. At approximately 24 days post infection a harness is fitted to each calf to allow them to acclimatise to it. At approximately 26 days post infection a collection bag is suspended from each harness and faecal collection begins. Collection bags are changed several times daily. Collection will continue until a humane or scientific end point is reached.

From larval challenge onwards, calves are appraised and clinical signs recorded e.g. rectal temperature, respiratory rate and effort at least daily. Veterinary treatment or euthanasia at the humane end point are aided by these assessments. Therapeutic treatments to alleviate clinical signs may be administered by or under the direct control and guidance of the NVS or veterinary clinician. Continuation of treatments may be delegated by the veterinarian and administered by experienced animal care staff.

Animals are likely to be housed singly during production. This aids administration of therapeutics and collection bag changing which could be distressing if having to isolate frequently from a larger pen to perform these tasks. Conspecifics may also interfere with collection bags and reduce faecal/larval recovery which is detrimental to the project.

No calves which have been infected with REDACTED shall be considered for release from the Act, and they shall be humanely euthanased. A blood sample may be recovered post-euthanasia for a further screen.

Other typical husbandry procedures outside of the scope of the Act may occur during the lifetime of the calves in REDACTED's care which include:

- transportation by road
- temperature monitoring
- weighing
- castration
- disbudding

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

During the rearing phase there are not likely to be any adverse effects of procedures applied. Sampling routes and techniques are mild. There is potential for transport stress and/or related disease. Healthy calves are transported straight from farms of origin to site and are given electrolyte treatment shortly after arrival to guard against dehydration and transport stress. Other treatments are unlikely and only given if prescribed by a vet.

As in all calf rearing enterprises there may be losses from non-study-related diseases e.g. calf scour and joint ill. These will be treated appropriately wherever possible but calves not responding to treatment may be euthanased.

Adverse reactions to registered vaccines rarely occur. If seen it consists only of painless or mildly aversive swelling around the injection site. No treatment is necessary in these instances.

The act of infection, faecal sampling and harnessing of calves is no greater than mildly invasive or aversive.

Calves infected with REDACTED can, at worst, develop severe ill health and may die. Hyperpnoea and tachypnoea are seen. At least daily examination of each calf from approximately day 7 post infection is required, along with appropriate treatment which enables most calves to tolerate the infection reasonably well. A few may be naturally refractory to infection, but the majority will require regular treatment.

Some discomfort is created by giving frequent injections for treatment. The greatest frequency for these is likely to be between days 7 and 21 post infection. Clinical signs usually settle down once patency is reached so the number of injections is reduced and kept to a minimum using long acting or enteral preparations wherever possible.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

- Approximately 30% shall reach only mild severity

  Approximately 50% shall reach moderate severity

  Approximately 20% shall reach severe severity

These figures include those calves reared as 'back-ups' with the expectation that they shall not be worked with for production. The incidence of work with back-ups is minimal at <0.5% of all calves worked with in production in 8 years. This last occurred when just 2 calves were used in 2011.

What will happen to the animals at the end of the study?

- Rehomed

A retrospective assessment of these predicted harms will be due by 27 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

REDACTED are highly host-specific and cannot reproduce outside of a host. Therefore in order to produce a vaccine from attenuated REDACTED larvae, a small number of bovine calves are infected with REDACTED which are allowed, under controlled conditions, to go through their natural life cycle. This process generates enough larvae from approximately 30-40 calves per annum to satisfy global demand for the vaccine.

What was your strategy for searching for non-animal alternatives?

Although research into ways of producing an effective vaccine in vitro have been conducted by several institutions and REDACTED has supported that work, to date none have been successful and hence there is no alternative than to work with calves to produce the larvae.

Dictyocaulus viviparus can survive in alternative hosts, but these are not as suitable for large scale production as bovine calves.

Why were they not suitable?

Guinea pigs can support small *Dictyocaulus vivaparus* larvae infections under experimental conditions but cannot support the maturation and reproduction of the parasite; therefore cannot supply larvae for production.

Deer and llamas can harbour *Dictyocaulus viviparus* infections but the faecal yield would be low and the animals far harder to source and manage than bovine calves.

A retrospective assessment of replacement will be due by 27 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The vaccine has been produced in much the same way for many decades. Vaccine sales have fallen slightly over recent years however the projection is that there will be some increase during the life of this licence. The number of animals worked with in production will likely be unchanged despite the predicted increase in vaccine sales, however an overall increase in animal usage is being proposed for this project compared to the previous license because of the reporting of procedures applied on-farm (POLEs) where historically these were omitted. The increase is 100% compared to the previous license on the assumption that approximately half of the number of animals sampled are acceptable to be worked with. It is anticipated however, that due to plans to refine the supply of animals, the vast majority of animals will be acceptable and the increase not be required. It must be considered however that the preferred supplier(s) may be lost at any time due to disease, movement restrictions, business decisions by them etc. and the process of finding and screening new suppliers/animals be conducted. In this case, it is reasonable to assume that many more calves may be sampled than 'normal' and these procedures be returned thus increasing actual usage.

Ways to recover more larvae from the raw harvest (without changing the infection dose or in-vivo process at all) have been identified. Therefore, it is predicted that more larvae can be recovered from the same number of animals to accommodate any increase in sales. Furthermore there is a degree of overproduction. Some contingency is essential to absorb any QC batch rejections etc. but the growth in sales which is predicted shall absorb some of the overproduction.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The number of animals worked with has decreased proportionally to the number of vaccine doses being sold in recent years, and is currently well balanced. It is being proposed that refinements in the Secondary Production process may help to recover more larvae from raw harvest, which in turn could reduce the number of animals worked with, and/or enable more product to be made for no increase in animal numbers. It is also important to remember that there needs to be a degree of over-production of larvae to account for losses prior to vaccine blending, and output of larvae is not predictable for each animal so it would be a risk to reduce numbers too low.

The current team are committed to investigating potential animal reduction possibilities but it should be remembered that changes affecting the production process could be subject to official change controls or variations, which can take time.

What other measures apart from good experimental design will you use to minimise numbers?

Good communication with product marketing is key to knowing how much product is required for sale. It is possible to work back from that and estimate the number of animals required. To give enough time to rear calves we are always working to a sales prediction e.g. we need to know before we procure calves in the spring, how much vaccine will be sold the following year; because it is that which those calves will be working towards. The sales predictions included in this license address this although there is potential for change due to market forces.

A retrospective assessment of reduction will be due by 27 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will work with approximately 30-40 male dairy or dairy cross-breeds per anum at approximately 5 months of age at point of infection. They will be reared on-site from approximately 2 weeks of age. Prior to infection no adverse effects are expected. The infection process is minimally invasive but the effect of infection could be severe. Severe signs are ameliorated as much as possible by a non-specific treatment regime applied by vets or experienced animal care staff throughout the infection process with a higher likelihood for these up to and around patency.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Other species do support *Dictyocaulus viviparus* infections, but it is not feasible to work with them in a scale necessary for production of sufficient larvae for vaccine manufacture. Such species include:

- Guinea pigs
- Llamas
- Deer

The yield of larvae from these species per animal is far lower than that of bovines so proportionally more would need to be worked with. Supply of these species has not been evaluated and may be problematic, and their housing and management systems are not as conducive for faecal recovery. The

availability of vaccines and/or therapeutics to ensure high respiratory (and other) health status plus offer treatments during the REDACTED infection or any other intercurrent illness is lacking.

The question of sentience is complex, but it is known that during the production process bovine calves can tolerate the infection well and produce a large yield of larvae. Other species may be considerably more averse to the process.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Where samples are required from the animals (blood and faeces), sufficient is taken in one brief session to perform several tests with the samples. Although these procedures are mild and minimally invasive, the overall number of procedures is reduced by adopting this practise.

Likewise, to reduce the frequency of disturbance when offering vaccinations, a vaccination schedule is very carefully planned to use multivalent vaccines where possible to reduce number of injections, plus combine as many compatible products into one vaccination session as possible.

During production, animals are scored and only treated when considered necessary by vets and experienced animal care staff. Where possible, long acting and/or non-injectable preparations are given to reduce the number of injections.

Calves have access to an excercise yard for a large period of their production process which enables excercise and socialisation. If not group housed, animals are always within close proximity, sight and sound of eachother. Environmental enrichment e.g. scratching posts and mineral licks are available throughout.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The Code of Practice for animals worked with under A(SP)A is adhered to at all times.

The process undertaken is not experimental and is already well refined and established having been in existence for many decades. The process is limited to a degree in the way it can be changed by the coverage of GMP accreditation, to which alterations require lengthy variation. To this end there are prescribed processes for much of what is entailed, and these are controlled by localised standard procedures which must be followed.

Should there be a lack of published guidance, the afore mentioned dedication of vets and animal care staff to discover and apply best practise which they may encounter or develop shall demonstrate the commitment to refining the process as much as possible.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The support network including several vets and other named persons in the PEL help to disseminate information posted from bodies such as the IAT, Home Office, NC3R's, RSPCA, UFAW, LARN, LASA etc. Having attended a number of events sponsored by these parties, and being a member of the IAT, I also directly receive mailings, notifications and invitations. Frequent updates are effectively disseminated within our organisation by the HOLC, and by all present at regular AWERB meetings.

The vets being worked with for this project are members of the Vets On-line Email (VOLE) network and British Cattle Veterinary Association (BCVA). Through these plus extensive experience in their roles, they have close connections with the veterinary community. Within these networks, important issues are highlighted, questions raised, connections made, and solutions suggested. It is a valuable resource. Farming publications are also received to the site in which welfare practises for cattle, rarely covered by the afore mentioned parties, are publicised.

The animal care team on site are active in investigating and applying new initiatives for the animals they care for. Some are connected by lineage or community to the farming fraternity and a degree of discussion into available technologies to enhanced cattle welfare does emanate from this source. It is considered a key in-house appraisal parameter of animal care staff that they demonstrate and apply continual improvements to animal welfare. Staff are keen to attend events where there is opportunity for education and networking which may enhance our shared commitment to our animals.

Explain the choice ofspecies and the related life stages

Male calves of dairy or dairy/beef crosses at approximately 5 months of age are the most suitable species for production of REDACTEDlarvae.

Cattle (from 8 weeks of age) are the target species for the vaccine and working with them to produce larvae yields a significant number in a manageable way. The larvae are recovered from the faeces of the animals and male bovine anatomy is conducive to achieving a 'pure' faecal harvest where the same process with females would lead to urinary and uterine contamination of the faeces. This would make the faeces unmanageable and increase the risk of pathogenic contamination.

The calf's body mass and lung development need to be optimally proportional to tolerate the infection and generate larvae. The process has been conducted in much the same way for many decades, and it is known that a dairy animal reaches optimal target weight of approximately 150-190kg at around 5 months of age. At an equivalent stage of lung development, a beef animal would have a greater body mass which would place greater demand on the respiratory and other physiological systems during an infection. Therefore, they could incur a more adverse reaction than that of a dairy animal. When infected with REDACTED under controlled conditions dairy breeds are most likely, along with careful management from animal care staff and vets, to tolerate the infection and produce acceptable numbers of larvae for a long enough period to satisfy demand for vaccine manufacture.

A retrospective assessment of refinement will be due by 27 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

170. REDACTED

Home Office

NON-TECHNICAL SUMMARY

171. Production of antisera and immune cells in fish

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
All fish species	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to generate antisera and immune cells from fish for research and diagnostic purposes.

This will support and improve the maintenance of aquatic biosecurity for farmed and wild fish as part of compliance with national, EU and international legislation regarding aquatic disease control.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With the decline in wild fish stocks, aquaculture, the fastest growing food-producing sector globally, is increasingly critical to future global food security. Infectious diseases causing significant losses to farmed fish continue to be a major constraint impacting on both economic resources and animal welfare. The sera generated under this project will be used in characterisation and improved understanding of aquatic diseases. The sera will be used in the development of diagnostic assays and in the regulatory testing of starting materials feeding into vaccine development for serious diseases of cultured and wild fish.

What outputs do you think you will see at the end of this project?

A successful epidemiology programme and accurate diagnostics are essential to prevent the introduction and control the spread of aquatic disease. The outputs from the project will improve our ability to detect and identify pathogens, to support UK aquatic biosecurity and comply with international legislation on aquatic disease. The availability of specific immunoreagents is vital to development, validation and implementation of tests designed to trace and control any spread of infection. Availability of reagents for pathogens present in the UK is also of considerable importance to follow the development or introduction of new strains of significant bacterial and viral pathogens that are defined by serotype.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The principal output will be evidence for policy and regulation. The improvement of our current serological tests and subsequent use in refined epidemiological surveys will aid the development of policy and regulations at both national and international levels, particularly in relation to the risk of exotic or emerging pathogens to native species in the wild and farmed environments. Outputs are typically in the form of advice reports, conference proceedings and peer-reviewed papers.

How will you maximise the outputs of your work?

Improved serological assays will be made public and may be suitable for commercialisation and uptake by the wider scientific/public community.

Additional benefits may be realised by use of these sera in fundamental and applied (translational) microbiological research and development of effective treatments.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Use of fish will be solely for the production of polyclonal antisera and immune cells.

Fish under procedure will receive a maximum of 5 injections of the antigen and adjuvant mix with an interval of aproximatelly 500 DD between immunisations; and blood samples might be taken to assess the immunoglobulin titres with a maximum volume of blood permitted of 0.4% of body weight per sample, and no more than 15% of total blood volume over any four-week period before the final blood harvest.

The antigen may be used with adjuvants. The adjuvant programme will be selected depending on the study, with as minimal local reaction as possible whilst remaining effective. Freund’s Complete Adjuvant (FCA) can be used only on the primary injection. For a fish weighing more than 50 g, the maximum volume injected per immunization by IM is 100 µL of the antigen/adjuvant emulsion in each of two sites. The maximum volume by IP is 100 µL of the emulsion in one site. Stable emulsions should be used with no more that 50% FCA mixed with antigen in aqueous solution. The antigen/adjuvant mixture will not exceed 100 µL in fish <50g or 200 µL in fish >50g. Alternative mineral oil vaccinations will also be considered (e.g. SEPPIC Montanide ISA) where evidence of reduced tissue reaction is provided. General anaesthesia with recovery will be administrated for the immunisation injection.

Immunisation by the oral/immersion route is preferred when fish size (i.e. small fish ≤20g) and antigen nature allows it. Antigen will be administrated either by bath or as a food additive.

Marking (optional) can take place together with pre-immunisation blood sample. May be carried out by visible implant elastomers (VIE), passive integrated transponder (PIT) tags or suitable alternative methods. Marking can be repeated if loss of the tag is observed alongside booster immunisation or

blood sampling. The most appropriate tag will be chosen depending upon the fish species and animal size.

The procedure described above will follow a full formal Study Plan. These Study Plans are developed following PREPARE guidelines (Smith et al., 2018) and require the consideration and approval of the AWERB and the Project Licence holder, before any experimental work commences. Copies of all approved Study Plans are filed in the Experimental Facility records area, by the Study Director, and in the electronic archive where they are readily available.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Bath immunisation in fish may cause loss of appetite for a short time.

Intramuscular (IM) or intraperitoneal (IP) immunised fish may develop lesions in the site of injection due the use of oily based adjuvants, especially when using Freund's Complete Adjuvant (FCA).

In IP injected fish, the most common type of reaction is a localised fibrinous peritonitis in the area adjacent to the injection site. Fibrinous strands typically form adhesions between the ventral body wall, spleen and pyloric ceca which may lead to mild and moderate lesions. IM immunisations are less common in fish, as the oil adjuvants can lead to the development of granulomatous inflammatory infiltrates. The IP route of injection is preferred over IM, except when using DNA-plasmids for the immunisation, where the IM route of infection has been shown to be more efficient.

Adverse effects due to the nature ofthe antigen:

- Anaphylactic shock- Unlikely. It will be avoided by suministrating the smaller amount of antigen/adjuvant possible and by following the recommended doses of immunisation.

- Inactivated pathogen used as immunogens may cause an infection – Unlikely, pathogens will be inactivated. When possible, antigen inactivation will be confirmed *in vitro* prior to immunisation (e.g. by growth in cell culture).

Adverse effects due to the nature ofthe adjuvant:

- Granulomas caused by infection or adjuvant – Antigen will normally be combined with an adjuvant in order to enhance the immune response. Adjuvants will be chosen to stimulate the required antibody response whilst minimising local tissue damage. Selection will depend upon the route of administration, the nature of the antigen and previous experience. In order to minimise any adverse effects of immunisation, the sites of injection will be well separated, and regular inspection will be made. If any fish show persistent or extensive lesions or signs of distress, the monitoring frequency will be increased. The advice of the NVS and the NACWO will be taken on whether the animal needs to be humanely killed by S1M or the non-S1M method as follows: surgical anaesthesia followed by the collection of blood sufficient to result in exsanguination, followed by removal or destruction of the brain.

Table 1. List of possible adverse effects, likelihood, estimated duration, controls and humane endpoints.

Adverse effects (What could go wrong)		Indicators (How we will recognise it)	Checks (How we will monitor it)	Estimated duration	Likelihood	Controls (How we will prevent or ameliorate harms)	Humane endpoints
Procedure-related	Injuries from anaesthesia, vaccination and bleeding procedures	Skin lesions, bruising/scale loss	Visual checks	< 24 hr	Likely- max: 40% of IM injected fish; less than 10% of IP injected fish	Appropriate procedures, training and skilled operators	Individual euthanasia if open/haemorrhagic lesions.
	Systemic allergic reaction (anaphylaxis)	Abnormal behaviour (extreme ventilation, unusual positioning, loss of equilibrium)	visual checks	< 4 hr	Unlikely	Correct dosage and use of adjuvants	Individual / population euthanasia if abnormal fish behaviour persists
	Side effects of vaccine components (adjuvants)	Lesions at injection site, temporary reduced appetite	Visual checks	< 3 days	Unlikely	Good hygiene during vaccination preparation and procedures, controlled dosage type of adjuvants, increased frequency of monitoring	Individual euthanasia if open/haemorrhagic lesions, or prolonged inappetence leading to emaciation
	Pathogenic disease (incomplete antigen inactivation)	Clinical signs of illness	Visual checks	< 2 days	Unlikely	Confirm effective inactivation, short term temperature manipulation outside of permissive temperatures	Individual euthanasia at confirmation of pathogen related clinical sign >mild. Population euthanasia if therapeutic treatments unsuccessful/ unavailable.
Not procedure-related	Aggressive interactions and cannibalism	Physical injuries to fins, eyes, skin. Observations of aggression/ cannibalism	Visual checks	< 3 days	Unlikely	Grading for similar size; Ensuring appropriate feed ration; Maintain environmental conditions (e.g. water flow, fish density) known to minimise risk; Tank enrichment	Individual euthanasia if injuries considered > mild (e.g. open / haemorrhagic lesions).
	Poor water quality	Abnormal fish behaviour	Visual checks + routine and responsive water quality monitoring;	< 2 days	Unlikely	Stock at and maintain fish biomass within appropriate loading rate (kg/m³/L, i.e. biomass per inflow) for temperature and fish size. Increase water/air inflow rates.	Individual / population euthanasia if abnormal fish behaviour persists after mitigation actions taken.
	Pathogenic disease (unrelated to vaccine antigen)	Clinical signs of ill-health	Visual checks	< 2 days	Unlikely	Prior health screen samples; use of in house spf fish, prevention of pathogen presence - via prior quarantine, prophylactic and therapeutic treatments as advised by NVS, biosecure working practices and facility; maintenance of tank hygiene	Individual euthanasia at confirmation of pathogen related clinical sign >mild. Population euthanasia if therapeutic treatments unsuccessful/ unavailable, or >25% of population affected.
	Non-pathogenic disease	Clinical signs of ill-health; poor performance	Visual checks; Growth monitoring	< 3 days	Unlikley	Checks on performance during quarantine and acclimation. Provision of complete commercial diets. Obtaining fish from proven reliable suppliers.	Individual euthanasia at confirmation of clinical sign > mild. Population euthanasia if >10% of population affected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

- 40% of IM immunised fish may reach MODERATE in recognition that the occasional use of Freund's Complete Adjuvant (FCA) may induce localised granulomas.
- 10% of IP immunised fish may reach MODERATE due the development of moderate lesions associated with adhesions in the ventral body wall.
- 60% of IM and 90% of IP immunised fish should not experience severity above MILD.
- 100% of fish immunised sorely by the oral/immersion route should not experience severity above MILD.

- 100% of fish used to maintain the stock density will not experience severity above SUB-THRESHOLD.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This license aims to improve non-lethal immunological tests currently used in epidemiological surveys. In contrast to molecular tests, which inform the presence or absence of a given pathogen, serological tests detect previous pathogen exposure and are needed for the designation of disease-free areas for trade purposes (visit OIE http://www.oie.int/animal-health-in-the-world/official-disease-status/) and inform on pathogen introduction and epidemiological surveys.

What was your strategy for searching for non-animal alternatives?

In vitro culture will be used to produce the antigen (i.e. use of susceptible fish cell lines for culturing virus). *In vitro* methods will also be used to confirm antigen inactivation prior to immunisation.

Alternative methods for polyclonal antibody production have been considered, such as recombinant antibody phage display. However, due the nature of the autologous antisera reference test material required and neutralizing capability of the polyclonal antibody, the use of animals is required. During this licence, advances in neutralising antisera production using non-animal platforms will be closely followed, as well as attendance at specialised workshops and networking on non-animal-based antibody production.

Why were they not suitable?

Suitable synthetic non-animal alternatives do not currently produce antibodies with the range of specificity and affinity required in the assays these sera will be used for. For serological test development known positive controlled sera from the host species (fish species) are required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Power calculations are not needed for this license. The number of animals used in each assay will be the minimum required to produce the volume of antiserum needed and will depend on the species chosen and the antisera titres.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Control fish (non-immunised fish) will not be used in this licence as the immune status of each individual animal will be determined in the pre-immunisation blood sample. However, fish stocking densities and population size are necessary considerations to ensure the expression of normal feeding and social (e.g. schooling) behaviour and to minimise aggressive behaviour. The minimun number of fish per tank will depend on the fish species, animal size, and the species needs following advice from fish husbandry experts. Experimental facilities offer a range of flexible tank sizes to minimise animal numbers while enabling basic social behaviours. Taking into account individual variation in response, a maximun of 400 fish over 5 years is expected to maintain stock density and produce the volume of antiserum required. Depending on the titre of the antisera, a single batch of antiserum appropriately stored will last for many years and may be shared with other laboratories in the same research field. Heterologous antisera against a small number of fish pathogens and anti-species immunoglobulins are commercially available. Where these have been demonstrated to be suitable for our purposes, these will be purchased.

What other measures apart from good experimental design will you use to minimise numbers?

Every effort is made to reduce numbers of fish used to a minimum, incorporating animal husbandry expert advice on fish social needs and AWERB scrutiny on each study plan. Additionally, within the constraints of available tanks sizes and appropriate animal numbers required for acceptable stocking densities and with respect to individual variation in immune response, large fish will used to generate larger and longer lasting volumes of sera from fewer animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Specific pathogen-free (SPF) common carp, Atlantic salmon and rainbow trout will be used for the antisera production under this License. Those species are the most relevant for UK aquaculture industry. The laboratory has more than 50 years of husbandry experience with these species. Variation in response between animals is minimised by size grading, and prior group holding in common conditions. Consideration is given to providing an appropriate environment, including enrichment such as shading and/or refuges, during experiments. Stock density, water current and conspecifics that promote social behaviour, plus nutritionally complete diets are carefully considered throughout the animal holding. Fish are stocked into experimental tanks by staff experienced in fish handling and are routinely acclimated after stocking prior to study initiation.

The adjuvant selected for the antigen emulsion will be the one that causes least discomfort but elicits the desired immune response. The selection of the adjuvant will be carefully justified in a Study Plan after discussion with the NACWO, NVS and the Licence Holder. Consideration will also be given to the route of administration when deciding the fish species and size. When possible, immunisation by immersion/oral route will be selected, to minimize the severity of the procedure (i.e. immunisation injections will not be needed).

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rabbits and mice are often the standard laboratory animals used for the generation of polyclonal and monoclonal pathogen-specific antibodies. However:

- Fish are less sentient than mammals, as they do not have the extensive cerebral cortex seen in the forebrain of mammals.
- Major differences in Ig isotypes and performance within lower and higher vertebrates exist. For this reason, for the planned reseach into fish diseases, mamalian antibodies are inadequate.
- The use of fish larvae for immunisation is not an alternative for the generation of positive sera as they lack a full developed humoral system. Furthermore, the likely yield of serum from such immature forms would be inadequately small.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Where possible, we will administer antigen by the mildest possible route - e.g. orally where possible, and only use parenteral routes where there is scientific evidence that the oral or immersion routes would be unsuccessful. Intraperitoneal (IP) injections will preferred to intramuscular (IM).

Changes to the diet prior to oral immunisation, to mitigate any adverse impacts on feeding (e.g. palatability adaptation) will be discussed with the NACWO and NVS and stated in the Study Plan.

General anaesthesia will be bath administrated prior to IP or IM injection and prior to blood sampling. Experienced PIL holders will conduct the anaesthesia following standard operating procedures.

Fish under procedure will be monitored via direct visual checks of condition and behaviour by both husbandry staff (during feeding and tank cleaning) and experienced PILs (at least daily) using standardised in-house scores sheets. The frequency of direct PIL checks will increase if adverse effects are present. If clinical signs associated with suspected infection with pathogen in use is observed (see Table 1) the animal will be schedule 1 method (S1M) terminated or killed by the humane non-S1M as follows: surgical anaesthesia followed of collection of blood sufficient to result in exsanguination followed by removal or destrucion ofthe brain.

Direct visual checks will be accompanied by video observations using underwater cameras mounted within tanks. Water temperatures are recorded automatically and maintained at ±0.2°C. Fish are normally fed at least once per day by hand. Hand-feeding means that fish feeding behaviour (a good indication of fish welfare) is better observed than if mechanically fed. Water replacement is normally maintained at D5 changes per day. Call out alarms are installed at the REDACTED facility which activates ifpre-set parameters are exceeded.

Consideration is given to providing an appropriate environment, including enrichment such as shading and/or refuges, during experiments. Stock density, water current and conspecifics that promote social behaviour, plus nutritionally complete diets are carefully considered throughout the animal holding. Fish are stocked into experimental tanks by staff experienced in fish handling and are routinely acclimated after stocking prior to study initiation.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Protocols used will follow the Home Office guidance: “Antibody Production, Principles for Protocols of Minimal Severity”. Fish blood samples will follow the guidance from Canada Department for Fisheries and Oceans, Canadian Council on Animal Care, September 2004. 4.0 Blood sampling of Finfish.1-15.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

During this licence, advances in neutralising antisera production using non-animal platforms will be closely followed, as well as attendance at specialised workshops and networking on non-animal-based antibody production.

Explain the choice ofspecies and the related life stages

Rabbits and mice are often the standard laboratory animals used for the generation of polyclonal and monoclonal pathogen-specific antibodies. However, in recent years a greater understanding of humoral responses in fish has highlighted major differences in Ig isotypes and performance. For this reason, for the planned reseach into fish diseases, mamalian antibodies are inadequate. Therefore, after confirming materials are not available via other research groups or commercially, this licence seeks authority to produce autologous immune sera in fish to improve non-lethal immunological tests.

When possible, specific pathogen free fish will be used for the antisera production under this License. Atlantic salmon, rainbow trout and common carp are the most relevant for UK aquaculture industry. The laboratory has more than 50 years of combined husbandry experience with these species. Variation in response between animals is minimised by size grading, and prior group holding in common conditions.

We will preferentially use these species for the generation of control sera for the development of immunological-based diagnostic tests. However, wild caught-fish will be used in the absence of commercially available stocks (e.g. European eel).

To generate positive immune sera, the fish need to be capable of generating a strong measurable humoral response. The first appearance of IgM in lymphocytes varies considerably among fish species. The use of larvae for immunization is not an alternative for the generation of positive sera as they lack a full developed humoral system. Furthermore, the likely yield of serum from such immature forms would be inadequately small. Thus, this license seeks authority for the use of juvenile and adult fish for the collection of large amounts of control sera.

Home Office

NON-TECHNICAL SUMMARY

172. Protection after heart attack or stroke

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand how heart and brain tissue can be saved from damage following a heart attack or stroke.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heart attack and stroke are the leading cause of death worldwide and present a huge burden on health systems such as the NHS. These diseases occur when an artery supplying either the heart muscle or the brain respectively is blocked, disrupting the delivery oxygen and nutrients as well as the removal of waste products. This inevitably leads to death of the tissue that is without blood supply, which can lead to both severe long-term disability and increased mortality in patients.

What outputs do you think you will see at the end of this project?

This project will develop and test novel protective drugs for heart attack and stroke, in order to pave the way towards the use of these compounds in patients. The information gathered from this project will allow us to see how these substances affect the heart or brain and what doses and treatment regimens are most likely to be effective. We will also examine whether lifestyle changes (such as diet and exercise) or pre-existing diseases alter their effectiveness.

We aim to publish in high-ranking journals in order to inform the scientific community. I also regularly take part in public engagement activities, such as Pint of Science, REDACTED-wide Science festival, "Naked Scientist" and appear in the popular press in order to inform the general public about the progress and new findings of our research.

Ultimately, the above results and achievements will pave the way towards the use of novel compounds in patients with heartattack and stroke.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

Initially, our fellow scientists will benefit from our findings about the underlying mechanisms of health and disease in heart attack and stroke. We publish in prestigious journals and are active members of many scientific societies with regular participation at meetings.

In the second line, we anticipate bringing at least one of our novel compounds towards use in patients with heart attack or stroke within the next 5 years. Drug development is a long and complicated process, but we are confident that this project will enable us to move forward to a first-in-man study on this timescale.

How will you maximise the outputs of your work?

My group is very well connected, not only locally, but also on a national and international level. The quality of our animal work has made my group one of the leading groups in the country investigating damage during heart attack. We regularly publish our results, including negative outcomes or unsuccessful approaches.

My group and my collaborators are very active on various outreach channels, including twitter, popular press, radio, and websites. The general public has access to all our findings and we widely share our knowledge. We have a large number of collaborators world-wide, which work together with us to maximise our findings and make translation towards patient care more likely.

Species and numbers of animals expected to be used

- Mice: 4400
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically either purpose-bred genetically-altered animals are used or genetically normal mice will be used. The breeding protocols follow standard breeding procedures.

In a subset of animals certain conditions such as exercise, administration of substances or alteration of diet will be applied in order to mirror more closely the conditions in humans. This includes pre-existing lifestyle (exercise or diet) or pre-existing medication.

Finally, animals will be subjected to surgical procedures to induce either a heart attack or a stroke. These final procedures will be performed under terminal anaesthesia and the animal will not be allowed to recover.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Overall, the animals will only suffer mild discomfort and no lasting harm. REDACTED

The surgical procedures will be performed solely under confirmed general anaesthesia REDACTED. We further aim to perform any interventions, REDACTED. Only rarely it is necessary to do this beforehand.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol 1: mild

Protocol 2, 3: non-recovery

Protocol 4, 5: mild

Protocol 6, 7: moderate

Protocol 8, 9, 10: mild

What will happen to the animals at the end of the study?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Information about the distribution of the drugs, effects on the heart and brain, or blood pressure and exercise tolerance cannot be answered using cell-based models.

The novel drugs which will be tested with this license have already undergone extensive testing in suitable non-regulated models in cell culture, isolated cells or isolated organ preparations. Therefore, we already know most of the mechanisms of action and have information about possible toxicity, dosing and the most effective treatment regimen. However we need to confirm efficacy in animal models before we can translate these compounds to human use. Furthermore, these animal models have to mimic the

situation of patients as close as possible. This can be done by an alteration of diet, exercise, application of pre-existing medication, and the use of pre-diseased genetically-altered models.

What was your strategy for searching for non-animal alternatives?

We are already using isolated organ applications for testing in the heart (Langendorff preparation). This cannot be done with the brain.

Why were they not suitable?

Cell lines cannot mimic important conditions, such as exercise, and do not have crucial confounding elements, such as circulation or the blood brain barrier.

There have been decades of research trying to find a suitable cell-based model of ischaemia (lack of oxygen to tissue)/reperfusion (re-introduction of oxygen and blood flow to tissue), but so far none have been found.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is determined by previous experience with an identical methodological approach under a different license. Furthermore, we will use power calculations based on our previous data to calculate numbers for each individual experimental setting.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

I use the NC3R Experimental Design Assistant (EDA) in order to thoroughly design the studies.

In addition, I am on an EU committee (COST Action "Cardioprotection") which aims to standardise ischaemia/reperfusion experiments throughout Europe considering the 3Rs as well as highest scientific standards. Within this consortium, my group is one of the reference groups for acute heart attack in mice.

What other measures apart from good experimental design will you use to minimise numbers?

Wherever possible, we try to assess as many parameters in a single animal as possible and reduce the numbers in one treatment group to an absolute minimum that the statistical analysis will allow us as determined by power analysis. This includes performing sophisticated imaging techniques which allow us to gain much additional information about the heart attack or stroke in a single animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The present project will use either wild-type mice and rats or genetically-altered mice. The genetically-altered strains are lacking important mechanistic elements which helps us to understand the mechanisms of how we can protect against heart attack or stroke. We are already breeding these genetically-altered lines under a different license and the animals do not show any clinical signs.

The main aim of the license is to test protective effects in heart attack and stroke, and as both models will be performed under terminal anaesthesia they are therefore free of any suffering.

The alteration of diet or exercise and administration of substances are the most refined models used to determine these important factors which can influence the outcome of heart attack and stroke. There will not be any lasting harm and only mild discomfort for the animals due to these models.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice and rats are the most useful species from which it is possible to obtain relevant and meaningful physiological and pathophysiological information. Especially non-invasive imaging such as MRI and PET cannot be performed in smaller species. Furthermore, mice allow genetic manipulations in order to more specifically study the underlying mechanisms.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We closely monitor the animals throughout the experiments. This includes the use of sophisticated heart and brain function monitors, such as ECG and blood flow monitor (doppler), as well as temperature control. If anaesthesia is applied, the efficacy is monitored closely throughout the procedure. Should any anaesthesia or surgical problem occur which would potentially harm the animal, the experiment will be terminated and the animal humanely killed.

In protocols or procedures where anaesthesia is not used, animals will be monitored for any deviation from normal health and behaviour and should any signs appear animals will be killed immediately.

The animals are allowed to acclimatise to either the exercise protocol or the dietary changes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the NC3Rs Experimental Design Assistant (EDA) see https://www.nc3rs.org.uk/experimental-design as well as the following guidelines:

for pilot studies (https://www.nc3rs.org.uk/conducting-pilot-study);

ARRIVE guidelines, https://www.nc3rs.org.uk/arrive-guidelines;

IMPROVE guidelines for stroke models: https://www.nc3rs.org.uk/news/improve-ing-animal-welfareexperimental-stroke-research;

published guidelines to assist with planning animal research and testing, such as the PREPARE guidelines: http://journals.sagepub.com/doi/full/10.1177/0023677217724823

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I receive regular updates REDACTED about news and advances in the 3Rs.

Explain the choice ofspecies and the related life stages

Since the effects on hemodynamic parameters and the elimination/distribution of compounds are essential parameters of a pharmacotherapy, isolated organ systems cannot be used. It is not possible to gain this information in vitro since the whole-body system needs to be intact due to the influences that administration, distribution, metabolism and excretion have on the availability and efficacy of the compound.

Furthermore, changes in exercise levels, diet or pre-existing diseases cannot be mimicked without animals.

Rodents are the smallest possible species where interventions, such as ligation of a coronary artery or occlusion of a brain artery in order to induce a heart attack or stroke respectively are possible.

In addition, rodents offer the possibility to use genetically-altered models in order to mirror patient conditions (such as pre-existing diseases) more closely.

Horses, Donkeys, Ponies, Cross-breeds	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project is to provide a service for the supply of blood and other biological materials for use as controls in diagnostic testing, quality assurance, and research projects requiring biological materials. The samples supplied from the various species will be used in evaluating diagnostic tests for a variety of animal diseases. The project is demand driven and all individual requests for samples will be ethically approved and only supplied once a written case outlining why the samples are required and why no alternative source is possible. The quality of samples produced and their timeliness are important to the success of the research that this project licence supports.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is a requirement to supply blood, faeces and other materials for scientific purposes, for use as standards and negative control material, in the development of and the maintenance of laboratory techniques, in undertaking research projects, at this and other establishments.

REDACTED

What outputs do you think you will see at the end of this project?

This is a service licence sup

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The supply of this blood and biological material allows peer reviewed research to be undertaken at the organisation and other public health organisations, with the associated increase in scientific publications and outputs. These benefits are more longer term (months to years depending on nature of the disease and the research project) due to cumulative nature of scientific research in working towards

a better understanding of disease processes and the ability to control them with the development of new tests and vaccines.

Supporting the ongoing testing requirements from the establishments customers, for use of complement fixation tests or similar tests for the purpose of international trade and diagnostic testing.

The quality assurance unit will be able to continue to supply proficiency testing material to laboratories fulfilling the needs of the establishment and other laboratories.

The diagnostic tests it supplies underpins the national capacity for disease diagnosis with the associated impact on animal welfare, also its import/export testing which is necessary to prevent the spread of certain diseases. The benefits of being able to run these tests are realised mostly short-term.

How will you maximise the outputs of your work?

The organisation made a strategic decision some years ago that all supply of negative control blood and biological material required within the organisation should be under one service PPL to maximise the 3R’s benefit by adding better oversight over tissue requests and reducing the number of animals needed through re-use. Whenever possible sample requests from different users will be aligned to that one sample event provides material for several projects, thus reducing the sample frequency for each animal. This benefit has been further maximised by supplying control material to other institutes.

Species and numbers of animals expected to be used

- Cattle: 20
- Sheep: 50
- Goats: 10
- Pigs: 20
- Domestic fowl: No answer provided
- : 10

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

1. Withdrawal of blood by venepuncture from a superficial blood vessel. In pigs this could also include the jugular or anterior vena cava. (AA/AB local)

2. Optional Manual withdrawal of faeces from the rectum and/or rectal swabbing (mammals only).

3. Optional Nasal swabbing mammals only. (AA)

4. Steps 1, 2 and/or 3 may be repeated in situations where serial blood samples are required from the same animals. Frequency will be limited to 10 times a month in these situations and up to 30 times a year. (AA/AB local)

5. Optional chickens and turkeys only, euthanasia by exsanguination by cardiac puncture under deep terminal anaesthesia (AC).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Pain caused by the insertion of a hypodermic needle according to good veterinary practice, during the sampling. Stressed caused by restraining the animals during procedures.

Sterile blood sampling procedures and careful handling of the needles plus good restraint will be used to minimise damage to the blood vessels and inflammation caused to the vein.

Heamatomas will be prevented or controlled by pressure on the site immediately on removal of the needle/cannula.

Blood withdrawn from animals will be kept to the minimum practicable volume, but will be governed by the following:

No more than 15% of the blood volume should be removed in any 28 day period.

No more than 10% of the animals' blood should be taken in any 24 hour period.

Total blood volume will be estimated as 60ml/kg body weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild

What will happen to the animals at the end of the study?

- Kept alive
- Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Biological material such as blood and faeces are the basis for a lot of laboratory tests involved in animal health and veterinary diagnosis, therefore the negative control material has to replicate this.

What was your strategy for searching for non-animal alternatives?

This licence supplies biological material to tests that are either already established for disease control purposes or in the process of being developed.

Wherever possible samples collected post mortem will be used to supply the need for material, however as these laboratory tests are used to diagnose disease in the live animal, there is often the requirement to use fresh material, to avoid post-mortem changes issues.

Why were they not suitable?

These tests require ante-mortem samples and there is currently no alternative.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

By reviewing the predecessor of this licence, the requests for samples using the previous licence and the animals used throughout its duration.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The experimental design is based on matching demand for blood through the request form to numbers of animals maintained to supply the blood. Animals will also be sampled on a rotational basis in order to reduce the burden to each individual.

What other measures apart from good experimental design will you use to minimise numbers?

The number of animals used is minimised by re-using them. This allows a smaller number of animals to provide control blood across the establishment and other research establishments. Whenever possible, tissue requests from different users will be aligned to reduce the number of sampling events for each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Withdrawal of blood by venepuncture from a superficial blood vessel. In pigs this could also include the jugular or anterior vena cava.

Optional Manual withdrawal of faeces from the rectum and/or rectal swabbing (mammals only).

Optional Nasal swabbing (mammals only).

Steps 1,2 and/or 3 may be repeated in situations. Sampling frequency will be limited to 10 times a month in these situations and up to 30 times a year.

Optional chickens and turkeys only, euthanasia by exsanguination by cardiac puncture under deep terminal anaesthesia.

Faecal sampling from the animal's environment where possible.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The samples request state mature life stages. For the number of small blood samples required this would lead to an unacceptable level of animal usage if these were done under terminal anaesthesia.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The establishment has a group of experienced and knowledgeable staff who are able to perform the necessary procedures and restraint quickly and efficiently. Personal licence holders and animal technicians undergo regular refresher training as per the establishments competency framework.

Where possible the animals will be acclimatised to the restraints and handling techniques for the procedures they will undergo.

Positive reinforcement will be used as part of the acclimatisation and training process.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Home Office The Harm–Benefit Analysis Process _Advice note

Home Office Guidance to Animal (Scientific Procedures) Act 1986

Home Office Code of Practice for the housing and care of animals bred, supplied or used for scientific purposes

OIE (World Organisation for Animal Health) Manual of Diagnostic Tests and Vaccines for Terrestrial Animals

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By attending regular Named Animal Care and Welfare Officer meetings and through on going communications with the NTCO and NIO at the establishment as well as reviewing literature, staying informed of recommended refinements/replacements, engaging with stakeholders such as National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs), Laboratory Animal Science Association (LASA) and RSPCA.

Explain the choice ofspecies and the related life stages

The animals used on this licence are the main commercial livestock, equine and poultry species of disease control interest in the UK and the materials supplied with this licence will be used for diagnostic, import/export or laboratory tests (including research) for disease these species. For test performance (sensitivity/ specificity it is necessary to use the same species. The vast majority of animals used will be adult, on occasion juveniles may be used if required.

Home Office

NON-TECHNICAL SUMMARY

174. Radiation-induced intestinal carcinogenesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To study the effects of exposure to x-rays on the induction of intestinal carcinogenesis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The International Commission on Radiological Protection (ICRP) is an independent Registered Charity, established to advance for the public benefit the science of radiological protection, in particular by providing recommendations and guidance on all aspects of protection against ionising radiation (ICRP.org). ICRP have a long history of use of data from large scale radiation accidents, including those from the Japanese atomic bomb survivors where alimentary tract cancers were shown to be an important component of the overall risk of late effects following high dose-rate radiation exposure. Additional epidemiological studies e.g. Ozasa et al, IJRB 95:879-891 2019, review epidemiological studies of individuals who were exposed to atomic bomb radiation and their children who were conceived after parental exposure to radiation have contributed a large amount in terms of our understanding of the late health effects of atomic bomb radiation and it's transgenerational effects. The epidemiological studies, in particular, have demonstrated increased radiation risks for malignant diseases among survivors including those exposed *in utero,* and possible risks for some non-cancer diseases.

In their publications the ICRP describe in detail the process for use of epidemiological data, including a-bomb survivor studies, in parallel with animal experiments, in particular the doubling dose from the megamouse studies to come to conclusions regarding the population based risks of radiation exposure in terms of cancer and genetic (heritable) effects. In brief, the incidence data and the background levels of disease are used to define the doubling dose, which is then converted to risk per unit dose. The risks from different types of disease are summed and averaged to calculate overall detriment. For induction of all cancers, the current risk is calculated to be 5.5% per Gray for the whole population, and for heritable effects the risk is of the order of 0.2% per Gray. However, ICRP are explicit in that these figures are uncertain, and that population based risks cannot be applied to individuals, and, further make a clear case for further work to more fully characterise population based and individuals risks in terms of specific cancer types.

The work undertaken on this Project Licence will be the completion of an experiment currently in progress where genetically predisposed mice are being exposed to one or two doses of x-rays at different ages. The completion of the study was delayed due to concentrating on an acute study using gamma irradiation and breeding issues with the C57BL/6 *Apc*$^{Min/+}$ colony. These mice have been successfully bred at this establishment for over 20 years and these issues have now been resolved. The completion of this study will give information on the effectiveness of a split-dose of radiation on the induction of intestinal tumours i.e. are the doses additive and what are the effects of irradiation at different ages on tumour number. Pathological examination of selected tumours from each group will be undertaken and DNA extracted from the tumour material for use in molecular studies comparing gene losses in tumours from the different experimental groups.

What outputs do you think you will see at the end of this project?

The CONCERT and MELODI SRA and roadmaps identify a number of key uncertainties in radiological protection which are of high priority for research. These include: (i) the risks posed by low doses of radiation, (ii) the effects of different types of radiation, (iii) the impact of age at irradiation, (iv) the role and identity of genetic factors in radiation sensitivity and (v) the importance of interactions between radiation and other contributory risk factors for radiogenic diseases.

The studies proposed in this Project Licence use a genetically altered mouse model of gastrointestinal cancer and will provide information on the relative biological effectiveness of x-rays given at two different times for *in vivo* gastrointestinal cancer induction (addressing uncertainties (ii and iii) and on the gene loses in the tumours induced (addressing uncertainties iv and v). As such, the proposed project is of high priority for the UK Department of Health which sets research priorities in the UK. The information obtained in the proposed project will feed into the development of refined models for cancer risk estimation in human populations.

As detailed above, the results from animal studies are crucial to support low dose epidemiological studies, to provide clear scientific understanding to underpin appropriate and thus effective radiation protection. Ultimately, the project results might also inform personalised radiation protection which could eventually be implemented on the basis of genetic risk as well as other factors.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The results from previous animal studies examining the induction of intestinal tumours by ionising radiation and the *Apc*$^{Min/+}$ mouse model have already contributed to the evidence base for providing advice and guidance to international organisations (*e.g*. The International Commission on Radiological Protection (ICRP), International Atomic Energy Authority (IAEA)), relevant government agencies (*e.g.* Department of Health), and the nuclear industry.

There is clear epidemiological evidence from the Atomic Bomb survivors that age at irradiation is an important factor, the younger you are at exposure, the longer you have to live leading to a greater risk of cancer. Current work is the evaluation how epidemiological studies of background radiation and childhood cancer can improve the understanding of the effects of low-dose radiation (https://www.ncbi.nlm.nih.gov/pubmed/31751953). ICRP have also recently highlighted there is a lack of evidence on these effecthttps://www.icrp.org/publication.asp?id=ICRP%20Publication%2012.

During the course of this project, a greater knowledge of the effects of cumulative exposure administered as two separate doses given at neonatal ages (2 and 10 days old) combined with irradiation as young adults and adults (30, 45 and 90 days old) and aged adults (180 days old from a previous experiment) on radiation-induced intestinal carcinogenesis will be obtained. This will give information on the effects of irradiation at different ages and if a second, later irradiation has any effect on tumorigenesis i.e. are the effects additive?

In the longer term, molecular biological analysis of the tumours will provide information on the genes and gene losses involved in tumour formation which will further inform radiation protection legislation

and guidelines and be useful in addressing the identity of genetic factors in radiation sensitivity in people with *APC.*

The results from animal studies such as those undertaken in this project are crucial to support low dose epidemiological studies, to provide clear scientific understanding to underpin appropriate and thus effective radiation protection. Ultimately, in the future, the project results may also inform personalised radiation protection which could eventually be implemented on the basis of genetic risk as well as other factors.

How will you maximise the outputs of your work?

The results from these studies will be presented at meetings and conferences (for instance the annual European Radiation Protection Week) and submitted for publication in the open scientific literature and thus add to the knowledge base available to researchers worldwide and used by ICRP, UNSCEAR and WHO in their future radiation protection guidelines. The raw data from individual tumour counts and size data will be placed on STORE (http://storedb.org/store_v3/)
to allow future use by other researchers and avoid repetition of animal experimentation.

Species and numbers of animals expected to be used

- Mice: Inbred and genetically altered mice, 1,250 animals during the project licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice used for breeding will be mated at 5 or 6 weeks of age and kept for their useful breeding lifespan (usually 3-4 litters).

Mice exposed to x-rays as neonatal animals will be placed in Corex boxes in their nesting material (as they are not expected to move around the cage) and adult mice will be placed in the boxes without any nesting material as this allows them to run around freely. The mice will exposed to either 2.5 Gy x-rays (5 minutes) or 5 Gy x-rays (10 minutes). Mice which are sham-exposed will be placed in the x-ray machine for similar times. After exposure or sham-exposure they will be returned to their home cages. Mice will be killed following 200 days after their last exposure.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Based on previous experience with our x-irradiation system, we do not expect to see any initial effects in adult mice resulting from the irradiation procedures. In previous experiments, we have not seen any effects in neonatal mice (e.g. rejection by their dam, being found dead) after their return to their home cage and therefore, don't expect to see them in these experiments.

As the experiment progresses and the mice age, some of the mice will bear an increased intestinal tumour burden and may show moderate signs of this disease, including pale feet, ruffled fur, inactivity, lack of appetite, weight loss and may show rectal bleeding or rectal prolapse due to tumours in their colo-rectal region. Mice will be scored using a body-condition scoring system (Ullman-Cullere and Foltz, 1999) and closely monitored for clinical signs of disease and will be killed if they show overt signs of disease.

Some female mice (< 5%) may develop mammary tumours and these will be killed if the tumour is greater than 12 mm diameter (in practice, this is shortly after the tumour has been discovered and before any ulceration has occurred).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Breeding mice.

All C57BL/6 *Apc*$^{Min/+}$ mice will develop intestinal tumours as they age.

Apc$^{Min/+}$ mice used for breeding purposes (about 25%) will be expected to be assigned a moderate severity after 100 days of age as they will have developed intestinal tumours and they may show moderate signs of this disease, including pale feet, ruffled fur, inactivity, lack of appetite, weight loss and may also show rectal bleeding or rectal prolapse due to tumours in their colo-rectal region.

Apc$^{Min/+}$ mice not required for future breeding are killed and 50% of these will be assigned a mild severity as they will be greater than 50 days old (the earliest age that tumours have been seen to develop). The other 50% of mice will be killed at or just after weaning and they will be assigned a sub-threshold severity as they will show no signs of tumour development.

F1 experimental mice

All F1 C57BL/6 x CBA/Ca *Apc*$^{Min/+}$ mice exposed to x-rays or sham-irradiated will develop intestinal tumours and will be expected to be assigned a moderate severity. Control F1 C57BL/6 x CBA/Ca wild-type mice which are exposed to x-rays will be assigned a mild severity as they will not develop any tumours.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to investigate the effects of ionizing radiation on the gastrointestinal tract. The C57BL/6 *Apc*$^{Min/+}$ mouse model is an established model of radiation-induced intestinal and mammary carcinogenesis and, as such, it provides the best experimental model for this work.

What was your strategy for searching for non-animal alternatives?

Lower organisms such as invertebrates, plants and micro-organisms and intestinal organoids.

Why were they not suitable?

Lower organisms such as invertebrates, plants and micro-organisms are not suitable because they do not have the same gastrointestinal tract structure as mammals.

Intestinal organoids which are multi-cellular intestinal systems developed from intestinal stem cells are proving to be a promising model for the testing of pharmaceutical and food compounds. They can now be cultured in 3-dimensional systems and share many intestinal features including a highly folded epithelium structure consisting of crypts and villi similar to native intestinal epithelium but they lack some of the essential components of the gastrointestinal tract such as the enteric nervous system, vascular systems, lymphatic systems. Some intestinal organoids are being used as models of colo-rectal cancer however, they are unable to reproduce the individual gene losses and the progression of the disease, especially at the early stages and are not representative of the heterogeneous nature of the tumours. The other limitations of intestinal organiods are that the cells must be embedded in Matrigel^{TM} and before they can be grown in 3-D, which creates organoids that are of differing shapes and sizes and lack the gross anatomical features of the intestine and a few weeks after the seeding of cells to the 3-D scaffold, the model deteriorates which could be due to the lack of nutrients and oxygen starvation. Until the problem of long-term maintenance of the organoids in culture is addressed they will be unable to develop cancer and not able to replace *in vivo* carcinogenesis studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The experimental group sizes have been calculated using power calculations and statistical modelling undertaken from previous experimental results with the aim of using minimum group sizes to produce statistically valid results, aiming for 95% confidence levels.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The numbers of animals used have been minimised on the basis of previous experience with this mouse model and with statistical advice from the in house statisticians and the use of the NC3R's Experimental Design Assistant. Using results from previous irradiation studies on the F1 C57BL/6 x CBA/Ca *Apc*$^{Min/+}$ mice model we have been able to reduce the numbers of mice per group by 50% i.e. from 50 per group to 25 per group.

What other measures apart from good experimental design will you use to minimise numbers?

The numbers of intestinal tumours induced in the model following x-irradiation will be evaluated as the experiment progresses with the aim of minimising the group sizes once statistically valid results have been obtained.

The interpretation of the results will be undertaken with the advice of statisticians and the statistical methods applied will include t-tests, ANOVA, Poisson statistics and regression analysis, as deemed appropriate to the data obtained. Once published in scientific journals all the experimental results will be placed on the STORE database of European Radiobiological Studies (http://www.storedb.org.) which will allow future analysis of the results and mean that other researchers will not have to repeat the studies.

The use of animals specifically for molecular studies will be avoided / minimised by long-term archiving of intestinal and mammary tumour tissues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice have been chosen for these studies because they are the lowest vertebrate group in which well-characterised models of intestinal cancer have been developed, they are genetically similar to humans and their use maximises the potential use of genetic markers in molecular studies and the potential for interpreting results using genetic databases.

The project will use the C57BL/6 *Apc*$^{Min/+}$ mouse model of intestinal carcinogenesis which is a well-established model of radiation-induced cancer.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have shown previously that irradiation at immature life stages (embryo and fetus) do show small increases in tumour numbers but giving two doses of x-rays *in utero* may cause their death as immature life stages are known to be more susceptible to irradiation and the mice would need to develop into adults before any effects are seen.

The use of species that are less sentient is not possible as they do not have the same gastrointestinal tract structure as mammals.

The use of terminally anaesthetised animals is also not possible as they will not develop tumours following the irradiation.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will only breed sufficient animals to meet out planned experimental needs. All mice will be group housed and maintained to the highest standard for welfare in line with Home Office regulations and approved by our Named Veterinary Surgeon; rodents like to shred, burrow and nibble and hide in dark places, environmental enrichment is included in their cages for them to shred and burrow under, shelters to hide in and tunnels to run through.

Some of the mice will bear an increased intestinal burden and may show moderate signs of this disease. All mice will be closely monitored for clinical signs of disease, and will be humanely killed at the end of the experiment or as soon as they present with overt signs of disease.

Experience gained under the previous Project Licence where rectal bleeding, due to an increase in the number of large intestinal polyps, was observed in experimental groups given 2 and 180 day or 10 and 180 day x-ray exposures has led to a change in the experimental groups in this study. The 180 day exposure groups have been removed from the study and an earlier time-point of 45 days has been introduced. This will also reduce the maximum life-span of mice in the longer term groups from 380 to 290 days (the average life-span of a F1 C57BL/6 x CBA/Ca *Apc*$^{Min/+}$ mouse is 450 days).

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Compliance with the ASPA (Animals (Scientific Procedures) Act) 1986 regulations - https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/662364/Guidance_on_the_Operation_of_ASPA.pdf

Regular reference to the Animals in Science Regulation Unit Guidance - https://www.gov.uk/guidance/animal-research-technical-advice

Regular reference to the ARRIVE Guidelines published by the NC3R's - https://www.nc3rs.org.uk/arrive-guidelines

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Attending courses on the 3Rs, use of the NC3Rs website to check for advances in the 3Rs during the course of the project. Literature searches will be undertaken during the study to check on *in vivo* and *in vitro* developments in this field.

Explain the choice ofspecies and the related life stages

We are using a genetically altered mouse model of intestinal carcinogenesis. Adult mice will be used for breeding purposes and neonatal and adult mice will be used for exposures to x-rays in this Project Licence. Studies using aged mice were undertaken in the previous Project Licence; but no effect of a second dose of x-rays at 180 days was observed and so the experiment is being expanded to look for effects of irradiation at younger ages. Based on previous work, It might be expected that the neonatal exposures might give a higher incidence of intestinal tumours when combined with a second exposure which will give much needed information on the effect of age at exposure on tumorigenesis.

NON-TECHNICAL SUMMARY

175. Regulation of lymphocyte biology by ubiquitin and ubiquitin-like modifiers

Project duration

5 years 0 months

Project purpose

None selected

Key words

lymphocyte, immunity

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

During viral infections, lymphocytes - components of our immune system charged with responding to and eliminating foreign agents - develop from a few small, innocuous cells into many millions of large killing machines able to efficiently detect and kill infected cells. This transformation is accompanied by

extensive changes, many of which are poorly understood. We are interested in one of these changes which helps controls how these cells proliferate and function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

These studies may produce several potential bene-fits, most notably in improved basic knowledge about how immune responses are induced, maintained and controlled. Such knowledge may also contribute to our understanding of how these systems some-times go wrong, such as during autoimmune diseas-es. Furthermore, insights gained from this project are also likely to apply to other bodily systems in health and disease.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We use mice, as they are readily genetically modi-fied to allow us to alter specific parts of the immune system so that we can test the function of these com-ponents and because mice mimic human physiology very well. We use experimental groups of 5-8 in most cases. We expect to have to breed up to 1000 mice per year for 5 years (the great majority under a 'be-low threshold' severity limit). Many animals will be used for post-mortem tissue analyses, in which case no in-life experimental interventions will take place.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The majority of mice will be used only for breeding or as a source of tissues & will not be subjected to any interventions. Where mice are used in experiments, these will usually be designed to test how their im-mune systems deals with different stimuli. These studies will normally involve giving a chemical or mi-cro-organism that promote reactions in the body sim-ilar to vaccination. These animals will undergo brief discomfort from the injections to give the substances. There may be possible local inflammation (similar to having an insect bite), and potentially a brief period where animals have a fever / feel "flu-y" or lose a lit-tle bit of weight loss because the eat a little less for a few days as a result of immunisation with substances that stimulate immune cells. Most of these effects will be slight (similar to people with a cold) or occasion-ally may be moderate (more like a person having the flu). Some animals will undergo exposure to radia-tion, to suppress their immune systems. This is to al-low us to monitor how the new immune cells that we give them (taken from the bone marrow of another humanly killed mouse or from a

blood sample) move around the body and function. We can't get this in-formation any other way. Animals are kept in a spe-cial system of caging after the radiation treatment un-til the new blood cells have taken over to make sure they have no risk of infection. Once the new cells have moved around the body the animals should have no long-term adverse effects on their welfare. Mice will be humanely killed at the end of any exper-imental studies.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We use a type of white blood cell (T-cells) that originally came from human volunteers and are now grown in dishes in the lab to test how different genes work. However, these cells have been changed by living outside the body and do not behave like 'real' T cells from animal or human tissues. In particular, the cells aren't flexible and can't change the way that immune cells do as people and animal age or during infection. The changes that occur during these processes can only be investigated in the lab properly from cells that are taken directly from animals or within living animals.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will take several approaches to minimise the numbers of animals required. We are careful how we breed animals aiming only to produce enough animals to perform studies and to keep for new breeding pairs. However, even careful breeding practices will produce some animals who can't be used because they don't have the right combination of genes. We will only proceed to using live animals in experiments if preliminary data generated from cells in the lab are strong enough to justify them. We use statistical methods for all our studies that use live animals to check that we are using the right number of animals to make sure that we have the best chance of good results. This means we are using neither too many animals or too few.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse immune system closely replicates that of humans. Although the proteins we are interested in are expressed throughout the body we will generate mice that only lack them in small parts of the immune system, to ensure that potentially harmful effects in other tissues throughout the body are avoided. We use anaesthesia and pain-killers if this is better for the animals. Where we need to use chemicals that change the immune system we will always use the least harm in order to give us the data we need. Similarly, we will always try and give the compounds in a way that is least painful for the animal (so in food or water rather than by injection) whenever we can.

NON-TECHNICAL SUMMARY

176. Regulation of neural circuits and behaviour in fish by the pituitary and adrenal hormones

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

zebrafish, medaka, stress, behavior, development

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This programme aims to investigate the effect of early life stress exposure on adult behaviour and physiology using fish. Exposure to stress during early life is a major risk factor in developing psychiatric diseases in adulthood in humans, but the underlying mechanisms are still not fully understood.

One of the major players involved in mediating the stress response are the hormones produced by the Hypothalamo-pituitary-adrenal (HPA) axis such as Glucocorticoid (GC) and Adrenocorticotrophin (ACTH). In this propject, we aim to study the effect of altering the level of these two major hormones during development and characterize subsequent behavioural and physiological modifications in fish. Next, we will identify the brain regions and molecules that are involved in mediating the effects of the GCs and ACTHs. Lastly, we aim to find compounds that can alter the effects produced by early manipulation of GCs and ACTHs. The understanding and identification of molecules involved in GC and ACTH's effect during development may open up new possibilities to tackle psychiatric phenotypes induced by early life stress exposure.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This results will provide fundamental knowledge about how key stress hormones alter physiological and behavioural processes. Further, the results obtained will provide candidate molecules involved in mediating the long-lasting and powerful effects of stress hormones in shaping the brain and behaviour. We will further gain mechanistic insight into the function of these molecules. Given the strong conservation of the stress response system throughout vertebrates, the mechanisms that we identify in zebrafish are likely to be also found in mammals including humans. The molecules identified in this project present potential targets for developing therapeutics for stress-induced disorders in humans.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Zebrafish (8100) and Medake (2160) over the course of 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Phenotypes of genetically modified animals produced in this proposal are expected to have no or low adverse welfare effects. However in the unlikely event that breeding of transgenic animals has

potentially harmful phenotypes, the offspring will be killed humanely.

The main methods used in thie project are behavioural testing of adult and larval stage fish. The behavioural testing sessions involve video recording natural exploratory and social behaviour of animal while animal is allowed to freely swim in a tank. This procedure is expected to produce no harmful phenotypes.

In some procedures we will perform behavioural testings after the animal has been treated with pharmacological compounds. As the treatment duration is short (less than 2 hours), we expect low adverse welfare effects. However, in rare cases, if the experimental animals display compromised movement and visible sign of distress during treatment, the animal will be sacrificed immediately in an humane manner.

In some procedures we combine the behavioural testing with after subjecting an animal to a stressor. Different stressors will be used, but for all of them shortest possible duration of treatment will be applied so that the treatment. The expected level of severity of such a treatment is mild. However, in rare cases, if the experimental animals display compromised movement and visible sign of distress during treatment, the animal will be sacrificed immediately in an humane manner.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The complexity of behavioral regulation by stress cannot be studied using in vitro cell cultures as this requires coordinated interaction of multiple organs. The pituitary and adrenal gland in particular produce multiple hormones in a dynamic manner. We currently do not have possibilities to culture such complex system in tissue culture. Furthermore the stress regulation involving pituitary and adrenal gland is only found in vertebrates. Therefore invertebrate genetic model systems such as fruitfly and worms do not have similar systems. Nevertheless, we will still strive to identify those cases where we can avoid using animals during the experimental design phase. For example, as a large amount of literature on stress biology is available using rodents, we will use this information. Thus, we will only address those questions in zebrafish that have not been already addressed using other species. For some questions, simulation and modelling based on existing data could provide an answer. For those questions, we will seek a close collaboration with mathematicians.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We estimate that we will need to use 8100 zebrafish and 2160 medaka over the course of 5 years. This estimate is based on our own pilot work as well as our own published data. We have extensive

experience in studying zebrafish behavior under stress therefore we can accurately estimate the number of animals required for obtaining the results for certain experiments. As more behavioural results become available, we will conduct additional evaluation to see whether the number of animals can be further reduced from those currently proposed. We will also use the latest statistical methods for data analysis to reduce sample size. For our larval behavioral analysis, whenever possible, we will use early stage animals which do not fall under regulation.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Fish represents the most refined animal model for studying the effect of the stress hormones of the Hypothalamo-Pituitary-Adrenal (HPA) axis. The stress regulation of behaviour has been traditionally studied in rodent models especially using mouse. However the HPA axis is a conserved vertebrate feature and can be studied in fish. It cannot be studied in invertebrate genetic model system such as flies or worms.

Optimisation of animal welfare is achieved by different approaches including:

1) Animals will be exposed for a short duration of stressor treatment.

2) Pharmacological treatment will use previously published “safe” dose.

3) The behavioural testing involves non-invasive monitoring of naturalistic behaviour

4) Animals are monitored continuously during the entire behavioural testing session to look for signs of distress.

5) At any time during experimental procedures, if animals show clear sign of distress then they will be sacrificed immediately in a humane manner.

Home Office

NON-TECHNICAL SUMMARY

177. Regulation of T cell homeostasis and function in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to identify and characterise the mechanisms controlling how particular immune cells called “T cells” are kept in a normal functioning state in both health and in disease conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We do not fully understand how T cells are maintained in an optimally functional state throughout the life course. New T cells are produced continuously throughout life. Immune function declines with age, and it is unclear what mechanisms are defective in aging T cells or the communication pathways within cells that are required for their optimal function. Understanding these pathways is important as they are amenable to manipulation by pharmacological agents.

What outputs do you think you will see at the end of this project?

We will understand how continuous T cell generation contributes to maintaining a full and active immune system, how ‘memory’ T cells, that can remember specific infections, are made and kept and how memories to new infections are sorted and stored along side existing memories.

Our studies of how communication pathways inside cells control new generation and sustenance of existing T cells, will allow us to better predict how anti-inflammatory therapies influence the function of T cells and what impact this has on host immunity as a whole.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Understanding how T cell-mediated immune responses are generated and maintained has never been more important. Training the immune system to respond to pathogens through vaccination remains a front-line therapy, in the face of the ever growing spectre of anti-microbial drug resistance. Targeted T cell-mediated immunotherapy has finally come of age and is one of the fastest developing areas of cancer treatment. Vaccines and reactivation of anti-tumoral immunity depend on the generation of T cell memory. Therefore, understanding how T cell memory is established and maintained is fundamental for development of such therapies.

How will you maximise the outputs of your work?

We aim to publish all novel, robust research findings consequent from the project, whether results represent new findings and insights or simply support a null hypothesis. This will be achieved by

publication but also storing manuscripts with pre-prin servers such as BioRXiv to maximise speed of dissemination of new data.

We also collaborate extensively with mathematical modellers who perform sophisticated modelling meta analysis of data to extract the maximum information possible.

Species and numbers of animals expected to be used

- Mice: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, we study the function of immune cells following either genetic or pharmaceutical intervention. Transplantation of immune cells is also a key method to be able to follow the behaviour of a defined cohort of cells in the context of a normal immune system. As such, mice will typically be subject to drug conditioning, to allow injection of cells to become settled and established in a new host. Mice may then be subject to blood sampling to allow longitudinal analyses or killed to allow more detailed analysis of immune cell function. A single procedure would therefore typically involve 3-6 separate steps and monitoring continue for as few as a few days or as long as several months.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

For the majority of experiments, analysing immune function following an intervention of some kind, mouse health and behaviour is not expected to be altered as a consequence. Infection of mice with specific infectious agents such as influenza virus, may result in transient weight loss, from which most mice recover. The condition of mice will be carefully monitored and weight loss not permitted to progress beyond defined limits, instead killing the mouse before severity limits are breached. Establishment of tumours is not expected to impair normal function or health. Nevertheless, tumour size will be strictly monitored to ensure tumour size does not exceed defined limits and result in impairment to physical function of mice.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For 70% of experiments, we expect only a mild severity. For mice either subject to live pathogen infection or tumour engraftment, we expect severities to reach moderate levels.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because of the complex physical and temporal arrangement of the immune system, whole body model systems are required to unravel functions under homeostatic conditions as well in inflammatory scenarios. While it is possible to generate information regarding regulation of some aspects of the immune cell behaviour in cell culture it is not possible to mimic homeostatic or immune responses to infection in vitro.

What was your strategy for searching for non-animal alternatives?

We considered using in vitro cellular immunology assay systems and immortalised cell lines.

Why were they not suitable?

In vitro systems, while useful, do not fully replicate the complexity of immune interactions or disease pathogenesis in vivo and it is essential to use appropriate and robust animal models to dissect these processes. Immortalised cell lines can be useful tools for testing broad principles or signalling pathways, the way in which signalling pathways are configured varies considerable between different tissues and indeed, the same cells at different stages of differentiation. Therefore, studying primary cells in vivo is critical to understand the context specific functions we proposes to investigate here. Furthermore to develop therapeutic approaches with potential to alleviate human disease it is necessary to establish parameters influencing efficacy in an animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

It is difficult to predict the full course of experiments that will be undertaken in the course of pursuing a project over a five year period. However, individual experimental design are subject to power

calculations to estimate the number of mice required for a single trial and then the number of trials required to provide statistically robust evidence of any differences.

For objectives 1 and 2

Approximately 30 GA lines are required for these objectives, although other novel strain combinations may be required as dictated by experimental findings during the project. Generating novel strain combinations to test gene functions genetically is a key component of the proposal. As such, generating and maintaining the 30 or more lines required for the proposal will require a breeding colony of approximately 100 cage capacity using approximately 600 mice/year (assuming an average 4 month breeding life per pair).

To establish statistically robust results for monitoring immune responses by T cells in vivo, or comparing mouse strain phenotype will typically require 3-5 independent replicates using 10-16 mice per replicate and a total of between 30-48 mice for a given strain, including littermate controls. We estimate that a single experiment a month for each research associate (of which there are 3), using ~20 host mice, will require ~750 mice /year. ~2/3 of these experiments will be under protocol 2 and ~1/3 under protocol 3. Therefore we require approximately 2500 and 1250 procedures for protocols 2 and 3 respectively over the five years of the project.

For objective 3

Generating and maintaining the 10 lines and congenics required for this objective will require a breeding colony of approximately 50 cage capacity using minimally 300 mice/year (assuming an average 4 month breeding life per successful pair, but ~10% breedings fail).

To establish statistically robust results for monitoring T cell behaviour/phenotype in vivo, or comparing mouse treatment and control groups will typically require 3-5 independent trials using 10 mice per trial and a total of between 30-50 mice for a given condition, including littermate controls. We estimate that two experiments per researcher (of which there are 3) a month, using 20 host mice, will require ~750 mice/year. Approximately half of these experiments will be under protocol 2 and remaining experiments split between protocol 3 and 4. Therefore we require approximately 1900 procedures for protocols 2 and ~950 procedures for each protocols 3 and 4 overt the five years.

Summary

Protocol 1 :. ~5000.

Protocol 2 : ~4400

Protocol 3 : ~2300

Protocol 4 : ~1000

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have taken advice from statistical collaborators to take an experimental approach that aims to maximise the detection of experimental effects in a given trial, and then to test for reproducibility of experimental findings between trials. For mathematical modelling experiments, we use just as many mice as are required to allow robust estimation of model parameters. These are typically kinetic experiments and concentrating mouse sampling over the periods of greatest dynamics is critical for this. Conversely, fewer mice need be sampled in less dynamic periods. Such uneven distribution of sampling results in most efficient use of mice. Model fitting can also identify areas of uncertainty that would benefit from improved sampling frequency. Such iteration between experiment and modelling is a central principle in avoiding oversampling and therefore redundant use of mice.

What other measures apart from good experimental design will you use to minimise numbers?

Where ever possible, we use both male and female mice.

Breeding strategies for GM REDACTED ensure that, where possible, control groups can be taken from littermates or that control and experimental GM lines are derived from common parentage to ensure background genetic composition is equivalent.

Use of multiparameter single cell analysis methods permits several experiments to be performed and data collected from individual mice - studying more than one immune cell type from the same individual for instance.

Mathematical modelling is an integral methodology of our work. This informs optimal experimental design but also substitutes for empirical experimentation. Models make predictions that can be validated by much smaller experiments rather than large empirical experiments that might arrive at similar conclusions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In order to achieve our goals we propose to use mouse models to study the development and function of the immune system for several reasons. Mouse transgenic and knockout techniques are well-established and their haemopoetic system has been intensively studied and bears extensive similarities to that of humans. There exists a vast array of reagents facilitating the study of the immune system in contrast to the situation in other documented species.

Our procedures are of mild/moderate severity and have clearly defined endpoints.

However, it is not possible to fully predict the nature or severity of any potential defect and for all types of mice there will be careful monitoring for possible adverse side effects. Careful monitoring of strain characteristics will be employed and the information collated on databases to monitor whether phenotypes exceed their usual characteristics. Animals exhibiting any unexpected harmful phenotypes will be killed using a Schedule 1 method, or in the case of individual animals of particular scientific interest, advice will be sought from the local Home Office Inspector.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

To our knowledge no other species of lesser sentience can fulfil the requirements of this programme to the same extent as the laboratory mouse.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have gained a detailed understanding of the genetic and chimeric mouse systems employed in this project. We have specifically developed the use of the conditioning drug busulfan to allow generation of bone marrow chimeric mice. This represents a substantial refinement of the traditional conditioning methods of lethal irradiation of mice, which have numerous well documented welfare costs to mice. Drug treatment is non-lethal and, at the doses employed experimentally, very low toxicity.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

With assistance of our local biological services staff, we monitor the 3Rs literature and newsletters, as well as scientific literature for new opportunities for refinement. For adminstration of substances and aseptic surgical techniques, we have established best practices informed by guidelines pubished by the Laboratory Animal Science Association.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We remain alert to technological advances that permit refined use of mice or replacement with in vitro model systems, as well as monitoring the 3Rs literature and newsletters.

Explain the choice of species and the related life stages

The aim of our research is to better understand how the immune system is maintained in a healthy functioning state throughout life. Because of the complex physical arrangement of the immune system, whole body model systems are required to unravel functions under homeostatic conditions as well in disease scenarios. While it is possible to generate information regarding regulation of some aspects of the immune cell behaviour in cell culture it is not possible to mimic homeostatic or immune responses

to infection in vitro. The mouse represents a relevant and tractable system to study the immune system. Mice are readily amenable to genetic manipulation, which is a key tool exploited in this project. The immune system of the mouse , next to that of human, is the best characterised immune system of any organism, and for which there are the greatest number of tools and reagents available to study. The natural life time of the mouse, at around 1-2 years, makes possible life long studies of immune function.

NON-TECHNICAL SUMMARY

178. Regulatory Assessment of Chemical Safety for Aquatic Vertebrates (Fish)

Project duration

5 years 0 months

Project purpose

None selected

Key words

Fish, Environment, Chemical, Risk

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to generate high quality data for regulatory risk assessments of chemicals that have the potential to reach the aquatic environment.

Data for regulatory risk assessment is a necessity under many national jurisdictions. It is used to ensure adequate protection of wild fish and other aquatic organisms from chemicals that are released into the environment by the activities of man.

A retrospective assessment of these aims will be due by 12 September 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Regulatory risk assessments are made to help with decisions for the proportionate regulation and management of chemicals that could move into aquatic environments. The benefits of the regulatory risk assessment process are twofold: • Chemical products that are a demonstrable risk to fish and the aquatic environment are ruled out of marketing and manufacture. • Chemical products that are demonstrably safe for the aquatic environment are authorised for use, which in turn accrues all of the benefits intended from the development of that product, be it improved protection of crops, or animal or human health.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The species of fish selected will depend on the purpose of the test and the regulatory context. For example, the majority of initial testing for EU regulations will use a representative cold water species, namely Rainbow Trout. Additional testing for further characterisation of risk tends to use smaller, fast growing species, namely Fathead Minnows, Zebra Fish and Rice Fish. Assessments of Bioaccumulation in Fish can use larger species, namely Common Carp and Bluegill. In total, up to 11,000 fish may be used over a period of 5 years, to generate regulatory data on this project.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The strategy for testing is carefully managed to ensure that all existing data on the properties and toxicity of the chemicals is used in order that only the minimum testing needed is carried out. However to establish the risk of the chemical to fish, testing in the initial stages of risk assessment is classified as severe. The fewest possible numbers of fish are used, but the fish are not fed, and some of those fish are likely to die. To avoid this as far as possible, the test is short (maximum of 4 days) and the fish are observed very frequently. Where signs of impending death are seen, humane interventions are taken. This involves removing affected fish and humanely killing them immediately. All testing is performed according to the International Test Guideline (OECD 203 Fish; Acute Toxicity Test).
Some testing is designed to assess the survival and growth of very young fish fry. The young fish larvae are observed frequently while they grow up over several weeks. They are cared for and fed in the usual way. Where signs of impending death are seen, humane interventions are taken. This involves removing affected fish and humanely killing them immediately. All testing is performed according to the International Test Guideline (OECD 210; Fish, Early Life Stage Toxicity Test).
In the later stages of risk assessment, the affects on the fish are less severe, with the outcomes being effects on growth rate in juvenile fish. It is necessary to anaesthetise fish for short periods so that they can be accurately weighed. These growth measures take several weeks to determine and the fish are cared for and fed in the usual way. This test is considered as moderate severity. Where fish do not eat normally and become thin, humane interventions are taken. This involves removing affected fish and humanely killing them immediately. All testing is performed according to the International Test Guideline (OECD 215; Fish, Juvenile Growth Test).
Some parts of the risk assessment process look at how fish accumulate the chemicals that they are exposed to, and how they leave the system of the fish after exposure. During this process, fish are cared for and fed in the usual way. This test is considered as mild severity. Where fish do not eat normally and become thin, humane interventions are taken. This involves removing affected fish and humanely killing them immediately. All testing is performed according to the International Test Guideline (OECD 305; Bioaccumulation in Fish, Aqueous and Dietary Exposure).

The European Union has also recently required that many chemicals are assessed for their ability to act as endocrine disruptors. In fish, this assessment involves breeding fish in defined groups, and assessing the number of eggs they can produce when exposed to the chemical. At the end of the test, fish are terminally anaesthetised and sampled for circulating levels of egg protein hormones, which when elevated in males, indicate that endocrine disruption is occurring. This test is considered as moderate severity. Where fish do not breed normally and become bloated with unlaid eggs, humane interventions are taken. This involves removing affected fish and humanely killing them immediately. All testing is performed according to the International Test Guideline (OECD 229; Fish Short Term Reproduction Assay).

All the fish used will be humanely killed at the end of each test, and no fish is used for more than one test. The majority of testing is performed for EU regulatory requirements. In some cases, tests may be performed for other worldwide jurisdictions, and may use tests with exact equivalency to the OECD Test Guidelines, but such test are only undertaken with the express permission of the Secretary of State.

A retrospective assessment of these predicted harms will be due by 12 September 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Tests using fish are currently required by regulators and are considered the only way to be sufficiently certain that wild fish will be protected by the results of the risk assessment. However, research is on-going to look for alternatives ways of being equally sure of protecting wild fish without testing fish in laboratories (e.g. by using living cells cultured from fish gills). Currently no alternative approach is accepted by the regulator, however on every occasion over the 5 year life of the project, we will ensure that:

- The testing is required to satisfy a regulatory imperative.
- Satisfactory data is not already available.
- No non-animal alternative method would be acceptable to the regulator.

A retrospective assessment of replacement will be due by 12 September 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

It will always be established that any testing has a clear regulatory requirement for the protection of wild fish in the aquatic environment, and that unnecessary repeated testing does not occur, by ensuring that adequate, acceptable data for fish does not already exist.

The minimum number of fish that can be used is determined by the regulatory guideline that ensures the scientific robustness and credibility of the statistics used to determine the result of the risk assessment.

Some guidelines allow for a further reduction in fish numbers in certain circumstances, e.g. when the chemical has properties that allow prediction of how it will interact with tissues reliably, and testing can be minimal to check these models. These minimised testing approached will be used as an alternative wherever is itpossible to do so.

A retrospective assessment of reduction will be due by 12 September 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The species used are those recommended by regulatory guidelines. Sometimes there is a choice, and in these cases, the species that is the most representative of the wild fish in the environment to be protected are chosen. In some cases, the fish used are not directly comparable with the population to be protected, but instead are fast growing which means that the length of the tests can be shorter.

All of the species used prefer to live in groups, and so no fish will be deliberately isolated. Where a fish is isolated by circumstances, this will not be allowed to continue for more than a few days.

Fish are also stressed by disturbance and handling and so these will be kept to a minimum, and where handling is necessary, it will use ways that are known not to cause any damage to gills or scales.

In some tests, it is likely that a proportion of the fish may die. Where this is the case, the fish will be observed very frequently and where signs of impending death are seen, humane interventions will be taken immediately. This involves removing affected fish and humanely killing them. Additionally, any fish that is showing other signs of sickness beyond that expected will also be humanely killed straight away. For example, fish may not grow as they normally would, or may not breed as they normally would, and this would be expected in some cases, but any fish that is visibly losing condition, or is visibly egg-bound, would be humanely killed.

A retrospective assessment of refinement will be due by 12 September 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

179. Repair, replacement and regeneration of cartilage and bone

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Sheep	juvenile, adult, aged
Rats	juvenile, adult, aged
Rabbits	aged, adult, juvenile

Animal types	Life stages
Pigs	juvenile, adult, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Evaluate novel therapies or technologies to facilitate the repair, regeneration or replacement of cartilage or bone.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cartilage has important functions for joint lubrication, ease of movement and shock absorbing. Damaged cartilage can be extremely painful and can significantly impact quality of life. Cartilage has limited repair capacity: when cartilage is damaged and repairs without help from medicines or surgery, it is often of lower quality than the original tissue, with reduced shock absorbing properties. In joints, severe damage to cartilage can be accompanied by damage to the bone surface beneath. Repairing damage to bone is applicable to multiple clinical settings, from traumatic head injuries, to craniofacial and maxillofacial reconstruction, to dental surgery.

Repair or regeneration of cartilage and bone can be affected by multiple mechanisms and factors, such as the formation of new bone cells, tissue and new blood vessels, mechanical stimulation or weight bearing. The efficacy of a technology to assist cartilage or bone tissue regeneration, or replace damaged tissue, must be evaluated in the context of these interacting factors as much as possible, *in vivo*.

Surgery, cell therapy (including stem cell and cartilage cells), or physical implants (e.g. plates, screws or artificial joints) are currently the major strategies to repair or replace cartilage and bone. The optimum strategy must be stratified to the patient's individual needs.

The work conducted in this project can answer lots of questions about new strategies and technologies to repair, regenerate or replace bone or cartilage, for example: how well can different materials replace or repair damaged tissue, how should they be attached, are they compatible with the existing intact tissue; ways to administer stem cells, ways to improve stem cell therapy (for example how many stem cells to administer and when and for how long)? The models and protocols described in this project will be applicable to multiple clinical fields, from osteoarthritis, to sports injuries, to head trauma, craniofacial or maxillofacial trauma, to dentistry.

What outputs do you think you will see at the end of this project?

Data will support product development, product registration, patents, and ultimately lead to new products.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

For research Sponsor companies, data can assist elimination of inadequate candidates prior to further costly development, and further animal research.

In the long-term these studies will benefit patients with various musculoskeletal diseases or conditions: the impact of this work is applicable in multiple treatment fields.

How will you maximise the outputs of your work?

Whilst publication of results would not be discouraged, it is expected that in most cases publication or dissemination will not be possible as the research will be conducted as a commercial service to companies.

Internally, the organisation will review processes and procedures after the completion of experiments, and use that experience to inform and develop future studies.

Species and numbers of animals expected to be used

- Pigs: 150
- Sheep: 150
- Rats: 150
- Rabbits: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will undergo invasive surgery to create injuries in bone or cartilage. These injuries may include:

- damage to the cartilage and/or bone in one knee joint of a sheep, or complete removal of a piece of cartilage (the meniscus) in one knee joint of a sheep;
- removing a piece of bone from the top of the skull of a rat, or removing multiple pieces of bone from the top of the skull of a rabbit, pig or sheep.

These injuries will then be treated with new drugs or materials. In some cases, the injuries may be left untreated as a comparison to the new treatment under investigation.

The injuries will be created under general anaesthesia which could last up to 3 hours for larger animals, depending on the defect or treatment required. The recovery from anaesthesia can be around 1-2 hours with prolonged anaesthesia like this, during which animals will be uncomfortable and disorientated. Pain and discomfort is expected during the subsequent recovery period (days – weeks), which we will manage with pain relief, and antibiotics will be provided if required. These will be administered with food, as injections, or as dressings.

If a drug or cellular treatment is being investigated, these may need to be administered on numerous occasions during the experiment, for example with food, as injections, or dressings. We may also need to take multiple blood samples from the animal during the experiment. The animals will need to be restrained for these procedures, and occasionally it may be useful to anaesthetise them. To prepare for this the animals are handled regularly to get them used to the staff and reduce any distress caused by restraining them as much as possible.

The animal may need to be anaesthetised on other occasions after the surgery to take CT images of the injury, for example to see how well the injured tissue is repairing, or if the test material is still in place. These sessions of anaesthesia will be quicker than the initial surgery, but the animal will still need to take medication and need some time to recover afterwards.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Pain, discomfort, lameness or reluctance to bear weight on operated legs is expected during the recovery period after surgery, and these signs may be accompanied by some weight loss. We would expect these signs over a 1-2 week period (with improvement over this time frame) particularly for more invasive surgeries on larger animals, such as the joint surgeries on sheep.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

All animals are likely to experience moderate severity effects as a result of the protocols described, although this is expected to be short-lived.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cartilage and bone are complex tissues which interact with surrounding matrices and tissues and whose growth and maintenance is affected by the mechanical stimulation of joint motion and weight bearing. These conditions are almost impossible to replicate in *in vitro* or *ex vivo* tissue when looking at functional healing or remodelling especially over longer time frames (i.e. months).

What was your strategy for searching for non-animal alternatives?

Non-animal alternatives have not been considered for this project, as the aim is to evaluate products and treatments in a replication of the clinical setting, including multiple factors of movement, weight bearing, the environment within the joint and blood supply for example.

It is expected that research conducted under this project licence will be based on supporting *in vitro* and *in vivo* evidence.

Why were they not suitable?

Non-animal models, for instance mechanical models or cell cultures, could replicate some of the factors involved in the healing process, but would not provide good information on integration, longevity or wear of implants for example, or replicate multiple important factors simultaneously such as the environment within the joint or surrounding tissue, weight bearing or blood supply.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated animal numbers are based on examples of likely study designs and timespans, for instance:

- up to two large animal (pigs or sheep) studies a year, using a maximum of 15 animals per study (150 animals per 5 years),
- one GLP study in smaller animals (e.g. rats) per year, requiring 30 animals (e.g. one group of 30 or one group each of 15 males and females, according to OECD guidelines).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

- For experiments using the joint, one leg will be operated on, leaving the opposite leg as a control. For skull defect experiments, multiple injuries can be created in larger animals (pigs and sheep), so control conditions can be measured alongside treated conditions. This helps to eliminate the need for separate control groups in most studies.
- We encourage the use of non-invasive imaging and measurements (for example CT scans or observing weight bearing) to eliminate the need for including extra animals to be killed at earlier timepoints.
- Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures, before commencing larger studies - where possible, pilot study data will be included in the main study.
- We frequently recommend cadaver studies to Sponsors, and use cadavers for model development and training opportunities.

What other measures apart from good experimental design will you use to minimise numbers?

- Pilot studies with 1-2 animals can be conducted, for example for significant changes to products or procedures.

- In skull injury models in larger animals, we can replicate treatment conditions within each animal as well as between animals, which increases the number of measurements we can take as well as improving the reliability of these measurements.
- We encourage the use of non-invasive imaging and observations (for example CT scans or observing weight bearing) which can give us extra functional information during the study, rather than just looking at tissues at the end of the study.
- We routinely harvest tissues and organs from experimental animals for research and training purposes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Sheep models are often used for research into osteoarthritis, joint damage and repair. Sheep joints are a close representation of human joints mechanically and the thickness of cartilage is more similar to humans than other animals. For cartilage repair studies, just one leg will be operated on and medication will be provided to reduce pain and minimise the risk of infection, so movement and weight bearing will be disrupted as little as possible, other than the discomfort following the surgery and injury itself.

Calvarial (skull) defect models are often used for research into bone regeneration. These are not load bearing and do not interfere with mobility. In smaller animals, these can provide basic and mechanistic information in shorter timespans than larger animals, for instance studies. In larger animals, information can be gathered on multiple treatments in larger injuries and over a longer timespan.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

For protocols 1 and 2 it is not possible to use smaller species as the differences in bone size (and therefore the size of implant used and the load applied to it) and the growth rates of these animals compared to humans makes the information we gather less accurate and less useful.
More skeletally mature animals are more useful for these purposes.

For bone regeneration studies (protocol 3) it is possible to use less sentient animals (mice, rats) in some cases, e.g. for basic research or mechanistic studies.
However it will sometimes be necessary to investigate bone regeneration in larger defects or over larger time periods, and less sentient animals would not be suitable for these studies.

Zebrafish and amphibians are an emerging model for orthopaedic research, but fish bone structure is diverse and there are larger cellular and structural differences between fish and human bones compared to other mammals, and the regeneration of amphibian bones in response to injury can differ widely from that of humans. For functional assessments of injury repair with novel treatments in a clinically relevant setting, the presence and structure of the long and flat bones along with the requirement for particular articulated joint movement and weight bearing means mammals are a more appropriate model forthese projects than fish and amphibians.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We routinely provide post-operative pain relief and antibiotics, and are prepared to extend the provision of these where necessary. All animals are closely monitored immediately after surgery, and then observed closely in the days and weeks after surgery, for instance their mood, grooming, movement, weight, eating and drinking,how the wounds look.

All the animals arrive to the facility at least two weeks before studies start. We try to receive larger animals for larger studies even earlier (e.g. four weeks) so that they can get used to the new surroundings and staff. During this time staff can start to train the animals if this will be needed for the experiment, for instance to stand still for blood sampling. Smaller animals (rats and rabbits) will also be handled frequently before the study to get them used to staff and being handled.

All animals are provided enrichment whilst in the facility, such as chew sticks or treats and raised tunnels for rats; raised steps, a hiding place and dietary enrichment for rabbits; chains, balls and bars for pigs to chew; chews and room to explore for sheep.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our facility is GLP-certified and experiments can be performed to GLP-certified standards where required; non-GLP studies are performed to the same standard operating procedures.

The PREPARE guidelines cover many topics that are usually discussed between the research team and Sponsors whilst developing protocols, and an adaptive approach to these will be useful for planning specific studies and continuing the project.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Our research staff actively seek opportunities for training and continuing professional development. We circulate the NC3Rs newsletters and take part in IAT and LASA activities. We communicate openly about animal welfare and suggestions and ideas for improvements are welcomed from all staff members.

Explain the choice ofspecies and the related life stages

Using bone injuries in rats and rabbits is a useful way to investigate the properties of new treatments in the short-term; the injuries created are much smaller than in larger animals and the healing will be quicker. This is an efficient way to investigate or compare new treatments quite quickly. Juvenile or adult animals would be used as their general growth rate should remain constant during the course of experiments.

Larger animals (pigs and sheep) are useful to evaluate products in the final stages of pre-clinical development: scaffold and implants of a similar size to those which would be used in humans can be applied; larger defects can be studied; and repair can be monitored over a longer time period (as could be expected in the human clinical setting). The size and weight of sheep, and the thickness of their cartilage, are more similar to humans than other laboratory animals. Juvenile or adult pigs and sheep would be used as they will be more skeletally mature and their general growth rate of new tissue should remain constant during the course of experiments.

NON-TECHNICAL SUMMARY

180. Respiratory system models

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To investigate and target mechanisms involved in diseases of the respiratory system, and where the respiratory system provides a relevant model, to investigate mechanisms involved in other immunological and inflammatory clinical conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite progress in the discovery and development of medicines, there is still a significant unmet need in the treatment and prevention of respiratory diseases (that affect lungs and airways), and diseases that involve inappropriate function of the immune system (immunological diseases and disorders). For example, within the EU, it was reported in 2015 that diseases of the respiratory system accounted for 8.5% of all deaths although in the UK specifically this stood at 14.1%.

Other diseases with high personal, social and economic costs (e.g. allergies and inflammatory diseases) have underlying immunological causes. The National Institutes of Health (NIH) estimated in 2006 that up to 23.5 million Americans suffer from autoimmune disease that are typically disorders in which the immune system attacks the body in error rather than concentrating on attacking non-self ('foreign') cells or targets. This is the third most common category of disease in the United States after cancer and cardiovascular disease, and reviews show that the prevalence of these types of diseases is rising (2019 information). The US National Institutes of Allergy and Infectious Diseases (NIAID) estimated in 2011 the cost of treating autoimmune disease in the US as greater than $100 billion annually.

The respiratory system with immune system involvement is a relevant system to investigate how respiratory and immunological disorders occur and develop. It can be used to investigate potential new targets and biological pathways common to some of these diseases, and to check that new treatment approaches work. Through examining information obtained from patients and determining how immune biology and disease are linked by genes, it is anticipated that new, specific and effective ways of treating diseases will be identified. Where targets are thought to be involved in development of respiratory disease, the use of animal studies designed to assess respiratory system changes will be essential to identifying and assessing possible new treatments.

What outputs do you think you will see at the end of this project?

This licence supports a wide range of methods to enable investigations of inflammatory and immunological systems that underlie many types of diseases, including those of the respiratory system. The respiratory system will also be used as a relevant model environment to provide information on

common mechanisms that underlie different systems and disease indications (to enable subsequent expansion of research into a wider range of disease indications when mechanisms in common exist).

Studies will generate essential information to support scientific programmes aimed at identifying and understanding new ways of treating diseases of the respiratory system, or to investigate immunological mechanisms. Experiments will be carried out to establish if animal models focused on parts of the respiratory system allow assessment of immune or inflammatory processes, or processes involved in other diseases which share mechanisms.

We will generate data on the effectiveness of potential new medicines in comparison to other treatments, and determine how the medicine might distribute throughout the body. This will aid selection of potential new drugs for the treatment of both respiratory diseases, and for other immunological and inflammatory conditions. The data will contribute to medicine development programmes to address unmet medical need in a range of disease types, to benefit patient health. It is also anticipated that work carried out under this licence will be included in scientific publications to enhance scientific understanding in this field.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The information generated from this work will contribute to medicine development programmes to address unmet medical need in a range of disease areas.

It will be an early step in a long process to confirm the relevance of targets that are involved in disease or to confirm how well a potential new medicine works, and will be used to support later clinical trials when new medicine effectiveness is tested in humans. Patients will benefit over relatively long timescales because medicine development can take many years.

It is intended that there will also be shorter timescale benefits to society derived from work carried out under this licence through contribution to this field of science. It is the intention that information derived from our work will be published in the scientific literature.

How will you maximise the outputs of your work?

Work is expected to be included in scientific publications as part of the process of investigating and validating new disease targets and new treatments for disease. Additionally where work is considered to be 'pre-competitive' (e.g. method development or model validation work), whereby it does not contain information that is subject to intellectual property constraints, it will be considered for publication.

This continues an established approach, as demonstrated by previously published work as part of consortia such as the EU Innovative Medicines Initiative that ran between 2010-2015. Additionally, REDACTED also supports the view that publication of unsuccessful approaches ('negative data') is a valuable scientific output from properly conducted research, and this type of data would not be excluded from a publication strategy.

Information generated using this licence is stored in a searchable backed up company database, so that it is always accessible to other internal company researchers. Therefore, data will be recoverable in the future, even after likely project and personnel changes, and the information will be a valuable future resource to reduce the need to repeat and re-establish competency in a field of research.

Species and numbers of animals expected to be used

- Mice: 9000
- Rats: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

In most cases, an immune response will be initiated in an animal through exposure to an agent such a virus (e.g. influenza) or bacteria that engages with the innate immune system (the part of the immune system that produces a quick and general response to an environmental challenge) or will use an agent such as an allergen that will trigger an adaptive immune response (a very specific response that takes time to develop but which then will exist for a very long time). Agent exposure could be via injection using a syringe or direct to airways of the respiratory system by dosing liquids through the nose or direct to the windpipe whilst an animal is briefly and lightly anaesthetised. Alternatively, animals could be exposed to an irritant or chemical vapour within a chamber over minutes or hours to start an inflammatory process.

Many animals will have samples or measurements taken during experiments (e.g. blood samples taken from veins), or they may be anaesthetised so that imaging of organs can be carried out to determine disease progression, and to determine how effective an ongoing treatment may be. The types of imaging methods would include use of X-rays or magnetic resonance imaging (MRI), similar to ‘scans’ that humans might experience in a hospital visit.

Many animals will receive potential new medicines, either during or after immune responses are established or changes to the respiratory system have occurred. Such compounds could be dosed via a variety of administration routes (e.g. oral, intravenous or via inhalation) on single or multiple occasions, over days or weeks. Some animals could undergo brief surgery to implant dosing devices that slowly release the medicines over hours or days.

All animals will be humanely killed at the end of each experiment to enable collection of samples that cannot be ethically collected from live animals without unacceptably compromising their welfare (e.g. taking large blood volumes or taking whole organs for study, such as lungs).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

In the majority of cases animals will not show specific signs of distress or abnormal behaviour following initiation of immune responses, although body weight loss may be noted (e.g. 5 - 10% reduction in weight compared to before treatment, lasting several days).

Following exposure of mice to some strains of influenza more pronounced weight loss is noted (up to 20% loss of bodyweight) peaking about a week after exposure, although mice typically recover weight within a further few days.

Sometimes additional adverse signs can be noted after different types of treatments, (e.g. injections of agents that activate the immune system). These activities could result in reduced mobility (usually for up to several hours) and raised or stiffened fur for periods of up to several days before signs disappear.

Mice exposed to bacterial airway infection (of the strains characterised for use within this institution) do not normally demonstrate adverse effects over the timescales of most experiments, but animals will always be monitored for weight changes and appearance of any clinical signs.

Rats that are exposed to aerosols or inhaled dry powder formulations of potential new drugs usually show only mild adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Experience during work under previous licences indicates that at least 60% of mice are expected to show no more than mild effects following treatment. Up to 40% of mice will likely, demonstrate a cumulative moderate severity experience, or at least a period of moderate severity at some point during experiments.

The majority of rats (greater than 75%) will likely experience cumulative mild severity, and up to 25% of rats will experience moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Living animals are able to function because of complex coordinated systems that are made up of many different types of cells in separate organs. Some parts of these systems can be reproduced in isolated artificial plastic (*in vitro*) experiments, but the integrated interactions between cells and the effects of those interactions on wider processes and mechanisms that are, for example, found in the respiratory system are not easily and completely replicated outside a living animal. The inflammation and immunological systems that help to keep the body healthy are very complex, highly coordinated, dynamic communication networks that can respond quickly to injury or infection. They consist of sequences of events that are common and conserved in mammalian species, and hence results from experiments carried out in rodents can be compared and translated to the human setting. These responses involve many different cell types (such as white blood cells) as well as signalling molecules that are produced by those cells or the layers of cells (known as epithelium) that line the airways of the respiratory system. Responses are coordinated to identify disease causing organisms (e.g. a virus or other pathogen) or damaged tissue, and act to alert and recruit other cells and signalling molecules or activate processes that can lead to structural changes in organs.

Additionally, investigations into disease states that are the result of altered or mis-functioning mechanisms, or investigations into highly organised body systems require the use of mature functioning tissue that cannot currently be fully replicated, grown or kept alive outside animals (*ex vivo*). The mucociliary clearance system (a good example of such a coordinated mechanism) that is composed of mucus layers and beating cilia within the airways and lungs acts to clear foreign bodies from the respiratory airways. Whilst a wide range of information from isolated cell systems is generated as part of the investigatory process to increase our understanding of basic mechanisms and how potential treatments target or affect many functions, understanding the integrated response in a whole animal with a physiology that is common with humans is vital to guide potential medicine progression to human clinical trials.

What was your strategy for searching for non-animal alternatives?

Models using types of isolated human and animal cells have been developed and widely published in the scientific literature, and are used as part of development of new medicines. The vast majority of these are models that use flat cultures of cells growing on plastic that are able to address focused questions to a certain level of complexity with a limited number of cellular interactions.

The continuing progress with development of in vitro three-dimensional modelling systems such as 'lung on a chip' and epithelial organoids have started to address some of these challenges with cellular interactions, but are not yet at the levels of complexity required to mirror the clinical disease situation.

Why were they not suitable?

Despite much progress since being first published in 2010, the three dimensional (3D) lung-on-a-chip systems and model derivatives do not yet provide the full level of complexity and integration available within a living animal, or provide the inter-connected body-wide systems where cells and organs continuously communicate. Lung on a chip development has also concentrated on the gaseous exchange parts of the lung rather than conducting airways which play an important part in many aspects of respiratory disease. Additionally, systems using cells are not yet adequately able to model potential drug distribution and elimination from the body which results from a compound passing through organs such as liver and kidneys.

Non-animal systems such as organoid cultures which are 3D cellular structures held within a matrix gel, are not yet characterised to a stage where we can have confidence in the clinical relevance of data generated from using them. Tissue slice models are also used as in vitro tests. These experiments involve taking a tissue such as lung and preparing many small pieces that can then be used for individual tests, but in most cases those models, and also cell based models, lack physiological relevance due to the test system not experiencing the flows, physiological oxygen concentrations and pressures that exist within the blood vessels and airways of living animal systems. As such, those technologies are not yet able to model closely enough the complex environments needed for a system to be used to translate results to a complicated disease-like situation.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates of animal numbers that are likely to be used over a five year period are based on the experience of related work and projects previously supported under licence authority within REDACTED. There is an anticipated steady rate of projects likely to require information that cannot be gained from non-animal alternatives. Also considered in these estimates is the likelihood of changes to research priorities as a result of continuing scientific advancements in many areas of science. Because we are familiar with the types of models that are likely to be used and know the resources that we have available we can estimate the number and type of studies that will likely be required over the life cycle of a licence.

We use accepted statistical principles based on the main readouts from each model together with knowledge of the variability those readouts to inform on animal numbers required per type of study to produce statistically useful information.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

All experimental work is planned with input of statisticians to ensure that experiments provide high quality data without using an unjustified number of animals. For example, the size of experimental treatment groups will either be based on existing data, or small trial (pilot) studies will be carried out to generate guidance information that will show the variation of the biological system and readouts being assessed. Understanding variation and what constitutes a meaningful biological response to a treatment allows a statistician to calculate treatment group sizes that can be used to ensure that statistically meaningful comparisons can be made between treatment and control groups. These design principles aim to reduce the possibility of experiments not generating decision making data that could lead to the need to repeat work and hence use more animals.

All experiments undergo review from a panel of multi-disciplinary and independent specialists in planning stages. Experience has demonstrated that independent peers bring a range of viewpoints and specialisms to the design of animal studies, resulting in challenge to convention.

Where the effects of potential new medicines or control treatments are tested, we will often include an assessment of the blood or tissue levels of that substance from the same animals that are being used to look at effects of treatment. This allows direct comparison of treatment effects and compound levels and reduces the number of animals required overall. Animals will be randomly assigned to experimental groups using a random number generation system. This will reduce bias in a design that could compromise the value of generated data and potentially lead to more animals having to be used if work were to be repeated. Additionally, for subjective readouts that require a person to make a judgement, bias in data interpretation will be avoided by using experimental blinding. Thus, those involved in making those assessments will not be influenced in the interpretation of readouts by knowing which treatment had been given to animals.

These robust study design measures will maximise the likelihood of generating non-biased experimental results, and limit the number of animals needed to generate good quality decision making data.

What other measures apart from good experimental design will you use to minimise numbers?

To reduce variation in biological readouts we will ensure that our facilities provide a constant optimal environment suitable for the species, and we will control the number of personnel involved in making any subjective experimental measures. By controlling variation in readouts, we aim to ensure that animal group sizes are the smallest possible to achieve the scientific objectives of the study.

For some model systems, rather than collect only terminal measurements we will employ in-life imaging such as MRI (or serial sampling) where we can take images or samples repeatedly from the same animals at different time points to monitor development of pathology or changes resulting from treatment. This approach will reduce the total numbers of animals required to gather decision making data because each animal will act as its own control, thus reducing readout variability and improving quality of data. Statistical information generated from analysing such data is likely to be more robust compared to data derived from single measurements from many different animals. The same principles apply to taking serial samples (e.g. blood samples) from fewer animals, provided that animal welfare or sample quality are not compromised.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Different models of short and long term immune system sensitisation and challenge, targeting distinct aspects of the immune system will be used to investigate the involvement of those processes in human disease. Some models will use chemicals derived from bacteria to mimic the effects of bacterial infection, or use chemicals that trigger the immune system to act as if a virus had started an infection. Sometimes proteins will be given to animals along with chemicals that boost the immune response (acting as an adjuvant) that together cause the immune system to react. The same protein put later into the airways of the respiratory system would then trigger a localised immunological allergic reaction that can be used to test treatments targeted at aspects of the induced immunological pathway in that system. The project will also use extract of house dust mite which is a commonly detected allergen associated with respiratory diseases such as asthma. Some models will include viral or bacterial micro-organism infection with or without additional challenge. These microorganisms will be tested in mice because it's known that this species is susceptible to both respiratory infection and allergen- induced respiratory system inflammation.

The animal models used for this programme of work have been chosen and, where necessary, will be developed further to represent the least severe and most effective and robust ways of measuring immunology and inflammatory mechanism changes over both short and longer duration experiments. The durations of experiments will be suited to the mechanism under investigation, and in the majority of cases pain, suffering or distress will be brief and symptoms will be transient. Any airway inflammation or infection changes in these experiments is usually mild and would normally not cause any obvious signs of distress. Body weight loss is known to be a sensitive measure of the severity of infection. Changes in weight will be monitored to assess the models, and also limit the possibility that an animal might develop adverse effects that are more severe than are needed to reach an answer to a scientific question. Each approach described above models distinct aspects of human diseases or processes involved in multiple diseases and are carried out for only as long as required for the relevant conditions to develop and potential new treatments to be assessed.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Rats and Mice are the lowest orders of animals that have immune responses similar to humans and, additionally, allow us to take blood samples as well as monitor how the immune system is functioning during treatments. This means that we can correlate the level of potential medicines in the bloodstream with the effects on the immune system in the same animal at the same time.

To undertake the work proposed in this licence the animals must have reached an age where they have functioning immune systems, and this precludes use of animals of less than 6 weeks of age (but preferably of at least 8 weeks of age). By this age immune system responses have matured to a sufficient extent to include working innate and adaptive systems (that can fight a broad range of potential attacks against the body), and have immunological memory (the developed ability to quickly recognise something that the body has previously been exposed to, such as an allergen). Most immune and respiratory system model assays last for several days and it is therefore impractical and unethical to keep animals anaesthetised for the duration of the sample collection periods. Even the shortest investigations of adaptive immune responses require greater than 6 hours for responses to develop, and therefore, it would not be possible to carry out the majority of procedures under terminal anaesthesia.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals on studies will be monitored daily, and any adverse clinical signs that could be treatment related will be recorded and scored by reference to a specific scoring system for each type of experiment, therefore allowing monitoring of potential trends and modification of treatments if necessary.

We will continue to investigate the use of non-terminal imaging techniques that allow repeat measurement of disease relevant parameters (e.g. changes to sizes of organs and vessel walls, flow rates of blood, amount of swelling, fluid build-up) within same subjects during the development and treatment of pathologies, e.g. pulmonary hypertension. These within-subject measurements over time carry great statistical power because inter-animal variability is reduced, and thus smaller treatment groups are needed to demonstrate statistical differences between treatments. When using imaging methods we may also change the type of diet to increase imaging quality by reducing background environmental fluorescence. The nutritionally complete chlorophyll free diet used in place of standard rodent diet will allow improved imaging data to be collected without affecting animal welfare. The licence holder will also maintain familiarity with this field of science to make sure that relevant advances in the scientific area can be incorporated in work.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The published principles and philosophies behind the PREPARE (2018) and original ARRIVE (2010) guidelines have been incorporated into the sponsoring company's internal project planning standards of care and standard operating procedures. All work carried out under authority of this licence will undergo assessment of the study design during planning stages as part of a peer review process that is based on those guidelines, and will include statistical consultation. Facilities and processes are audited by independent bodies such as AAALAC International which has published guidelines and procedures to ensure work is carried out to high ethical and humane standards. The following published documents will advise on experimental design, animal welfare and husbandry during the life cycle of this licence:

- Kilkenny C et al (2010). Improving Bioscience Research Reporting: The ARRIVE Guidelines for Reporting Animal Research. PLoS Biol 8(6).

- Smith A et al (2018). PREPARE: guidelines for planning animal research and testing. Lab Anim; 52(2):135-141.

- Percie du Sert N et al. The ARRIVE guidelines 2019: updated guidelines for reporting animal research. BioRxiv. 2019: 703181.

- NC3R's - Responsibility in the use of animals in bioscience research: expectations of the major research council and charitable funding bodies (2019).

- Guidance on the operation of the Animals (Scientific Procedures) Act 1986. (Home Office 2014).

- LASA - Guiding principles on good practice for animal welfare and ethical review bodies. (2015)

- Prescott MJ, Lidster K. Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156, (2017).

- Review of harm-benefit analysis in the use of animals in research. Report of the Animals in Science Committee Harm-Benefit Analysis Sub-Group chaired by Professor Gail Davies (Nov 2017).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The role of the sponsoring company named information officer (NIO) includes the sharing of animal welfare, best practice and 3Rs related information. The NIO also liaises directly with REDACTED project licence holder network through their own regular meetings, and also raises this type of information and discussion points at the institutional Animal Welfare and Ethical Review Body (AWERB). The licence holder for this work regularly attends both these groups and is also separately aware of the 3R's related work of the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and the Royal Society for the Prevention of Cruelty to Animals (RSPCA). Experience to date has shown that 3Rs issues and advances are highlighted, discussed and actions are implemented within REDACTED centrally and effectively via these forums.

Explain the choice ofspecies and the related life stages

Work under this licence will use rats or mice. Animal models cannot yet be replaced in all pre-clinical research because they are required both to answer basic mechanism related questions and to assess the activity of potential new treatments, in complex inter-connected environments which are only found in live animals. Although there are known respiratory and immunology differences between species, the similarities in systems and published knowledge of underlying immunology means that rodents, and mice in particular, are valuable and relevant model systems for the work proposed in this licence.

The animal models used for this work have been chosen to assess mechanisms, and developed to be the least severe and most effective and robust methods of measuring structural, immunological and inflammatory changes. Mice will be suitable for the majority of the immunological work, due to availability of commercial reagents and assays as well as genetically altered animals. Rats will be used where a rat model provides information that translates to human biology more directly than a mouse model. Rats are widely used in safety assessment studies and use of rats will provide a direct comparison with toxicology and drug metabolism data to support a clinical dose calculation.

We will use adult animals. For most of the proposed work we require an established immune system, able to respond to a challenge according to the animal's genetic status. For rodents, this would typically require animals of at least 8 weeks of age. Most animals will not be genetically altered, but we will use genetically altered animals where we wish to investigate the role of genes of interest that might be involved in human disease.

Home Office

NON-TECHNICAL SUMMARY

181. Response to novel and emerging human pandemic disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
Ferrets	juvenile, adult
Pigs	juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to support Government and national response to emerging and novel pandemic diseases, human and animal. Enabling them to understand it better and introduce effective control methods.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

REDACTED

What outputs do you think you will see at the end of this project?

This project licence will provide an improved understanding of pandemic infections and their control. The initial objectives is to contribute to the increased understanding of SARS-CoV- 2 and mechanisms for its control.

Information arising from the work will be communicated to PHE, the Department of Health and the national Governments. Research findings will be disseminated in the form of papers and presentations .

Positive control sera for use in testing and establishment of assays for research purposes.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The population as whole will be benefit by development of disease-mitigation measures leading to the reduction of the impact of pandemic disease outbreak, as it should reduce both the amount of illness and mortality in the population and economic effect that it has. Benefits for humans and other animals where zoonotic infections are indicated.

How will you maximise the outputs of your work?

- Communication to stakeholders, funders, and the general public.

- Dissemination to other scientists and collaborators
.

- Positive control sera will be offered to other organisations undertaking testing and research that require this material

Species and numbers of animals expected to be used

- Ferrets: 96
- Pigs: 20

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Protocol 1 : Vaccination, swabbing, blood sampling and infection with SARS-COV-2

Protocol 2: Injection and blood sampling

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Protocol 1: Animals will experience repeated mild discomfort from sampling or administration of substances, animals may be anaesthetised where the discomfort of the procedure is deemed to be greater than that of inducing sedation or on safety grounds. In some animals (particularly the virus control groups) clinical disease signs including general signs of illness (inappetence, lethargy, fever) and respiratory signs (cough, sneezing, difficulty breathing) may occur. For as estimated duration of up to 14 days, signs may wax and wane during this period a prodromal or sub-clinical period, variable clinical presentation, resolution periods are anticipated. ‘Vaccinated’ animals may experience transient pain at the inoculation site during administration and as the local immune response develops.

Protocol 2: Animals will experience mild discomfort from the injections and blood sampling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol 1: 25% moderate, typically the virus control group

75% mild, typically the intervention groups

Protocol 2 : 100% mild

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A complete biological system is required to study the immunological response to vaccination and challenge, and also for polyclonal antisera raising .

What was your strategy for searching for non-animal alternatives?

None see above

Why were they not suitable?

Cell culture and other techniques can only be used (understanding of virus, development of vaccine) in the build up to the animal experiment to maximise the chances of a successful outcome. Response to vaccination and challenge needs the complete animal's biological system and full immune repertoire.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Ferret numbers have been estimated based on related research publications, programmes and project licences using ferret vaccination models.

Pig numbers have been based on likely demand for antisera.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The use of a statistically valid minimum number of animals per study will be determined based on expert advice from a professional Biostatistician. Animal studies will be designed in a consistent manner so that inter-study comparisons and data analysis can be performed.

The use of the pig, rather than smaller species such rabbit or ferret means an individual animal will produce more antisera so reducing the numbers required

What other measures apart from good experimental design will you use to minimise numbers?

Animal studies will be designed to maximise collection of biological materials and, where feasible, run in parallel. This will potentially reduce the number of control groups required and therefore increase the data output and research questions that can be addressed. Materials generated during the study will be utilised for in vitro test assays e.g. serum will be harvested to assess immune response and later used as internal controls for other serological assay, limiting the requirement for reagent generation in additional animals. Similarly animal tissue harvested at post mortem.

The number of pigs used for antisera raising will be based on need for the volume of antisera produced

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

From the SARS-CoV-1 work the ferret is considered the most appropriate model for humans, other than non-human primate.

The pig is used as the protocols are well established for producing relatively large amounts of high titre hyperimmune pig serum against viral antigens

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

They lack the specific biological similarity to human lungs and absence of a complete immune repetoire.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The protocol 1 experiment has its disease-relevant clinical observation criteria and score sheets. No animal will be allowed to progress beyond the described humane end point using a 2-3 times daily monitoring system. On site veterinary teams and animal welfare officers (NVS and NACWO qualified) who participate in each study.

Protocol 2 is for antisera raising, this protocol has already been substantially refined and minimal numbers of injections and blood samples are undertaken and the adjuvant used has minimum adverse effects but still gives a suitable antibody titre.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Best practice information is obtained from NC3Rs, IAT, LASA and the RSPCA. There is frequent knowledge exchange between UK institutions working with ferrets. Publications and articles are also reviewed during the approval process prior to each individual study. Where specialist training is required, inter-institutional exchanges and training visits are organised.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The Establishment is a signatory to the NC3Rs and applies the Culture of Care in animal studies. The Establishment frequently attends or organises external symposia on laboratory animal welfare REDACTED. Staff attending these meetings provide meeting feedback reports locally. In addition, the establishment has a Species Care and 3R Committee where all PILs and animal users are invited to attend. Specialist topics are presented and refinements, such as environmental enrichment, are communicated and opportunities are used for implementation. In addition, specialist knowledge exchange is organised by field and lab exchanges with other organisations, eg PHE and Universities.

The Establishment follows the PREPARE and ARRIVE guidelines

Explain the choice ofspecies and the related life stages

Research into SAR-COV-1 and initial work SARs-COV2 has shown the ferret to be the most biologically relevant hosts apart from non human primates.

For antisera Pigs are the appropriately large size to use minimal numbers of animals for the volume of serum required.

- Protocols are well established at the institute for producing high titre hyperimmune pig serum against influenza virus antigens. Similar protocols can be applied for a different antigen, SARS-CoV-2.
- REDACTED

NON-TECHNICAL SUMMARY

183. RUNX, MOZ and associated gene functions in normal tissues and as therapeutic targets in cancers

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The genes encoding the AML1/RUNX1 transcription factor and the transcriptional co-activator MOZ are critical for haematopoietic development and are frequently rearranged or mutated in human leukaemia. The over-reaching aim of this project is to investigate the functions of RUNX1, MOZ and their associated genes, in haematopoietic development, maintenance and malignancies. The project aims to understand how alterations in these genes and their functions lead to malignancies and in doing so potentially identify new therapeutic targets.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is estimated that one out of 2 persons born after 1960 will be diagnosed with some form of cancer during their lifetime and although treatments have dramatically improved, still half of the patients do not survive their disease for more than 10 years (source: CRUK website). Leukaemia is the 13th most common cancer in the UK, with around 10,000 new cases diagnosed and around 4,600 deaths (representing 3 % of all cancer deaths) in 2016. Treatments of Acute Myeloid Leukaemia (AML) have not dramatically changed, or improved, for the last 30 years. The current treatments are very debilitating, associated with high morbidity and inappropriate for a large fraction of patients. Therefore, there is a pressing need for the development of more specific and efficient therapies.

What outputs do you think you will see at the end of this project?

- Understanding how genes control the generation and maintenance of blood cells. New Insights could be translated in in vivo generation of blood cells required to treat cancer patients by transplantations or with immunotherapies.

- Elucidating function of these genes studied in development of disease, specifically haematological malignancies (leukaemia, lymphoma).

- Identification of novel therapeutic targets for treatment of blood disorders and cancers.

- Rationale for generation of new drugs by drug discovery teams and pharmaceutical companies.

The research findings will be published in high impact peer reviewed journals and will be of interest to clinical and academic scientists. In addition, our work programme has clear implications for the treatment of patients with genetic blood diseases or patients suffering from leukaemia. The new findings generated could lead to defining new strategies to generate human blood generating cells

(haematopoietic stem cells, HSCs), critically needed for bone marrow transplantations for complete cure of leukaemia.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The main beneficiaries will be other scientists, health professionals and pharmaceutical companies as well as patients with leukaemia. We anticipate that patients won't be able to benefit from this work within the time frame of this project licence.

How will you maximise the outputs of your work?

On a weekly basis the REDACTED.. In addition, laboratory members will attend national and international scientific conferences which are both discipline-specific as well as cross-disciplinary and are attended by the full range of academic, clinical and commercial scientists. We will also strive to ensure that the research performed will be published in high quality, peer reviewed journals of international standing. The laboratory has an excellent track record for this REDACTED. Data will be published in international open access scientific journals, made available online through REDACTED, as soon as possible. Publications in high quality journals will improve the laboratory's capacity to recruit and train future scientists.

Press releases relating to findings arising from the proposed research for local and national mass media will be managed by dedicated press agents within The REDACTED. We also regularly organise open days, school days and laboratory tours where fundraisers, patients and their families and school children can come into the laboratory and at these events, we explain our research to them.

One significant potential outcome of our work is the identification and validation of new therapeutic targets for leukaemia. In order to explore and enhance any potential therapeutic benefits of our research, we will meet twice a year with the onsite Business Development Manager responsible for the management of Intellectual Property (IP). Concrete plans to develop industrial collaboration, involvement with Research Technology development laboratories or engage third parties will be devised as findings emerge.

Species and numbers of animals expected to be used

- Mice: 4,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A typical investigation of the role of a gene in blood cell development and/or maintenance would involve the use of genetically altered mice and their wild type counterparts as controls. In some instances, there may be evidence of the gene being essential for development and therefore, embryonically lethal. In such situations, no lasting distress or suffering to the animals is anticipated. However, in order to overcome these lethality outcomes, there may be a requirement to introduce compounds in mice in order to induce these genetic alterations conditionally in specific tissues/cell types. Additionally, agents may be administered to evaluate the functional consequences of these genetic alterations, such as the ability of the stem cells to divide and the evaluation of genetic /signalling pathways critical to generate blood cells. In some instances, cells will need to be transplanted to evaluate their functional capacity with or without these genetic alterations. To this end, mice may be conditioned prior to transplantation either by administration of immunosuppressive drugs or by exposure to irradiation. For studies involving mice with reporter genes associated with these alterations, mice may be imaged under recovery anaesthesia throughout the study. In order to obtain experimental readouts animals, will have blood micro-samples taken from superficial veins.

Leukaemia is not associated with pain during the period in which we conduct our observations. Disease will be monitored regularly by either using blood sampling from peripheral vessels or by imaging methods such as fluorescence under brief general anaesthesia. For some procedures that involve surgery under general anaesthesia, we will administer pain killers and monitor the mice closely during recovery. At the end of an experiment or when an experimental goal has been achieved earlier than anticipated, the mice will be humanely culled, either with or without preceding terminal bleeds under non-recovery anaesthesia.

Mice will be group housed in ventilated cages which have their environment enhanced with items such as tunnels, houses, nesting material and gnawing blocks.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most procedures in the protocol, such as irradiation of animals, blood sampling or injection of cells and compounds are not associated with significant side effects. Mice developing leukaemia of solid tumours exhibit signs of disease, such as hunched posture, “goose-bumps”, piloerection and poor levels of socialising and interaction. In more progressed models of the disease animals may display signs of anaemia and hind limb paralysis. Under these circumstances, and whenever else an animal displays

features of ill health, or at the end of each experiment, mice will be humanely euthanized using a Home Office sanctioned method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of mice are only expected to experience the mildest clinical symptoms due to leukaemia before being humanely killed. Additionally, some mice will experience the discomfort of repeated administration of therapeutic agents. We will aim to utilise the least stressful route of administration and the smallest of volumes wherever possible.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The role of genes associated with normal development that are also dysregulated in cancers will be researched as far as possible using non-animal methods. However, the simplicity of the laboratory-based systems relative to the more complex animal model wherein the interactions of different cell types within tissues is intact and similar to the human body, renders it unsuitable to draw concrete scientific conclusions.

What was your strategy for searching for non-animal alternatives?

We perform pilot experiments with laboratory based generated cell lines, established cancer cell lines, or primary samples, to evaluate the potential roles of the candidate genes of interest. Once we have obtained results that support and inform us on the potential role of these genes, we will be able to design appropriate animal experiments.

Why were they not suitable?

Currently, there is a lack of a non-animal system that can accurately model the homeostasis of complex haematological organs and epithelial tissues or the development of cancers in these tissues. This is because these events take place in very complex cellular architecture, involving interactions between many different cell types which cannot be reproduced in laboratory-based experiments. Therefore,

without the use of a live, whole animal experimental system, the biology of haematological and epithelial homeostasis and malignancies cannot be meaningfully studied.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Data available from the literature or from pilot studies conducted in our laboratory are used to perform power analysis to determine an appropriate sample size for the definitive experiment. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.

Based on past experience, group sizes of between 3 and 12 animals (dependent on the readout, fewer for transplanted leukaemia compared to spontaneous leukaemia in Genetically Modified (GM) mice) per experimental group suffice.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

In previous studies, power analysis was utilised to determine the minimum number of animals required per experimental group. This helped reduce utilisation of unnecessarily large groups of animals other than those needed to achieve the experimental goal.

Wherever possible, alternatives to culling at defined time points such as use of live bioimaging or repeated blood sampling to follow disease development and response in real time were used.

In addition to the use of laboratory-based systems, wherever possible, pilot experiments were carried out to test for the extent of an expected phenotype prior to a full scale confirmatory experiment. For disease models, the cryopreservation in multiple aliquots (collection and preserving of samples) of normal and humoural cell populations and samples, eliminated the requirement for continuous production of cohorts of mice.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be performed if applicable and, after analysis of the results, group sizes for subsequent experiments will be determined based upon these data. As far as possible, multiple parameters will be

evaluated in a single mouse. Live imaging of the same animal at multiple time points also greatly reduces the numbers required. Whenever possible, tissues and samples from related studies may be acquired from other groups for analysis before carrying out large scale studies of our own.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice have been chosen for the study because they represent the least sentient species from which meaningful experimental data can be generated, while exhibiting considerable genetic and biological similarities to humans with regard to their blood forming system. Only a mammalian model system has the potential to accurately mimic both the anatomy and complex cell biology, including normal and malignant tissues and the associated microenvironmental interactions, of the human counterparts. Furthermore, there is considerable experience in the wider scientific community regarding the use of mice as a model system for human malignancies and many reagents exist for the phenotypic characterisation of mouse cells.

General welfare and humane endpoints will be defined and adjusted according to the guidelines published by Workman and colleagues (BJC 2010, 102, 1555-1577). The techniques used have been carefully evaluated to minimise distress to the animals. Mice used in surgical procedures will receive anaesthesia, analgesia and post-operative rehydration by subcutaneous injection, followed by careful observation. In other areas, irradiation doses will be administered at a level sufficient to induce bone marrow suppression but no other long term consequences; intra-femoral injections will be not be performed routinely, only where the scientific justification is high; and in studies that result in the initiation of malignancy, animals will be closely monitored for health status and killed by a Home Office approved method when signs of ill health are displayed. In all Protocols, best practice will be followed in the administration of substances and the removal of body fluids (Morton et al. Laboratory Animals (2001) 35, 1-41).

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Less sentient animals do not have a haematopoietic system. Mice are far more similar to humans than other animals possessing lungs e.g. birds or reptiles and this is critical both for using reagents like drugs developed for human targets and for translating findings to the clinic. Cancers develop over many

weeks to months, so use of terminally anaesthetised animals or immature animals is not practicable. Also, immature mice lack a functional immune system which is desirable in cancer research.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The techniques used have been carefully evaluated to minimise distress to the animals. Mice used in surgical procedures will receive anaesthesia, analgesia and post-operative rehydration, followed by careful observation. Animals will be monitored closely and carefully especially for pilot studies involving the administration of novel substances. In other areas, irradiation doses will be administered at a level sufficient to induce bone marrow suppression but no other long term sequelae. Intra-femoral injections will be not be performed routinely, only where the scientific justification is high. In studies that result in the initiation of malignancy, animals will be closely monitored for health status and killed by a Home Office approved method when signs of ill health are displayed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).

We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)]. Administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.

Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23]

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our NACWO, NVS and HO inspector.

Explain the choice of species and the related life stages

Mice have been chosen for the study because they represent the least sentient species from which meaningful experimental data can be generated, while exhibiting considerable genetic and biological

similarities to humans with regard to their blood forming system. Only a mammalian model system has the potential to accurately mimic both the anatomy and complex cell biology, including microenvironmental interactions, of normal and malignant human haematological organs and epithelial tissues. Furthermore, there is considerable experience in the wider scientific community regarding the use of mice as a model system for human malignancies and many reagents exist for the phenotypic characterisation of mouse cells.

One of the over-arching aims of the project is understanding the contribution of master regulators and their associated genes in blood cell development and in tissue homeostasis (stability). A second goal of the project is the long term applicability of these findings in delineating mechanisms of disease progression. To address this, all life stages need to be utilised. Specifically, embryonic and neonatal stages will need to be employed for studies focusing on the development of blood generating cells. For studies aimed at understanding disease progression, mostly juvenile and adult forms will be utilised. In some studies, a combination of various stages may also be necessary, for example, cells from foetal stages may need to be harvested for transplantation in adult mice.

Home Office

NON-TECHNICAL SUMMARY

184. Safety evaluation of products to support the health and welfare of farmed fish

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

No answer provided

Animal types	Life stages
Atlantic salmon (Salmo salar)	juvenile, embryo, neonate, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to support the safety evaluation of new products, including veterinary vaccines, therapeutants, feed materials, feed additives and biocides, intended for use in the production of farmed fish. The principal objectives are (a) to provide data on the safety of the candidate products in fish, (b) to characterise metabolic pathways, distribution in the major organs and changes in tissue concentrations of the products and (c) to describe the biological responses of the fish to the product at cell and tissue level.

A retrospective assessment of these aims will be due by 01 October 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

These studies are necessary (i) to enable assessments of the safety of the products in the fish species for which the products are intended (the target species), including regulatory assessment for the purposes of product licensing, (ii) to identify the preferred treatment regime and to permit assessment of tissue concentrations during and following treatment, including regulatory assessment to determine withdrawal periods for the protection of consumers, and (iii) to understand the mode of action at cell and tissue level so that the products can be used safely and effectively.

What outputs do you think you will see at the end of this project?

The expected benefits of this project will be to:

1. Establish a platform which clients can access to develop products for aquaculture. A shortage of capacity at present is restricting the availability of new products for farmed fish.

2. Support the evaluation, development and licensing of new products to improve the health and welfare of farmed fish. These products will be used by salmon farmers to reduce losses due to salmon lice, gill disease and other infectious disease.

3. Generate high quality data to ensure that new licensed products are demonstrably safe for the animal, consumers and the environment. These data will be produced to the internationally recognised quality standards required by relevant regulatory authorities.

4. Support the production of fish as food that is safe, healthy and nutritious, economically sustainable, environmentally acceptable and produced to the highest animal welfare standards.

5. Tackle biological challenges which threaten the sustainability of an industry which supports jobs and economic activity in remote areas.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The benefits will be realised by:

1. Farmed fish which will benefit from improvements in health and welfare.

2. Husbandry and veterinary staff who will benefit from access to new tools to maintain and improve the health and welfare of animals in their care.

3. Aquaculture producers, processing companies and retailers who can expect marketing and price advantages based on reduced losses and more efficient production of fish with higher health and welfare standards.

4. Supply chain companies who will benefit from opportunities to develop new products and services.

5. The consumer who will benefit from access to food produced using products which have been developed according to established and assured safety and welfare standards.

How will you maximise the outputs of your work?

We will advertise our capabilities and expertise within our target market so that a wide range of clients can take advantage of these.

We will encourage our sponsors to publish study findings, including negative findings, where appropriate.

We will offer experimental models to research groups for testing novel products. Knowledge of these models will be shared and may be published.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically the product will be administered to experimental fish at the recommended effective dose and by the intended route, for example by voluntary feeding daily for up to 12 weeks or by bath or dip immersion or by intra-peritoneal or intra-muscular injection. In some studies, the product may be administered by oral gavage or intra-venous injection for experimental purposes in order to generate appropriate data for assessment. In target animal safety studies, the product may be administered at higher than the therapeutic dose in order to establish the margin of safety.

Fish will be held in tanks and observed closely during and following dosing and their behaviour and appearance will be assessed against established criteria. Any fish which show abnormal behaviour or appearance will be euthanased and examined.

Fish may be euthanased and sampled during the study. Samples are typically used to measure blood and tissue concentrations of the product at intervals during and following dosing or to assess histological or biochemical changes.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Handling and injection of fish may cause transient pain and distress which will be mitigated by the use of anaesthetics. Fish will typically recover from handling and injection within 24 h.

In safety studies, some fish are expected to show abnormal behaviour and appearance. In a preliminary study, where the safety profile of a product is unknown, there is a greater risk that fish will show more severe clinical signs or mortality in the absence of clinical signs.

Fish will be inspected at frequent intervals so that such signs are identified rapidly and the affected fish will be euthanased within 4 h of developing such signs.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most fish used in this project will experience no adverse effects other than the pain and distress associated with routine handling for weighing, allocation and dose administration, and will fall within the 'sub-threshold' or 'mild' severity limits. Approximately 15% of fish used in the project are expected to develop more severe or lasting changes in behaviour and appearance requiring euthanasia within the 'moderate' severity limits. Approximately 1% of animals are expected to reach the threshold for 'severe' severity classification or die within a short period in the absence of clinical signs.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 01 October 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project will test the effects of products on the intended target species which will be a species of farmed fish. Use of experimental animals is required since the behaviour of a new product in the animal and the response of an animal to a particular product cannot be modelled effectively using non-animal alternatives.

In studies conducted for regulatory purposes, the use of relevant animal models is a requirement of the regulatory authorities in order to properly assess the safety and efficacy of the product.

What was your strategy for searching for non-animal alternatives?

Computer simulation models. Cell culture models. Invertebrate models.

Why were they not suitable?

These non-animal models are either not available or not well-enough developed to provide the required high level of confidence in the results specifically as they relate to the target species.

A retrospective assessment of replacement will be due by 01 October 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For each type of study, fish numbers are based on the study design requirements of the regulatory authorities and on published data and/or past experience of appropriate sample sizes.

The estimated total number of animals is based on expected demand and capacity for approximately 32 studies using typical study designs.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The study designs use prior data to estimate the likely magnitude of variation in response due to random effects and the level of treatment effect which is practically valuable. The discrimination of the study design (ie its ability to distinguish treatment effects from random variation) is maximised by minimising the effects of random variation by the practice of using fish of similar age, source, size range and history, similar experimental tanks and consistent environmental conditions across each study.

Group sizes for voluntary feeding studies are determined by the requirement for fish to show a uniform feeding response. A minimum group size of 20 fish is used in these studies since this is considered to be the minimum necessary to overcome social hierarchy effects and provide an acceptable feeding response in the majority of individuals in the population.

Smaller numbers of fish may be used where dosing is by immersion, oral gavage, injection or topical administration. In (non-quantitative) safety studies, sample numbers required are those necessary to demonstrate the consistent presence or absence of clinical signs in each exposure group.

In time series pharmacological studies, numbers of fish reflect the number of sample points and the number of individuals required for sampling at each point. Repeat sampling of individual fish was considered but rejected since repeat samples collected from fish which have previously been anaesthetised and sampled may be unrepresentative of the population. In pharmacology/immunology studies which are required to generate quantitative data, numbers of fish used at each point are those necessary to provide an accurate and precise measure of the magnitude of response. This is determined separately for each study using sample size calculation methodology but is typically in the order of 10 fish per time point.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies may be used to determine the magnitude of effect of treatment and thereby the number of animals/samples necessary in pivotal regulatory studies.

A retrospective assessment of reduction will be due by 01 October 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The preliminary safety test aims to establish, using small numbers of animals, that exposure to the product at the proposed dose will not cause pain, suffering, distress or lasting harm in subsequent larger studies. Where relevant, a stepped approach is used to administer the product at the lowest, then medium, and then the highest proposed dose, so that the outcome at one level is known before moving to the next level.

The target animal safety study aims to establish the threshold dose at which the onset of signs indicative of pain, suffering, distress or lasting harm may occur. Animals which reach this stage will not experience severe or long term effects but will be rapidly identified and humanely euthanased.

Pharmacology/immunology studies aim to generate data on pharmacological behaviour of a product or the biological response to the product at the proposed effective dose which will have been shown to be

within the range of safe doses.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species and life stages used are those for which the products are being developed. Reliable data is important to ensure the safety of farmed fish and the consumer. Less sentient animals have not been shown to provide data which can be reliably extrapolated to the target animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Frequent monitoring.

Refinement of criteria used for making, describing and recording clinical signs.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

1. European Medicines Agency (2011) Guideline on the design of studies to evaluate the safety and efficacy of fish vaccines. EMA/CVMP/IWP/314550/2010. 10 pp.

2. European Medicines Agency (2011) Guideline on demonstration of target animal safety and efficacy of veterinary medicinal products intended for use in farmed finfish. EMA/CVMP/EWP/459868/2008. 14 pp.

Communication with sponsors and colleagues working in the field.

Explain the choice ofspecies and the related life stages

The fish species and life stages used in this project are representative of the farmed fish species and life stages for which the products are being developed.

The developers of the products and Licensing Authorities responsible for approval of new products require data from these target species for decision-making and formal regulatory assessment.

A retrospective assessment of refinement will be due by 01 October 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Rats	juvenile, adult
Guinea pigs	juvenile, adult
Beagles	adult
Pigs	adult
Cynomolgus monkeys	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The objective of the project is to evaluate the potential of new human medicines to produce unexpected and/or undesirable effects in test animals. The work is required for new medicines, for the safety of human volunteers and patients who will also take the medicines, and it is designed to meet the requirements of regulatory bodies in Europe and elsewhere, who must agree to the sale and use of drugs.

A retrospective assessment of these aims will be due by 14 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

As well as assuring the safety of human volunteers and patients, the successful conduct of tests will help bring
to market those materials which are safe and shown to be effective in the treatment or prevention of human diseases. Without these studies, progression of new medicines to early human studies and to patients could not occur in the current regulatory framework.

What outputs do you think you will see at the end of this project?

Data collected will include information on how various body systems essential to life are affected by potential new medicines, including effects on heart rate and rhythm, blood pressure, breathing rate and rhythm, changes to brain outputs and reflexes, changes to kidney function, changes to intestinal function. The data will be collected to the standards required by government regulators in the UK,

Europe and elsewhere, for identifying and excluding inappropriate medicines due to safety concerns, and enabling marketing of successful medicines.

Refined methods of conduct of specific data collection processes may be developed during the course of the project.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our clients, typically commercial drug companies, will benefit from the provision of high quality of data. This will to help them in their work to new and better medicines, to discontinue development of inappropriate medicines or to understand and manage the risks of new medicines prior to dosing in humans.

Work on this project may also provide data to inform ongoing human clinical trials.

Enabling development of successful medicines will benefit society through diagnosis, treatment or prevention of disease.

Identification of adverse effects can prevent future harms to human volunteers or patients by resulting changes to medicine development programmes.

The wider scientific community may benefit from publication of refined approaches to animal use.

How will you maximise the outputs of your work?

In house collaborations and information exchange with others within the organisation worldwide, identifying successful and unsuccessful approaches.

Collaboration with clients (knowledge gained on products).

On-going collaboration with NC3Rs, resulting in publications (see references).

Hosting scientists and animal carers from other establishments, including universities, to promote best practice.

Presenting outputs at scientific conferences (eg Safety Pharmacology Society conference), user group meetings and Universities REDACTED

Species and numbers of animals expected to be used

Beagles: 60
Pigs: 80
Cynomolgus macaques: 50
Rats: 5000
Guinea pigs: 150

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be given potential new human medicines by the same method that people will be given them - such as by mouth, by injection or by inhaling them. Inhalation of drugs generally requires that animals are made accustomed to close restraint in a purpose-made device, and/or are made accustomed to wearing a mask while breathing the medicines. Drugs will normally be given once only at one or more dose levels, and tests will be conducted to look at how the drugs affect the body systems, mainly the heart and lungs, the brain and central nervous system, the kidneys and the stomach and intestines. Some animals will have surgery conducted, under anaesthesia, and with use of pain relief, to allow the use of sensors to provide tests results automatically, such as heart rate or blood pressure. Some animals will be used on more than one occasion; typically this relates to animals which have undergone surgical preparation, as this approach minimises the total number of animals which undergo surgery.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Surgery can cause some discomfort, but this is prevented or minimised by use of appropriate anaesthetics drugs and pain relief. Pain or discomfort from procedures such as injections is likely to be very short-lasting. Behaviour may be affected by the drugs being given, and this may be measured by, for example seeing an increase in heart rate, but the effects are expected to be short-lived, perhaps up to 1-2 hours after giving the drugs.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The harms described above are expected to fall within the mild category for most cases. Where surgery is performed, as described, this would be noted as moderate severity, and may involve about 10% of the total number of animals. If drugs cause some change in behaviour or measured activity such as heart rate this may be considered as having a moderate effect in some animals, estimated at about 15% of the total number based on previous experience.

What will happen to the animals at the end of the study?

- Used in other projects
- Kept alive

A retrospective assessment of these predicted harms will be due by 14 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are useful to identify test item effects on individual cell types and on individual chemical pathways, they are currently not able to predict effects on whole body systems or to provide information on how much of a medicine is absorbed. It is not currently possible to acquire all of the information on how the body systems such as the heart , brain and lungs may be affected by new drugs, without using animals. This information is essential, to protect human volunteers and patients. The protocols described in this project are in accordance with regulatory guidelines, and are expected to be performed before government authorities will authorise giving new experimental medicines to people.

What was your strategy for searching for non-animal alternatives?

Although non-animal studies are part of a programme of work when developing new medicines, it is still considered essential by scientists and government regulators, to do work using animals, which this project describes.

Why were they not suitable?

There currently remains general scientific agreement that to protect human volunteers and patients, non-animal alternatives do not, as yet, provide enough information to replace animal studies.

A retrospective assessment of replacement will be due by 14 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Statisticians have performed calculations for each of the study types in this project and have provided advice on experimental design for all standard study designs within the project. This ensures that studies are correctly designed to meet the study objectives. Statisticians will be consulted on a case by case basis for any study that requires a non-standard design.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be used to investigate the potential of new designs to improve outcomes. These could include evaluation of new implantable devices, ways to analyse the data, or additional tests to conduct, leading to improved data quality.

A retrospective assessment of reduction will be due by 14 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Dosing of test items are usually by the same routes as the medicines would be given to humans; all very well established and common methods for the species to be used. Volumes of drugs to be given are in line with published guidance on minimising discomfort, and/or are known to cause minimal discomfort based on extensive experience at the site.

Blood sampling follows published guidance on suitable volumes which can be taken while minimising harms to animals.

Surgery is conducted with expert veterinary involvement in the creation of suitable regimes for anaesthesia and post-surgical pain relief.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species used are selected based on known standards of outcome which will answer the scientific questions; known industry and regulatory standards of models which will answer both scientific and regulatory questions; to enable comparison with other data being generated in the same species as part of the safety assessment of potential new medicines. Response to tests is assessed over a time period which would make continued anaesthesia impractical, and would interfere with the outcome in some circumstances.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Monitoring of on-going procedures is refined for cause as any concerns are identified; for example additional assessments may be included based on initial outcomes. The surgery and anaesthesia/pain relief protocols used in the programme undergo continual assessment and refinement to improve outcomes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of Diehl et al: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

Welfare end-points are developed in general line with publications on the topic, including the NC3Rs document from 2010 on dose level selection for regulatory toxicology studies.

Non-human primate housing is in compliance with the NC3Rs document on this topic from 2017.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are involved with other groups working in the same field, and have participated in analysis and publication of data in the scientific field to assess methods of conduct and outcomes. The licensee and others at the establishment have been involved with various working groups of the UK National Centre for the 3Rs (NC3Rs), over many years.

Explain the choice ofspecies and the related life stages

Many scientific studies have been conducted to demonstrate that the types of animals to be used in the project will provide results which reflect the likely effects in humans. The way in which each new medicine works in the body will be known, and the animal type(s) to be used will be chosen based on an understanding that the medicine will work in a similar way.

Another big advantage of using the listed animal types is the ability to compare the results with the results of tests in these same animal types which are used in other safety studies conducted to assess other questions of safety, and which are acceptable to the government agencies responsible for authorising use of the drugs in human volunteers and patients. Development of drugs can not currently be achieved without this approval by government agencies in the UK, elsewhere in Europe and in other parts of the world.

A retrospective assessment of refinement will be due by 14 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to determine whether angiogenic mechanisms within the REDACTED pituitary mediate melatonin regulation of seasonal REDACTED.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We will investigate the processes underlying the adaptation of animals to a changing environment. The project is based on our recent discovery that angiogenic mechanisms within the pituitary gland respond to seasonal changes in day length, i.e. photoperiod, generating pro- or anti-angiogenic isoforms of VEGF-A at different times of year. The differential expression of VEGF-A isoforms is regulated by the duration of melatonin exposure at night, which is the translator of photoperiodic information, and is predicted to result from alternative splicing of the VEGF-A gene, leading to seasonal remodelling of the vascular connections within the pituitary and paracrine regulation of pituitary endocrine networks that REDACTED annual cycles in reproduction, hair growth and other functions. Therefore, these studies are applicable to all animal species that have developed annual physiological cycles as a strategic means to ensure survival in a changing environment. In particular, the project is directed towards REDACTED that display robust seasonal cycles in their physiology but findings could also be extended to other animals such as horses. A better understanding of their processes of adaption will ensure improved efficiency in the farming and, potentially, equestrian industries. The impact of these studies extends to human health, in particular to the understanding, prevention and treatment of illnesses derived from day/night shifts in work schedules and trans-equatorial flying. Moreover, the impact can extend to the treatment of other diseases that show seasonal incidence such as certain types of depression and cancer. A key objective of this project is to unravel the way in which the photoperiodic decoder, i.e. the duration of nocturnal melatonin output throughout the year, can induce alternative splicing of the VEGF-A gene to generate the desired adaptive biological response (induction or repression of oestrus). We will tackle this vital question using animal models that exhibit annual physiological cycles at a given season, using in vitro, ex vivo and in vivo strategies. If the molecular and cellular signalling mechanisms underlying the adaptation to a changing environment can be more clearly understood, then both artificial and natural regulators of seasonal physiological cycles may be developed and REDACTEDled, and pathologies with seasonal incidence may be more effectively overcome. For instance, foodstuffs that regulate alternative splicing have been identified (e.g. broccoli, carrots, olive oil), and although much of the current work has focused on the effects of high fat diets, understanding the regulation of micro- vascular remodelling and intra-pituitary paracrine REDACTED by alternative splicing of VEGF may help us to recognise how, for example, different farming and breeding regimens could be implemented to improve the REDACTED of REDACTED in REDACTED (and potentially, horses, for instance how novel photoperiodic strategies could be used to enhance the welfare of horses subjected to trans-equatorial travel for breeding or competition purposes), and how the occurrence or recurrence of clinical conditions in humans (e.g.

prostate, breast and ovarian cancers, which are linked to melatonin production and VEGF production) could be better prevented and/or treated more effectively.

What outputs do you think you will see at the end of this project?

We would hope to determine the mechanisms of photoperiodic signal transduction involved in the adaptation to seasonal changes in the environment. It is well established that in photoperiodic species the duration of melatonin secretion from the pineal gland during the night translates the effects of day length on seasonal physiology, and that the pars tuberalis of the pituitary gland is the primary site of action of melatonin. Recent work in vitro has shown that the duration of melatonin exposure within the pituitary can induce alternative splicing of the VEGF gene, resulting in different outputs of VEGF isoforms, and that these isoforms can alter the production of prolactin and gonadotrophins. Similarly, the hypothalamic-pituitary portal system undergoes annual remodelling associated with the seasonally regulated differential expression of VEGF isoform output. Therefore, this appears to be a mechanism for seasonal adaptation to changes in the environment whereby the transducer (i.e the melatonin signal) of an environmental independent cue (i.e. day length) is decoded by an angiogenesis regulatory system that will affect not only the vascular connection between the hypothalamus and the pituitary gland, but also the function of at least two pituitary endocrine systems that regulate seasonal physiology. Moreover, preliminary work has shown that a similar mechanism operates in the horse, providing evidence that this could be a conserved mechanism for physiological adaptation to a changing environment. However, all work so far has been conducted either in vitro or ex vivo (using specimens collected from a commercial abattoir) and, therefore, an in vivo study is needed to demonstrate that indeed this system of adaptation operates in living animals.

We anticipate outputs that will include new publications on REDACTED of pituitary vasculature, presentations at endocrinology meetings, such as the annual meeting of the Endocrine Society in the US, engagement with the public on its physiological significance (previous work was reported in the national press), and potential for additional funding for interventions that could modify angiogenesis in the pituitary to modify seasonal physiology.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The outputs of this research will benefit the scientific community in the first place and ultimately the general public. Benefits to the scientific community will be derived from the clear understanding of how annual time is measured by animals that have adapted their seasonal physiology to the temporal changes in the environment. Although it has been well established that the pattern of melatonin secretion from the pineal gland translates the effects of day length (photoperiod) on the annual reproductive cycle, the mechanism for melatonin signal decoding has just begun to be elucidated. An ‘in vivo’ demonstration of the proposed decoding mechanism will provide convincing evidence to the scientific community that what has been shown ‘in vitro’ and ‘ex vivo’ occurs in living animals to enable them to adapt their physiology to the predictable annual photoperiodic cycle. The first output is expected for the spring of next year, when we anticipate communicating the preliminary results of this study at the annual meeting of the Endocrine Society (USA). Full publications reporting the results of this work are not expected before the end of the project in March 2022. The first publication of the ‘in

vitro' work related to this topic received extensive coverage by the national and international press, so it is possible that the results of the proposed 'in vivo' experiments will continue to be of interest to the media and reach a wider audience. Because it has been demonstrated that the melatonin duration-induced differential expression of VEGF isoforms within the pituitary gland affects not only the gonadotrophic axis but also the lactotrophic axis, and that this appears to be a conserved mechanism of adaptation across species, we anticipate that other pituitary endocrine systems, such as the ACTH axis to regulate the response to stress, and TSH axis to regulate metabolism, are likely to be under the same mechanism of REDACTED. Therefore, in the long term, the outputs of this study are likely to benefit the general public, as the information gained may be applicable to the treatment of aliments derived from insufficient light exposure, constant air travel, shift work, etc. That being the case, we also anticipate collaboration with industry for the production of drugs designed to alleviate those ailments.

How will you maximise the outputs of your work?

We will communicate through conferences, publications, press releases, interviews, and articles in the farming press.

Species and numbers of animals expected to be used

- REDACTED: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals receive either a subcutaneous implant and once daily injections, or twice daily injections for a maximum of 21 days. Blood may be sampled up twice weekly to determine hormone status, after which we will insert an indwelling cannula into the jugular vein (under local anaesthetic using aseptic technique) for one day. Small amounts of blood are sampled from this cannula up to a maximum of 60 times.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are no expected adverse effects apart from a small needle prick when the injection goes in and the cannula is inserted.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild for all animals

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

REDACTED of REDACTED in REDACTED is down to a complex interplay between the brain decoding light signals to tell the animal what season it is, the pituitary gland interpreting the signal, the blood vessels that carry the hormones around the body and the interaction of the hormones on the reproductive tissues. To understand how this is REDACTEDled requires studying this interplay in live animals.

What was your strategy for searching for non-animal alternatives?

We have undertaken extensive experiments on cells grown in culture to find out the proposed mechanisms and these experiments are designed to find out if the previous experiments in a dish are representative of real life in an intact animal.

Why were they not suitable?

They provide information about the potential molecular mechanisms, but we cannot find out if they a) happen in intact animals and b) are sufficient to change the physiology of the whole animal. To do this requires experiments in intact animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We are measuring hormone concentrations in REDACTED, and there is inevitably some variation between groups. However, we have modelled the numbers that we need in order to discover whether the changes we see will be sufficiently robust to be able to draw conclusions using standard statistical modelling programs. This helps us have confidence that the numbers we use are the minimum needed to obtain a reliable result, so that not to have to undertake additional experiments on animals.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We used a qualified statistical consultant, as an advisor to the project.

What other measures apart from good experimental design will you use to minimise numbers?

This is a very simple experimental design, but all tissues will be banked and will be used before further experiments take place, wherever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The experiment is designed to be minimally invasive (subcutaneous implant then daily intra-muscular injections, blood collection from a vein up to twice a week, followed by a cannula on the final day).

Local anaesthesia will be used for cannulae implantation and securing to the neck with a suture

Animals will be in sight and sound of other animals during the procedures and trained with positive re-inforcement (small quantities of food) during protocols.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

REDACTED are farmed seasonal breeders and the species that we are trying to identify the changes in. Mice and rats, and non-mammalian species are not valid animal models for the purpose of the study.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The procedures are as minimally invasive as possible. We will use local anaesthesia to implant catheters. Aseptic implantation of catheters with clean technique for blood sampling by trained and competent licence holders and technical staff and single use needles all minimise harms. Total blood samples obtained will be according to published guidance

https://www.nc3rs.org.uk/blood-sample-volumes

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Guidelines for the Housing of REDACTED in Scientific Institutions (PDF). NC3Rs guidelines for experimental design. LASA guidelines for blood sampling.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We work with the REDACTED, the NC3Rs and experts in the field to ensure that further refinements can be made wherever possible.

Explain the choice ofspecies and the related life stages

The purpose of the project is to understand how seasonal REDACTED is REDACTEDled in ewes, therefore we need to use adult ewes that are fertile.

Home Office

NON-TECHNICAL SUMMARY

187. Sensory and spatial processing in the mouse cerebral cortex

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, aged, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project investigates how information from different sensory modalities and spatial information are integrated in the mouse cerebral cortex in order to build representations of the outside world and to form memories. It also addresses how these processes are altered in certain neurodevelopmental disorders and in neurodegeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Of necessity most of neuroscience research in the past has focused on 'lower' cortical areas and relatively simple stimulus processing in anaesthetised animals. In order to really find out how the brain works one needs to study how different sensory inputs are integrated with internal representations of the world, and how the outcome relates to a meaningful behavioural response. The as yet understudied retrosplenial cortex is ideally placed to study these issues, but it is also one of the first brain areas to show deficits in Alzheimer's disease. Understanding the normal function of this area will therefore be an important foundation for testing potential treatments in mouse models of Alzheimer's disease.

What outputs do you think you will see at the end of this project?

The proposed research will add to the growing body of knowledge about how interconnected brain regions interact to encode and store (visuo-spatial) memories and how this varies according to the types of cue that are being used. Furthermore, we hope to establish how a specific cellular pathway known to be involved in the regulation of blood pressure is associated with cognitive decline in Alzheimer's disease and how drugs targeting this pathway can reverse memory loss. Finally, we hope to find out how different visual areas of the (mouse) brain work together in order to encode different aspects of the visual world, and how this process is disrupted in mouse models of the developmental disorder REDACTED. Primary outputs for all results of our research will be publications in international, peer-reviewed journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

While the most immediate beneficiaries will be other researchers with an interest in brain circuits supporting memory as well as in experience-dependent plasticity of sensory processing there are a number of other likely beneficiaries in the longer term. The work on the rRAS pathway in mouse models of AD is ultimately aimed at delivering novel therapeutic options to patients with Alzheimer's disease for whom there are currently very few treatments available, and none that address the root causes. The work on mouse models of REDACTED will ultimately benefit patients suffering from this condition as it will lead to greater understanding of the neural deficits which will in turn be a prerequisite for developing treatment strategies. Results of the research will be shared at the annual REDACTED Day organised by the REDACTED.

How will you maximise the outputs of your work?

Outputs of this work will be maximised by extensive collaboration. Work addressing objectives 1, 2 and 3 (visuo-spatial memory engrams and integration of sensory and motor cues in the RSC) will be done in collaboration with colleagues in the psychology department. Work addressing objective 4 (modulation of rRAS pathway in mouse models of AD) will involve collaboration with researchers in two other universities. Objectives 5 and 6 will be addressed in collaboration with colleagues working in neuroscience and in mental health at myREDACTED.

Knowledge will be disseminated by publication in leading journals in the field as well as through talks and posters at national and international conferences (e.g. British Neuroscience Association, Forum of European Neuroscience, European Visual Cortex Meeting), including both positive and negative results.

Species and numbers of animals expected to be used

- Mice: 2210

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will be raised either in a standard lab environment or their sensory experience will be manipulated in some way (such as raising in darkness or monocular lid suture). They will be trained on sensory discrimination or spatial memory tasks. They will have fluorescent substances injected into the areas of the brain under study, and will have a cranial window implanted under general anaesthesia. Their brain activity will then be imaged while they will be carrying out the tasks that they have previously been learning. Imaging will be repeated over the course of several weeks. In the end the animals will be humanely killed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals are expected to experienced short-lived (up to 48 h) post-surgical pain which will be controlled by analgesics. Animals are expected to exhibit some weight loss during the training on visual discrimination and spatial memory tasks which is likely to last for 2-3 weeks and will be carefully monitored.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The expected severity for all animals subjected to experimental procedures which include surgery under general anaesthesia is expected to be moderate. The expected severity experienced by animals bred for the maintenance of genetically altered lines is expected to be sub-threshold or mild in virtually all cases, very rarely moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The processing of sensory and non-sensory information by the brain about the outside world, the formation of memories, and the influence of experience-dependent plasticity as well as genetic factors can at present only be studied in intact animals which can integrate sensory experiences over time and produce behavioural responses in return.

What was your strategy for searching for non-animal alternatives?

I have considered both in vitro and computer modelling approaches.

Why were they not suitable?

It is impossible to maintain a whole brain and sense organs alive in isolation in order to test true circuit function, and even if this were possible, we would be lacking a behavioural readout.

Neurocomputational approaches have helped us in the past to interpret results obtained in vivo. However, real data collected in vivo are needed to feed into any models, and for the questions addressed here, such data are not available.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Statistical analyses will be based on comparisons between cohorts of experimental animals (e.g. animals which have been raised in a specific way) and control animals (e.g. normally reared animals).

Calculated experimental group sizes in order to achieve a desired statistical power depend on effect size. This can only be estimated here; we used Cohen's d as a standardised effect size (representing the difference between treatment and control means, calibrated against variability, see EDA). For a medium effect size and a power of 0.8 the G*Power software gives group sizes of 24 for comparison between two independent groups (means). Based on past experience we need to take into account a rejection rate of 20% (for insufficient quality of data etc.) and therefore estimate 30 animals per group.

On this basis we have calculated the following numbers of experimental animals.

Objective 1
(To elucidate what the retrosplenial spatial memory "engram" represents):

3 groups = 90 animals in Protocol 2

Objective 2
(To determine the contributions of visual and non-visual cues to engram formation)

9 groups = 270 animals in Protocol 2

Objective 3
(To elucidate how visual and locomotion signals are integrated in RSC during spatial memory acquisition)

3 groups = 90 animals in Protocol 2

Objective 4
(To elucidate the role of rRAS activation on spatial memory processing in the RSC and cerebrovascular function in mouse models of AD)

3 groups = 90 animals in Protocol 1

3 groups = 90 animals in Protocol 2

Objective 5
(To determine which visual functions are supported by which of the visual cortical areas in the mouse, and to which extent they are subject to experience-dependent plasticity)

4 groups = 120 animals in Protocol 1

4 groups = 120 animals in Protocol 2

Objective 6
(To elucidate how mutations of the CACNA1C gene affect experience-dependent plasticity and visually driven behaviour)

4 groups = 120 animals in Protocol 1

4 groups = 120 animals in Protocol 2

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Chronic (longitudinal) imaging will be used throughout this project, an approach that reduces the total number of animals both by obtaining more data from each animal and by the increased statistical power of paired over non-paired comparisons. For example, with only two time points at least twice as many animals would be needed with acute assessments, three times as many for three time points. Consequently, many more animals would have to be killed to achieve the same statistical power. Experimental design has been optimised based on many years of experience in my own lab and by drawing on the experience of others working in my or similar fields, as well as by participating in the REDACTED. I have also drawn on the NC3Rs EDA (Experimental Design Assistant).

What other measures apart from good experimental design will you use to minimise numbers?

Apart from experimental design, the second-most important factor in the reduction of the number of animals used will be efficient breeding. This includes optimising the breeding of genetically altered REDACTED in terms of crossing the right animals to achieve the maximum number of offspring of the desired genotype, as well as ensuring that the number of animals bred and the timing of their births allows the maximum to be used for experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

For this project we will use both juvenile and older mice, and the principle method of assessment will be in vivo imaging of brain activity. The assessment itself is pain-free, and if properly habituated, the animal should not experience any distress or suffering. Pain will potentially be experienced following

surgery to implant the cranial window through which imaging is performed. However, this surgical intervention is carried out under general anaesthesia, and the risk of pain will be minimised by the use of analgesics.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Only mammals have a cerebral cortex and therefore the neural circuitry whose function and plasticity will be studied in this project. Mice are the least sentient species in which visuospatial memory and visual experience dependent learning similar to that in humans has been observed. The work can not be carried out in terminally anaesthetised animals since these would not be able to engage in behavioural tasks, and higher cortical areas would be silenced by anaesthesia.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be monitored daily post-operatively (for at least 5 days) using an approved score sheet. Animals will be given analgesics at the beginning of any surgery and post-operatively. Animals trained on specific tasks will be habituated gradually to the experimental setup and the tasks. If trained animals show signs of distress or otherwise stop engaging in a task the session will be terminated and the animal returned to its cage.

We will endeavour to reduce the use of water control, for example by increasing the hedonic value of the reward (by adding saccharine to the water) where this is possible without compromising the engagement of the animal with the task. We will follow national guidelines drawn up by the NC3Rs working group on refining behavioural training of rodents for high-yield sensory discrimination tasks.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

REDACTED
In addition, we follow guidance (SOPs) issued by the NVS.

REDACTED, the technique central to this project. The working group will issue best practice guidance in due course, which will then be followed for this research.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

At REDACTED level, we are regularly updated on advances in the 3Rs by the HOLC/NTCO as well as the NACWOs and the NVS. These will be implemented during the project as soon as possible. In addition, we will attend an annual 3Rs symposium at which individuals from the participating universities showcase their 3Rs initiatives. I will implement any guidance issued by the NC3Rs working group on refining behavioural training of rodents for high-yield sensory discrimination tasks as soon as possible.

Explain the choice ofspecies and the related life stages

Mice are mammalians, like humans, and their brains are organised and function in a similar, albeit simpler way. Of all mammalian species they are the easiest to genetically alter, which allows us to study neurodevelopmental conditions and neurodegeneration as well as to label specific populations of neurons. We will use both young, adult and ageing mice in order to study perceptual and learning processes throughout the lifespan and to analyse the effects neurodevelopmental conditions and neurodegeneration.

Home Office

NON-TECHNICAL SUMMARY

188. Sex differences in brain and behaviour

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

Behaviour, Brain, Psychiatric illness, Sex chromosome, Sex differences

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Men and women differ substantially in their behaviour, and their vulnerability to a number of common and disabling psychiatric illnesses. Whilst we know the biology of the genders is distinct, there is little known about the routes through which gender-specific behaviours and disorder vulnerability arise. This project aims to increase our knowledge regarding the biological (particularly genetic and hormonal) mechanisms that may predispose to these sex effects.

A retrospective assessment of these aims will be due by 23 October 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

We are particularly interested in understanding the biological mechanisms by which males are more likely to be diagnosed with developmental disorders (such as autism and Attention Deficit Hyperactivity Disorder) and by which some women develop psychiatric illnesses during pregnancy and after giving birth. Identifying and characterising these mechanisms could potentially reveal new therapeutic targets for use in treating sexually dimorphic brain disorders.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will use wildtype and genetically altered rats and mice in this work; these species, in which genes can be modified, show considerable genetic and neural homology with humans, key attributes in terms of modelling psychiatric processes dependent upon altered gene function. Moreover, elegant behavioural tasks with established translational utility are already available for these species. We anticipate using ~2,500 mice and 600 rats over the course of the licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The majority of procedures carried out under this licence will be mild, and will cause no more than transient stress or pain; similar to my previous licences, I expect that approximately 80% of procedures to be carried out will be of severity rating ‘mild’, and ~20% ‘moderate’. Novel genetically altered animals

may exhibit unanticipated health issues. Administering drugs to pregnant mothers may have mild, adverse effects on the mother's health, or on rates of pup death/malformation. Transferring litters from genetically altered to wildtype mothers to test genetic mutation effects on mothering may lead to increased rates of pup-killing. In order to motivate performance in some behavioural tasks, a degree of food restriction or water restriction (up to 22hrs per day) will be necessary leading to potential weight loss. A minority of behavioural tasks will be aversively motivated (e.g. by mild footshocks, or by immersion in water) resulting in transient pain or distress. Neuroactive substances may be locally or systemically administered to some animals; these drugs may have mild, transient effects on behaviour. Surgical procedures may result in mild discomfort.

A retrospective assessment of these predicted harms will be due by 23 October 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We need to use animals in our research for several reasons. First, it is not yet possible to model the complexities of behaviour in isolated tissue systems or by using computer simulations. Second, our rodent lines will, in many cases, serve as direct models for human disease situations. Where our in vivo work suggests underlying molecular/cellular mechanisms for behvaioural abnormalities, these will be further explored in in vitro systems; the results of these studies will help to inform our in vivo work. Here possible, we will ask questions using either healthy human and clinical populations to which we have access, or cellular model systems.

A retrospective assessment of replacement will be due by 23 October 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will minimise animal usage through performing power calculations once initial pilot data are available to ensure that we breed and use the minimum number of animals for obtaining a reliable experimental results; we will also use as many animals from each litter as possible (either as experimental subjects or controls). We will continue to improve our behavioural methods such that fewer animals are lost through attrition e.g. failure to learn the task.

A retrospective assessment of reduction will be due by 23 October 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Existing genetically altered rodents to be used exhibit no adverse effects on health/wellbeing; any new mutants created will be monitored closely in consultation with a vet and experienced animal technicians, and. if necessary, will be treated/culled. The majority of behavioural procedures to be used will either be non-regulated, or appetitively-motivated with palatable foodstuffs; the water and food restriction protocols to be used do not result in adverse effects on general health or wellbeing. Where aversive procedures are used, these will generally be mild and will not result in long-term adverse effects; particular attention will be paid to animals undergoing such procedures. Any drugs given will be non-toxic, and will be given in suitable and minimal volumes of vehicle. All surgery will be performed under aseptic conditions under general anaesthesia, and all efforts will be made to minimise potential associated pain using an appropriate analgesic regime. Where animals exhibit adverse effects on health and wellbeing resulting from the procedures, they will be closely monitored and treated appropriately by Personal Licencees, technicians and/or the REDACTED vet; if these interventions do not improve the animal’s condition sufficiently, they will be culled (generally by a Schedule 1 method).

A retrospective assessment of refinement will be due by 23 October 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

189. REDACTED-mediated control of vascular function

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Blood vessels contain an inner layer known as the vascular endothelium This consists of single layer of endothelial cells which maintain healthy blood flow and vessel function. The endothelium acts in part

as a barrier to regulate transport of substances into the surrounding tissue. Excessive inflammation of blood vessels at specific locations can lead to mechanical damage that eventually causes heart attack or stroke. Therefore, identifying the mechanisms by which endothelial cells maintain healthy blood vessel function is important to devise new medicines to prevent disease.

This project aims to examine how REDACTED, an intracellular protein, regulates two important properties of endothelial cells that are required for healthy blood vessel function; mechanoprotection (=the cell's ability to protect itself from mechanical stress due to increased blood flow) and angiogenesis (=formation of new blood vessels). We believe that REDACTED's effects are mediated in part via interaction with another protein called "REDACTED". REDACTED is essential for maintenance of "caveolae" (=bulb-shaped invagination in the cell membrane) at the endothelial cell surface, and which flatten to protect endothelial cells from damage following mechanical stress. Caveolae also control angiogenesis as they contain numerous proteins involved in blood vessel formation. Therefore, we predict that the loss of REDACTED will cause a reduction in cell surface caveolae and, as a result, reduce the ability of the endothelium to protect itself following mechanical stress and control angiogenesis.

This project will test this idea using genetically modified mice in which key proteins of interest (REDACTED, caveolin-1[=the main component of caveolae]) have been deleted, and characterise the resulting effects in whole animals and in isolated tissues using cutting-edge imaging techniques.

Mechanical stress will be induced by injection of anaesthetised mice with an optimised dose of dobutamine, a drug which rapidly increases cardiac output, to induce mechanical stress in small blood vessels supplying the heart. 1-minute post-dobutamine treatment, mice will be humanely killed for removal of the heart tissue which will be used to measure blood vessel integrity and levels of key proteins. Some mice will also be transferred to a secondary establishment, where they will undergo the same procedure as described above but with an additional step in which sedated mice will be injected 1 hour prior to dobutamine treatment with substances which enable visual measurement of small blood vessel integrity. This will be achieved using specialised imaging equipment only available at the secondary establishment.

To assess angiogenesis, anaesthetised mice will be injected with ice-cold Matrigel. This solution contains factors that promote angiogenesis and allows us to measure formation of new blood vessels in living mice. After 7-10 days, the mice will be humanely killed via a Schedule 1 method prior to removal of the Matrigel plug for analysis of angiogenesis by microscopic visualisation of new blood vessels.

We anticipate publishing the results of this research programme in high impact open access journals. The animal work carried out as part of this licence will be reported in accordance with the ARRIVE guidelines in order to allow transparency and ensure that our findings can be reproduced, thereby minimising unnecessary follow-on animal experimentation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Data from our experiments will lead to a better understanding of how REDACTED, a protein which suppresses blood vessel inflammation, can protect the endothelium from mechanical damage and control the formation of new blood vessels through controlling expression of caveolae. This knowledge will be invaluable for researchers studying fundamental processes important in endothelial cell biology, cardiovascular disease and vascular injury. Another potential benefit would be validation of the REDACTED/REDACTED interaction as a viable target for developing new drugs for many cardiovascular diseases.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice are well established as the model system of choice for identifying the function of specific genes in controlling the functioning of the vascular endothelium in mammals. This is achieved by deleting the relevant target gene, and observing the consequent effects both on the mice and cells or tissues derived from them. We anticipate using approximately 900 mice over a five year period. This represents the minimum necessary and will be achieved using methods of analysis that rely on small numbers of cells, for example microscopy-based measurements of the number of caveolae present on endothelial cells, and by as far as possible using tissues from the mice that can be successfully analysed in the laboratory.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

For animals used in the production of genetically altered mouse models the likely/expected severity of procedures is mild. REDACTED endothelial cell - knockout mice are viable, fertile, have no physical abnormality, and demonstrate healthy blood vessel development with the potential of increased blood vessel formation in certain diseases (Kisanuki et al. Dev Biol 2001;230:230-42; Stahl et al. Blood. 2012;120:2925-9). Caveolin-1-/- mice are viable, fertile and display only mild physical abnormalities within the 3 months they will be used (Martin et al. PLoS One. 2012;7:e46242; Cohen et al. Diabetes. 2004;53:1261-70). Ear notching will be used to mark the animals and this will cause only mild momentary discomfort.

For experiments which require treatment with PI, FITC-albumin and/or dobutamine, all solutions will be prepared aseptically to reduce the risk of infection. Animals will be anaesthetised prior to drug treatments to minimise any discomfort and reduce the risk of error during administration, such as missing the peritoneum and hitting local organs. As animals will be killed via a Schedule 1 method before regaining consciousness, the likely/expected severity of procedures is non-survival.

For animals transferred to the secondary establishment, there is a risk of physiological and social stresses due to the handling, exposure to new sounds and smell, fluctuations in temperature and

humidity, disruption of light-dark cycle and separation from cage mates and caretakers. All possible measures to minimise this stress will be taken. These include providing animals will be provided with sufficient space, food and water during transport, and transporting in vehicles with appropriate insulation, temperature control, ventilation and lighting. Once housed at the secondary establishment, animals will be allowed to adapt to their surroundings for at least two weeks to allow them to settle into the new facility.

For animals injected with Matrigel solution, this must occur whilst the Matrigel is ice-cold as it is only in liquid form below 10°C. However, as only a small volume (0.2 ml) is being administered subcutaneously, there are no anticipated adverse effects. Matrigel solution will be prepared aseptically to minimise the risk of infection and will also be administered under general anaesthetic to reduce discomfort to the animal. Animals will then be closely monitored for the next 7-10 days and, if they do exhibit any adverse effects, will be killed humanely via a Schedule 1 method.

At the end of the proposed experiment, all animals will be humanely killed and harvested tissues fully utilised, thus the likely/expected severity is non-recovery.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We have considered using endothelial cell lines to replace mice for some experiments, but our own preliminary experiments in addition to data published by other groups indicate that, while useful for answering specific questions, cell lines do not recapitulate the properties of endothelia present in intact blood vessels in living mammals as they relate to the functions we are studying (angiogenesis = new blood vessel formation; mechanoprotection = limiting damage to the endothelium caused by mechanical stresses such as increased blood flow). However we will as far as possible use freshly prepared and immortalised human endothelial cell lines or other cell types to replace the need for mice as a source of cells and tissues.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The project has been designed to minimise the number of mice needed to make statistically meaningful conclusions form the planned experiments. From our experience we estimate that 10 mice will be sufficient to perform each in vivo experiment. If, through the course of the experiments, we can gain significantly relevant information with fewer animals, study designs will be changed accordingly. This is particularly relevant to the two photon imaging experiments, where data from our collaborators indicate that conclusions can potentially be reliably made using less than 10 mice per condition.

In addition, the increase in cardiac output is to be initiated via dobutamine treatment for consistency and reproducibility, thus reducing result variability. As a result, less mice will be required for statistical analysis than if using an alternative exercise-based method to increase cardiac output.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse is the lowest species known to have caveolae and express REDACTED in the vascular endothelium similar to humans. From a practical standpoint, the abundance of available tools (e.g. REDACTED in which target genes are deleted only in specific cell types) and functional information on both REDACTED/caveolae and REDACTED in mammals coupled with the relative lack of these in lower organisms make mice the only suitable model system for our studies. In addition, several steps will be taken to minimise stress resulting from drug administration (handling methods that minimise stress, single injections, shortest time possible between administration and humane killing) and transport between facilities (2 week period to adapt to new environment prior to express)

NON-TECHNICAL SUMMARY

190. Spatial Memory in the Hippocampal Formation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged, juvenile, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand the general principles of memory formation and consolidation from a neural network level in healthy and neurodegenerative brains.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We are the product of our past; our memories define us. Our daily experience is full of vivid details from various sensory systems; however, our memories tend not to include all of the sensory details. Little is known about how detailed sensory experience is stored into memory, likely through compression and reconstruction for long-term storage. Despite advances in understanding the molecular and synaptic correlates of memory, our neural-level understanding of memory processing is far less mature. I will study information processing for spatial memory in the hippocampal formation in order to gain the mechanistic understanding of memory formation and consolidation.

What outputs do you think you will see at the end of this project?

I intend to publish at least two papers on high-impact academic journals. These publications will contribute to our understanding of how memory works, in particular focusing on the role of the hippocampus and its connections to key areas in the neocortex, with an emphasis on the spatial component of memory.

In the course of my research, I will bring collaborators into my lab, as well as make visits to other labs. This will enable the dissemination of technical skills into the wider scientific community, ensuring that myself and others have access to the most relevant and refined techniques for our research needs. I intend to collaborate both within and outside of my host REDACTED.

I will also nurture and train the next generations of scientists through various means, such as workshops, promoting international collaborations.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The research that my group and I carry out will benefit different fields, including:

1. Neuroscience and physiology

Clinical evidence suggests that the hippocampus plays an important role in forming our daily memory. Animal studies have shown that several types of cells in the hippocampus respond directly to the location of the animals, which is one of the three key components for memory. My study intends to show the more general and direct contribution of these cells to memory processing in the hippocampus. I will

disseminate our results through peer reviewed publications, seminars and conferences, as well as deposit relevant data in open data repositories.

2. Computational neuroscience

Taking advantage of virtual reality system that we just recently developed, the experiments that I proposed here will take a new angle for understanding the neural basis of memory processing. This detailed data will be valuable to theoretical neuroscientists, and can be used to create increasingly accurate models and hypotheses that can be directly tested in the laboratory. Indeed, a main future goal of my group is to collaborate with the exceptional computational neuroscientists to promote this information exchange.

3. Brain-machine interfaces

There is growing interest in creating an interface between humans and machines. Such an interface has the potential to return mobility to those with spinal damage and return the facility to communicate to those who have lost it through disease. Through refinement of hardware and data processing techniques, as well as analysis of data, I will push the boundaries of what is achievable in terms of brain-machine interfaces and this will likely be of interest to those seeking to engineer such systems for use in humans.

4. Dementia

Alzheimer's disease is one of the most common types of dementia, however, effective treatment of the disease is currently missing. Identifying and targeting cognitive deficits at the early stage of the disease is critical for developing effective treatments to reverse or prevent the decline in cognitive functions. By building an understanding of the neural networks involved in memory processing, in particular the part of the networks which is affected early on in the Alzheimer's disease, we will potentially be a step closer to identifying neural targets and novel approaches to tackling the disease.

How will you maximise the outputs of your work?

Many people have an innate desire to understand the world and their own mind. Memory in particular has proven a fascinating subject to the general public. I intend to make my research accessible to the scientific community, as well as the layperson through various way such as conferences, workshops, articles, videos, and in art installations. In some ways it is only through art that scientific knowledge is truly processed on an emotional and intimate level, and where it has its greatest impact on the general population. As such, when I was contacted recently by an artist, I agreed to explore the possibility of dramatizing my work.

In details, to maximize the outputs of my work, I plan the following activities:

1. All data collected will be made freely available to the neuroscience research community at some point. I will first upload example data with a detailed explanation of data structures to Open Science Framework (OSF.io) as open access when submitting my results to peer-reviewed journals. Relevant data, including modelling data and analysis code, will also be made available through Github as open access, after publication. Finally, all raw data will be made freely available upon request after a suitable

period post-publication, allowing exclusive use of the data for research by my own research group and my collaborators.

2. I will continue my current collaborations with lab within and outside my host institute, and also actively develop new collaborations by organizing workshops and representing my own work in various conferences.

3. My study is concerned with memory at a network level, and may improve our understanding of the fundamental processes behind dementia, in particular Alzheimer's disease. So, I intend to collaborate with clinicians in the UK, as well as from China, to test the results that I observe in mice to see if we can find analogues in human patients, and potentially look for new therapeutic targets for tackling dementia.

4. I intend to organize symposiums related to memory processing, using the platforms that are open to the general public to attract clever minds from various backgrounds, bringing in new thoughts from different angles.

5. In2Science program is organized by a charity and aims to empower underprivileged students to achieve their potential in research careers by providing short-term work placements in various universities. I intend to continue contributing to the program, and encourage my lab members to do so too, supporting and inspiring new generations of scientists.

6. I will setup my own website and twitter account, giving the general public open access to my research outputs.

7. I will collaborate with artists and non-scientists, contributing to increasing public awareness and understanding of science. I will be open to consulting on art installations, films, exhibitions, and theatrical performances.

Species and numbers of animals expected to be used

- Mice: 1300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, a wild type or genetically-altered mouse undergo surgical procedures, which result in the attachment or implantation of the assisting devices for neural recording or manipulation.

After the specified recovery period, the animal commences behavioural training.
Simultaneously with training and testing of behavioural tasks, the animal undergoes neural recording,

with or without neural manipulations,multiple times.

After the completion of the experiment, animals will be humanely killed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Surgical procedures could potentially have adverse effects for the animals, such as weight loss, pain during surgery, post-surgical complications and infection. Only very small percentage of animals might have one or some of these effects for a short period of time. Appropriate approaches have been described in the protocols to minimize these effects and animals will be humanely killed if these adverse effects continue.

Water or food restriction used for behavioural tasks could potentially have adverse effects for the animals, such as weight loss, dehydration, ill health and discomfort. These effects are expected to be reversed when restriction is lifted. Hence, animals under water or food restriction will be monitored closely and checked daily. Animals will be given full access to water and food if showing any signs of adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Around 15% of mice will have a severity level of non-recovery.

Around 15% of mice will have a severity level of mild.

Around 70% of mice will have a severity level of moderate.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our goal is to study memory processing in the hippocampus at a neural network level. This can only be done in free behaving animals.

In vitro and computational approaches can partially help to understand molecular and cellular basis of the underlying mechanisms of memory processing; however, to achieve the understanding at the neural network level requires the integrity of the network, which can only be obtained by using intact animals.

Our approach of study memory processing is to connect the neural mechanisms to certain behaviours; hence the free moving/behaving animals are required.

What was your strategy for searching for non-animal alternatives?

There are a few non-animal alternatives that we have consider for this project:

1. Computational modelling;

2. in vitro studies;

3. research using human subjects.

Why were they not suitable?

1. Computational modelling.

We are collaborating/ will collaborate with theoreticians for computational modelling. However, modelling in our fields has it limits due to our limited understanding of the complex neural network. We will use modelling results to validate our empirical data and guide our experimental designs. Ultimately, we will need work on animal to discover the fundamental mechanisms for memory processing.

2. In vitro studies.

In vitro approaches help to understand molecular basis of the underlying mechanisms of memory processing; however, to achieve the understanding of memory process at a neural network level and establish its connection to behaviours requires the use of intact, free moving animals.

3. Using human subjects.

Non-invasive imaging methods have been used for studying memory processing in humans. However, these approaches have lower spatial and temporal resolutions, compared to the in vivo electrophysiological and 2-photon imaging approaches which are mostly available on non-human animals, apart from the limited use in clinic cases. To understand the circuits and cellular basis of memory processing, mice are the least sentient species that we can use.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

NC3Rs' Experimental Design Assistant is used, when applicable, to design experiments and determine the group size, which help to estimate the numbers of animals to be used. In particular, statistical power analysis is used to estimate the number of animals to be used. Pilot study and existing literature are used to estimate important parameters in power analysis.

However, it should be noted that physiological experiments are special in that the number of animals required will largely depend on the success rate of neural recording, which is hard to predict accurately in advance.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Mice are the optimal choice for this project due to the maturity of genetic and imaging techniques uniquely available for the species, and for the rich scientific record on studying memory in freely behaving animals. Specifically, mice are the least sentient species for the study. In line with the Animals Scientific Procedures Act 1986, the project is designed to minimize the total number of animals. NC3Rs' experimental design assistant, when applicable, is used at the experimental design phase for estimating the animal numbers. Based on my previous work, I anticipate that each experiment will require 15-20 data-producing animals in order to achieve sufficient statistical power. However, due to the technically demanding nature of the experiments, I estimate that only 25-50% of animals will produce data. Exact numbers will be adjusted on an experiment-by-experiment basis to minimise animal use.

What other measures apart from good experimental design will you use to minimise numbers?

1. We will conduct pilot studies with a smaller sample size. This will allow us to test our hypothesis, investigate potential unpredictable effects, examine the feasibility of our approaches and refine our experimental designs and methods, before committing to larger scale experiments involving a larger number of animals.

2. We will collaborate with theoreticians for computational modelling. We will use the modelling results to validate our empirical data and guide our experimental designs, therefore reducing and minimising the number of animals required.

3. We will continue experimenting on new techniques, such as higher channel density recording, to maximize the data that we collect for each animal, hence reducing the total number of animals used.

4. Our recording protocol is chronic recording, which gives us a chance to record different populations of neurons within the same animals. This will maximize the use of individual animals and reduce the number of animals required to draw statistically significant conclusions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice

Main methods:

1. Behavioural training and testing.

Habituation and behavioural training will be performed to ensure animals to cooperate with recording procedures to minimise any distress. Mild food or water deprivation will be used to motivate the animals. Body weight and other animal behaviours will be monitored and recorded, to ensure the least pain and distress.

2. In vivo neural recording.

Majority of the data generated from this PPL is from neural recording. There are non-invasive methods of monitoring and imaging neural activity. However, they lack either fine temporal resolution or fine spatial resolution. Most importantly, they cannot provide information about individual neurons. Therefore, to record neural activity at the single cell level, which is required for studying the questions proposed in the project, it is necessary to implant electrodes for electrophysiological recording or implant glass windows for imaging. The surgical approaches used are the least severe available, involving the smallest amount of tissue damage and the smallest number of minimal-sized holes drilled in the skull. Animals are given extensive post-operative care and closely monitored during the recording experiments and during interactions with other animals.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice have been chosen for the project proposed in this PPL as they are the least sentient species that is appropriate for studying questions regarding spatial memory.

The main focus of the project is to study memory consolidation at a neural network level by investigating the formation of spatial cells and their interactions. The two main classes of spatial cell, place cells and grid cells, were first discovered in rodents and these cells have been heavily studied in rodents ever since. Therefore, mice are one of the most appropriate species for this work as they allow for direct comparisons with past studies. Additionally, the majority of experiments proposed will involve the use of virtual reality techniques that require head-fixing animals to the experimental apparatus, a paradigm which is best-established in mice. Further, several of the other techniques required by the project have been developed specifically for this species, including genetic models, 2-photon imaging, and optogenetics. Indeed, mice are the only species which can take advantage of the combination of all these techniques.

Moreover, less sentient species, for example invertebrates, do not have brain structures homologous to the hippocampus, and thus are not an appropriate model for learning and memory in mammals.

Overall mice are the most appropriate and least sentient species to be used in the project due to the nature of the research questions and the techniques available.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be motivated to seek reward using mild food or water deprivation during training and testing of behavioural tasks, we will only use the minimum levels of deprivation necessary to achieve uniform consistent behavioural results (food deprivation to reduce weight to max 85%). Water deprivation will only be used in experiments where food deprivation proves inadequate. An inverse 12 hours day-night cycle is applied to ensure minimal behavioural inhibition, hence to minimize the level of the food/water deprivation required.

The surgical approaches used are the least severe available, involving the smallest amount of tissue damage and the smallest number of minimal-sized holes drilled in the skull.

Animals are given extensive post-operative care including antibiotics and analgesics where they will be deemed to be necessary. Analgesics are always administered pre-operatively.

Animals are closely monitored throughout the experiments and any signs of problems with implants or other aspects of surgery are immediately dealt with, or, if this is not possible, the animal will be humanely killed. Similarly, animals are closely observed and monitored during the recording experiments and during interactions with other animals.

Housing cages will be spacious and enriched with small toys, running wheels, shelters and chewable materials such as wooden blocks, unless these interfere with the experimental design or presented as a potential danger to the surgical implants/attachments. Animals will be housed socially whenever possible (i.e. when no danger to their wellbeing is present as a result, e.g. when another conspecific can cause severe damage to its implant).

For the animals with implants/attachments, extra precautions as follows will be taken to avoid the damage to the implants and ensure the wellbeing of surgerized animals:

1. Custom-modified cages, in particular, sufficient height of the internal space.

2. Suitable bedding and nesting materials. In particular, soft tissue is provided before surgery in order for animals to build their nests, which will be kept with surgerized animals.

3. Food will be placed on the floor of housing cages for easy access.

4. Selective enrichment which is appropriate, such as running wheels, open-top shelters.

5. Group-housing whenever possible. However, single-housing may be required when implants/attachments are made from chewable materials or have a significant intruding part.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Resources hosted on the NC3Rs website, in particular:

- ARRIVE guidelines on experimental design and reporting results.
- NC3Rs' experimental design assistant (EDA).
- LASA Guiding principles for preparing for and undertaking aseptic surgery.
- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.
- Online general information on:

  1. Rodent housing and husbandry

     https://www.nc3rs.org.uk/3rs-resources/housing-and-husbandry/rodents

  2. Welfare assessment of laboratory animals

     https://www.nc3rs.org.uk/news/fresh-approach-training-welfare-assessment-laboratory-animals

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Attend regularly the workshops organized NC3R (National Centre for the Replacement, Refinement and Reduction of Animals in Research) for the updates on advances in the 3Rs.

According to the updates on advances in the 3Rs, I will regularly revisit the protocols in the PPL, consult with NVS and NACWO for their expertise and advice, in order to implement the advances effectively.

Explain the choice of species and the related life stages

Adult and aged wild-type and genetically-altered mice will be used to study the function of the hippocampus in memory processing.

Mice have been chosen for the project proposed in this PPL as they are the least sentient species that is appropriate for studying questions regarding the neural network mechanisms of spatial memory. Histologically, intensive existing studies in mice provide substantial background knowledge and also help to develop a great variety of techniques including virtual reality, genetics and large population neural recording. Choice of mice for this project enables us to take advantage of both existing knowledge and advanced techniques, which are essential for our proposed project.

Both adult and aged mice will be used. Adult stage is chosen to study the function of neural circuits. Aged stage is chosen to understand the biological mechanisms of neurodegenerative diseases such as Alzheimer's disease. By comparing normal to diseased models at the aged stage, we hope to study the

pathological anatomical and physiological changes in the diseased brains and connect these with behavioural changes, in order to shine some light on the neural network mechanisms of these diseases.

Home Office

NON-TECHNICAL SUMMARY

191. Spinal cord circuits for pain and itch

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Although the spinal cord plays an important role in transmitting and modulating sensory information that is perceived as pain or itch, we still know relatively little about how this information is processed at the spinal level. The aim of this project is to identify and characterize functional populations of nerve cells in the spinal cord that are involved in pain and itch, to establish how they are organised into circuits that increase or decrease these sensations, and to determine how they contribute to pathological pain states.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is a lack of effective treatments for both chronic pain and itch (pruritus), and these therefore represent major unmet clinical needs. Understanding the nerve circuits that convey pain and itch, and characterizing the different cells that are involved, is likely to lead to the identification of potential targets for new treatments for these conditions. In addition, understanding the changes that occur in the spinal cord following peripheral nerve injury is necessary if we are to develop improved treatments for neuropathic pain.

What outputs do you think you will see at the end of this project?

The project will provide new information about the types of nerve cell within the spinal cord, how these are connected to each other to form circuits that process sensory information, and the roles of these cells and circuits in chronic pain and itch. Outputs will include publications in peer-reviewed open access journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Chronic pain and chronic itch are both common conditions, affecting around 40% and 25% of the population, respectively. At present, treatment for these conditions is often inadequate, and this is largely a result of our limited understanding of the mechanisms underlying these conditions. The improved knowledge provided by this project should lead in the longer term to the development of new forms of treatment for chronic pain and itch.

How will you maximise the outputs of your work?

We will continue to collaborate with other groups working on spinal cord mechanisms of pain and itch. We will disseminate our knowledge through peer-reviewed open access scientific publications, review articles and book chapters, as well as regular presentation of the data at scientific meetings.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Many of the animals will receive injections into the spinal cord of viruses that alter the expression of genes in specific populations of nerve cell within the spinal cord. These changes in gene expression will result in either an increase or decrease in the activity of the affected nerve cells, and we will test the effects of this on acute pain thresholds and on the amount of itching that results when itch-inducing chemicals are injected into the skin. Acute pain thresholds will be tested by using stimuli from which the animal can readily escape. These sets of behavioural tests will typically be performed on three occasions for each animal. Animals may survive for up to 26 weeks after the injections (in the case of those that are treated as neonates), but the survival time would typically be much shorter (e.g. 6 weeks).

The animals may undergo an operation that results in damage to a nerve in the hindlimb, or they may receive an injection of a chemical into one hindpaw that causes inflammation. Both of these will result in a persistent pain state in which the affected limb becomes more sensitive to mechanical stimulation and to changes in temperature, and again, this will be assessed by means of similar behavioural tests. In addition, these animals will undergo other behavioural tests, for example to assess the effect of treatments that suppress pain. Again, sets of behavioural test will typically be performed on three occasions for each animal.

Animals will survive for no more than one week after inflammation is induced, and no longer than 8 weeks after nerve injury.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals that receive injections into the spinal cord will receive post-operative pain-killers, and should show no more than mild discomfort following the operation. There will be transient post-operative weight loss, but they will rapidly recover and should show no other ill effects.

Animals that receive nerve injuries or develop inflammation will show relatively mild signs of pain that include increased sensitivity to mechanical and thermal stimuli. In the case of inflammation this may last for up to a week, whereas after nerve injury the effects may be permanent. The animals' ability to move around their cages is not reduced after these procedures, and they eat and drink normally.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals in this study (~70%) will only be used for breeding and maintenance under Protocol 1, and since these animals will have no behavioural abnormality, this procedure is classified as "mild".

Most of the remaining animals (~30%) will experience moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studies designed to investigate the organisation and function of nerve circuits in the spinal cord, together with changes in these circuits that underlie chronic pain states, can only be performed on animals. This is because animals provide the only source of spinal cord tissue in which the complex organisation of these circuits is retained and remains functional.

What was your strategy for searching for non-animal alternatives?

Non-animal alternatives would include human spinal cord tissue obtained post mortem or cultured cells.

Why were they not suitable?

It would not be possible to obtain human spinal cord tissue that was sufficiently well preserved for detailed anatomical studies or that retained live neurons and functioning circuits. It is impossible to carry out studies of this type on cultured cells, since these do not have the complex organisation of the intact spinal cord.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Power calculations have been used to determine group sizes for all behavioural experiments, and for other studies where this is appropriate (e.g. for determining the proportions of cells that respond to different types of peripheral stimulus).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Advice was taken from a local statistician and from online tools for performing power calculations.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding of mice with targeted mutations will involve homozygous animals whenever possible, in order to reduce the numbers that need to be generated to obtain sufficient mice of appropriate genotypes.

Tissue (either perfusion fixed or fresh frozen) obtained from mice will be stored in liquid nitrogen so that it can be re-used for subsequent anatomical studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use nerve injury models and inflammatory models to investigate chronic pain. These models are all well-established and widely used in pain research, and they have all been refined during the course of previous studies by many laboratories to model clinical conditions. None of these models will cause any significant alteration to the behaviour of the animal, and all animals will be monitored regularly.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are the lowest animals in the evolutionary tree on which these experiments could be conducted, and are the only possible species that could be used for these studies, due to the availability of genetically modified lines, which allow targeting of different nerve cell populations. Experiments will be performed on adult animals because there are changes in the structure and function of the spinal cord during development. Many of the experiments will be performed on tissue taken from animals that were terminally anaesthetised.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to

the animals?

Robust procedures for animal care and monitoring are in place. Environmental and behavioural enrichment are provided. Staff will ensure that all animals receive the highest standard of care. Where appropriate (e.g. before, during or after surgery) preventative measures (e.g. anaesthesia, fluid replacement, pain relief and heated cages) will be used.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will abide by published guidelines (NC3Rs) as well as local guidelines, to ensure best working practice. We will also adhere to the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere).

Explain the choice ofspecies and the related life stages

The experiments in this project will all be performed on mice because of the availability of genetically-modified animals that allow specific types of nerve cell to be identified and have their functions altered. Experiments will generally be performed in young adult animals, but in some cases injections have to be given to juvenile or neonatal animals, for example to allow targeting of different populations of nerve cells.

NON-TECHNICAL SUMMARY

192. Stock Centre and Cryopreservation Programme

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, juvenile, adult
Killifish	embryo, juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The purpose of this project licence is to create a centralised stock centre service to efficiently breed and maintain a source of fish, reproductive and genetic material for use in scientific experiments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The benefits of this aim are threefold: reduction of the number of fish being used within the facility; refinement of current husbandry methods; acquisition of highly technical skills.

A centralised stock centre is an efficient method for producing zebrafish lines, allowing reduced numbers of fish to be shared by multiple users. This principle has already been demonstrated in the current stock centre programme: multiple PiLs, under several different PPLs, are sharing popular lines, which has reduced the numbers of overall fish. It is also the principle employed by Zebrafish International Resource Centre and European Zebrafish Resource Centre. By offering this as a service, to both on-site users and off-site users, we reduce the total number of fish required for scientific use. Many experiments use embryonic forms which are under 5 days post fertilisation, and the centralised service allows us to use fewer adult fish. Its use is a refinement of colony management as it allows for a reduction of total animals used; as all the users effectively share the same fish, there is no replication of lines. The stock centre is maintained by highly skilled staff, who specialise in the maintenance of the available stock.

What outputs do you think you will see at the end of this project?

This is a service that will see a reduction in total number of animals used, and a rigorous form of colony management through the use of cryopreservation.

Through this work the facility also aims to develop refinements to breeding practice and programmes and which are o benefit to animal welfare. We always disseminate this information by presentation and publication to other interested stakeholders including researchers, veterinarians, legislators and other technical staff.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This will reduce the numbers of fish used, because genetically identical animals will not be reproduced across different PPLs. The service will also provide zebrafish to other scientifically approved establishments.

The cryopreservation programme will ensure the minimum numbers of fish will be held alive, while ensuring that all relevant genetic material is still available.

Additionally, the work we do in the stock centre will also benefit researchers, technical fish facility staff and external communities, if they chose to take up our ideas about colony management.

How will you maximise the outputs of your work?

These services are widely advertised with in the facility, with internal users free to brow the lines held on our database. We will look to advertise them more broadly outside of our own establishment, including adding a database to our webpage showing lines available for bona fide scientific establishments to browse and order from.

We actively disseminate developments and refinements we make to breeding practices by actively engaging with stakeholders through presentations at conferences, publication and public outreach. Our presentations and publications are to targeted audiences – for example we present developments to animal technologists in a different way than we might to researchers, reflecting their different needs.

Species and numbers of animals expected to be used

- Zebra fish: 20,000
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Protocol 1 describes the breeding and maintenance of fish lines, for the most part this is natural spawning. In some cases, these fish may be genotyping using a biopsy of the caudal fin or muccal swab. Protocol 2 describes the cryopreservation programme – which employs both cryopreservation and in vitro fertilisation. It is likely that most animals on this project licence will only be used for natural spawning, with a small percentage undergoing genotyping using a biopsy of the caudal fin, as most lines will be genotyped using fluorescent imaging of embryos under the age of 5 days post fertilisation.

Fish used in the cryopreservation programme will have potentially undergone caudal fin biopsy or muccal swab to determine genotype. These fish will be held briefly under general anaesthetic while gentle pressure is applied to the abdomen to extract gametes up to a maximum of 5 times with a rest period of at least 2 weeks between each gamete extraction. The majority of fish in the cryopreservation programme are unlikely to experience gamete extraction 5 times – a more likely experience would be 2 gamete extractions with a 4-week rest period in between.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are no expected adverse effects from natural breeding.

Potential harms may arise from the use of anaesthesia, which would include gill bleeding and this may happen in both anaesthesia in the cryopreservation programme and in genotyping using the caudal fin biopsy method.

Bruising from applied pressure may occur in the abdomen from the cryopreservation protocol, which can impede swimming.

In very rare cases, infection may occur from breaching the mucus membrane when taking a muccal swab.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Both protocols are mild and all fish in the programme are expected to fall within either the mild severity limit or into subthreshold.

In the breeding protocol, it is expected that 5% or less will fall into the mild category with the other animals falling into subthreshold category.

In the cryopreservation protocol, all animals are expected to fall in the mild severity threshold.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Fish are an increasingly popular research model and our aim is to provide a service to those using fish in scientific research setting for experimental purposes. Because of the nature of this project licence it is not possible to choose a replacement to fish.

What was your strategy for searching for non-animal alternatives?

None

Why were they not suitable?

We require animals to provide the necessary service.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animals we need to use is based on animal numbers used in the REDACTED, including amendments to the PPL to reduce the numbers of fish needed due both to changing scientific need and to the trails within the facility to refine and make of practices more efficient.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

As a service PPL, the main purpose of this project licence is to consolidate fish line sharing between research groups both within and externally to the estabishment and reduce numbers of fish used in other project licences overall.

We constantly check and monitor other project ensure that there is no duplication of lines of fish at the establishment, I attend a monthly fish facility strategy board meeting, at which colony management is regularly discussed. We have also designed a colony management taught course to help people manage colonies and we regularly monitor individual’s fish via the database. We have also been

instrumental in introducing our research groups to the NC3RS onsite representative and regularly setup legislative refresher courses for our research groups to remind them of their legislative obligations and the use of the 3RS. All of which is designed to address poor experimental design in the projects we supply fish to.

As well as using data harvested from the previous stock centre licence, we also calculated the numbers of fish required for the project, we used both the NC3Rs experimental design calculator and consulted with statisticians both internal to the establishment and external.

What other measures apart from good experimental design will you use to minimise numbers?

We use efficient breeding and considered colony management. We have setup many trials over the years, with the aim of increasing good welfare practice and reducing the numbers of fish used in research both at the establishment and more generally in the field. For this work and to help calculate the numbers of fish in the stock centre, we have used both the NC3Rs experimental design calculator and consulted with statisticians both internal and external

We regularly attend conferences and present this work. I have extensive networks and assess to different groups which allows us to keep up to date with new practice with in the field internationally.

We also actively promote the stock centre and cryopreservation service as we believe the sharing of animals between several other PPLs ensures optimal use of the animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

This is a service licence and the goal is to reduce the amount of fish produced across several other project licences, other establishments in the UK and other bona fide establishments worldwide. We will do this in two ways by identifying popular lines of fish through working group meetings that include researchers and by database analysis and then combine We will supply wildtype embryos and wild type adults for various purposes – including crossing to other strains of fish. We will also hold genetically altered lines of fish that are popular with researchers working on different project lines to consolidate lines, so we do not have duplications of lines within the facility, these are distributed as embryonic forms to interested scientific researchers be stored for future derivation and are not held. A cryopreservation service is also offered, this allows lines of fish gametes to be frozen and stored when

lines of fish are not actively being used – but may be required for further future scientific use. This is a refinement because it means that live fish are not being used.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

This is a service exclusively for zebrafish, killifish, Cavefish and a small colony of wild type Giant Danio, and as such it is impossible to use an animal that is less sentient.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will constantly review this project licence, which is possible through information mined from our extensive database, containing records going back almost 20 years and information about the fish lines including colony management, survival rates, breeding success, health status and cryopreservation success. We also regularly review the literature, attend conferences and workshops to ensure that all procedures we perform are as refined as possible.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

I follow Home Office guidance, but also follow other sources and publications including Zebrafish, Animal Welfare Technology, other publications. I perform publication review and speak to a wide variety of colleagues including legislators, research scientists, animal technologists and my extensive peer group.

For example –

Guidance on the operation of the Animals (scientific procedures) Act 1986 - https://www.gov.uk/guidance/guidance-on-the-operation-of-the-animals-scientific-procedures-act-1986

Zebrafish - https://www.liebertpub.com/loi/zeb

Animal Welfare Technology - https://www.iat.org.uk/atw

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I have very varied contacts with in the community, which include the NC3Rs, IAT and LASA and the Home office as well as constant contact with my peer group. All advances and new ideas will be

assessed and implemented if applicable.

Explain the choice ofspecies and the related life stages

These fish are part of a husbandry and welfare service to supply highly popular lines to multiple research groups, who would otherwise generate many more fish by individual research group duplication. We also hold lines for research groups in preparation for the fish to move onto other project licences at points when this is impossible in the first place, for example researchers who are newly arrived at the establishment and are still awaiting their own project licences. The cryopreservation service allows the archiving and re-derivation of lines with a useful scientific need and reduces the number of live fish. We determine the life stage of the fish generated either by the requests of researchers or, in the case of the cryopreservation programme by the demands of the technique.

Home Office

NON-TECHNICAL SUMMARY

193. Studies of Neointimal Formation in Response to Vascular Injury

Project duration

5 years 0 months

Project purpose

None selected

Key words

Heart attack, Vascular graft, Stenting

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Heart attacks cause more deaths in the UK than any other disease and survivors of a heart attack have a marked reduced life-span and quality of life. Heart attacks are most commonly caused by a disease called atherosclerosis, which involves the formation of a blockage within the hearts blood vessels

(coronary arteries) which stops blood flow. If a patient survives a heart attack, the current treatments for blocked coronary arteries are usually to either bypass the blocked artery with a section of the patients vein taken from their leg, or to reopen the blocked artery using a medical device called an angioplasty balloon which permits the placement of a wire-meshed tube (called a stent) to hold the artery open and allow blood flow. These treatments save many lives, but both have high failure rates in the long term as they cause injury to the vessels, causing them to re-block. These processes are called vein graft failure and restenosis respectively and are triggered by cells (vascular smooth muscle cells) from within the blood vessel moving and growing inwards to form a new blockage, termed neointimal growth and formation. As such, learning about how these blood vessel cells are regulated will provide useful information for the development of new medicines for the treatment of these underlying causes of such cardiovascular diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project will advance our understanding about how blood vessel cells and their associated molecules are involved in normal artery and vein function and how they are altered to contribute to re-blockage of bypass grafts or stented arteries, and ultimately the formation of new blockages that require further surgery or cause sudden death. If we can find which pathways or molecules cause the vessels to re-block and find a drug to prevent this from happening, then work within this project in the mid-to-long term may lead to the development of safe and more effective therapies. This would reduce the need for patients to undergo another angioplasty and stent deployment or further bypass surgery, and even prevent death from a second heart attack. Instead they may be able to take a pill to prevent such occurrences or it may be possible to treat the vein graft with a drug before it is used or add drugs to the stent, to improve their viability and applicability.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

This project proposes to use mice. Approximately 1500 mice will be used over 5 years (300 mice per year).

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Approximately 50% of mice will be maintained for breeding purposes and to provide animals for neointimal formation experiments, and this procedure is therefore classified as mild as no adverse effects are expected. Approximately 50% of animals will undergo surgery (15-20 minutes) in order to tie-off one of the carotid arteries or have a substance applied to the outside of the artery, in order to induce neointimal formation. At the same time some of these mice (about 50% of mice having surgery) will have osmotic mini-pumps implanted to deliver drugs/molecules under therapeutic investigation. In both instances, mice are expected to recover quickly and will be given pain killers and post-operative care just like people recovering in hospital. Due to the nature of the surgery this protocol is considered moderate, although no serious adverse effects are anticipated as our previous studies have shown that mice recover well following surgery and are feeding and behaving normally a few hours after their surgery. However, induction of neointimal formation within coronary arteries may result in sudden death due to a heart attack in a small number of mice (less than 5%). Animals will be killed at the end of experiments by an approved Home Office humane method and blood, tissues and cells taken for further laboratory study and scientific analysis after death.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Laboratory studies using isolated cells and tissues from either mice or humans will form a major part of the proposed studies and will be used alongside our ex vivo organ culture system to determine potential interventions in advance of any work in live animals. However, the complex biochemical changes that occur in response to vascular injury cannot all be modelled in isolated cells or ex vivo tissues, because they are influenced by a wide range of physiological factors that are unique to living animals. The study of whole tissues or cells isolated from those tissues facilitates refinement of our studies, as certain interventions and agents can be used that would not be possible (for reasons of toxicity, rarity or cost) in living animals. It also enables us to reduce our use of animals because many cells can be isolated from a single tissue and used for multiple studies.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The number of animals will be minimised by conducting initial studies in cells and tissues in the laboratory, with strictly controlled conditions to minimise experimental variability. Our extensive experience of such studies means that we can use historical data to perform power calculations to ensure that the experimental designs are biologically and statistically rigorous. In general, the experimental design will involve comparison of a control group with one or more intervention groups using statistical tests appropriate to the data. We will regularly review our designs in the light of the data generated to ensure that the results are statistically rigorous but do not involve the use of unnecessarily large groups of animals.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The vascular injury mouse models we have selected are virtually unique amongst experimental animals in that they develop neointimal formation (the root cause of secondary heart attacks in humans) without the need for intra-vascular injury and associated prolonged anaesthetic, so we have chosen them for our studies of the biological basis of vein graft failure and in-stent restenosis. Mice are also an appropriate species due to the availability of genetically modified strains and active inhibitors. Moreover, we have refined our use of osmotic mini-pumps to ensure we use the smallest models available, further limiting any potential adverse effects associated with their deployment. We have extensive experience in all of the models and methods to be used in this project and are confident that they are the most appropriate to address our research questions.

We will always use the least invasive procedure alongside anaesthetic and analgesic in such procedures to minimise animal suffering. We will also continuously monitor the outcome of our procedures in order to effectively minimise this suffering.

Home Office

NON-TECHNICAL SUMMARY

194. Studies of retinal ganglion cell damage in experimental glaucoma and optic nerve injury

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Glaucoma is a major cause of vision loss. It is caused by the loss of neurons that transmit visual signals from the eye to the brain. Using a rat model of glaucoma we determine whether is it possible to restore these connections and restore vision that has been lost by the time a patient is diagnosed. These treatments are likely to be drugs that are injected into the eye (a common route) to enhance the ability of remaining neurons to selfrepair.

The aims of the project can be summarised as:

1. Quantification of the extent to which retinal neurons degenerate in glaucoma.

2 The extent to which these cells can be recovered following treatment.

The objectives are:

1. The development of a treatment regime for the recovery of retinal structure and function in glaucoma

2. The development of techniques to show, definitively, that retinal recovery has occurred.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Glaucoma remains one of the major causes of vision loss in glaucoma. While there are effective treatments for many patients – usually by reducing the eye pressure, significant numbers of patients still experience significant vision loss. Current treatments focus on the prevention of progressive vision loss. No treatment has yet been developed for the recovery of vision that has been lost. We will address this shortfall by studying the earliest degenerative events the cells that transmit visual signal from the eye to the brain (retinal ganglion cells). In glaucoma, these cells lose their connections with the retina and can no longer transmit visual signals to the brain. Since they retain their connections with the brain they form the basis for developing treatments to restore the circuit that takes visual information from the real world to the brain. In these experiments we will determine the extent to which these connections and circuits can be repaired following the injection of drug into the eye. The ultimate goal is that we can restore vision that has been lost in glaucoma.

Another key benefit is that we will know the extent to which these drugs can repair the retina. This information is essential for the next step in developing a new treatment - a clinical trial. Results from work in our models of glaucoma will give some idea of the doses of drugs to be used and the size of the beneficial effect, information which is essential for knowing how many patients should be recruited to a trial and the nature of the trial end points (i.e. when we might say that it has or has not been successful).

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Rats, adult: 200; Mice, adult 650; Over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The maximum anticipated adverse effects are moderate. We induce mild damage to one eye in each animal and this is to model an eye condition that is (in terms of discomfort) asymptomatic. The majority of adverse effects relate to drying of the eye during examination or mild reactions to applied medications. Animals could experience a corneal abrasion- but these usually recover within 6 hours and are very rare (no cases to date in our group).

1. For the bead model of glaucoma induction, the degree of discomfort is minimal: animals show no change in behaviour following treatment. With the optic nerve crush model the effects on animal behaviour are minimal since we only aim for partial optic nerve crush and therefore ensure that the treated eye has residual vision.The possible adverse effects are that infection could occur at the site of ocular injection or conjunctival manipulation. These have not been issues with these techniques in our hands.

2. We will use LPS to activate the innate immune system but at low levels that are below the threshold to induce uveitis or significant weight loss. The greatest effect is that the animal can lose up to 20% of body weight- but our experience with this technique is that the weight loss is c 10% and animals recover in the weeks following injection.

All animals will be killed at the end of the protocol. Any animal that exceeds the threshold level for adverse effect will be killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Demonstration that retinal ganglion cells in experimental glaucoma requires an intact visual pathway. We need to demonstrate the anticipated route of delivery (by intravitreal injection) is effective and that functionally retinal ganglion cell show improvement over a 2-3 week period. Mice and rats have sufficient similarity with the human visual system in terms of optic nerve anatomy to justify their use.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We can perform dose ranging studies using retinal explants. We can also ensure high cellular yields by using multiple coloured dye labelling to label multiple retinal ganglion cells in each eye.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Both mice and rats have well developed optic nerves with features that match structure seen in human. The method that we have developed to increase intraocular pressure allows the controlled elevation in IOP in 90% of animal injected. Our IOP increases are modest and can be mitigated by the application of oculohypotensive medication. Both rat and mice tolerate the elevation of IOP well with no observable effects on activity/ weight.

NON-TECHNICAL SUMMARY

195. Study of Haematopoietic stem cell gene therapies to treat genetic-associated disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To assess the function and efficiency of blood (haematopoietic) stem-cell based gene therapeutic approaches to correct inherited genetic disorders and novel disease targets

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake thiswork?

Using blood stem cells, that are responsible for producing other cells of the immune system, for stem cell gene therapy, is emerging as a successful approach to treat several inherited genetic disorders. This involves making a functional copy of the gene in the laboratory and inserting it into a sample of the patient's own blood or bone marrow stem cells, using a modified virus so that the patient's defective cells now carry the correct genetic information. These genetically modified stem cells are then given back to the patient as an autologous (using one's own cells) stem cell transplant, where they can continue to develop into corrected blood cells.

Developments from both academic and biotech sectors have driven this approach through to clinical use, and stem cell gene therapy is now proving to be a highly successful, safe and long-term transformative treatment for patients with several life-limiting inherited disorders (including X-linked Chronic Granulomatous Disease, Wiscott Aldrich Syndrome, Metachromatic Leukodystrophy, Beta-Thalassemia, ADA-Severe Combined Immunodeficiency). Despite this progress, there is an urgent need to improve the processes for the manufacturing of cell and gene therapies to i) improve the drug product, delivering a higher chance of clinical success and therapeutic benefit to patients, and ii) to reduce the costs of manufacturing gene cell therapy products, as this currently presents the major barrier to making it more deliverable and accessible to patients.

In addition, founded on the progress and emerging clinical data achieved by current stem cell-based gene therapies, it is also now important to explore whether this approach can be used to treat other immune based inflammatory disorders, for which only palliative or prophylactic treatments are available. Basic research into whether a stem-cell based gene therapy approach can provide an effective and long-term treatment for these disorders is currently lacking. Demonstration of the safety and successful use of stem cell-based gene therapy by animal experimentation is an important component of this translational research programme and is a prerequisite for further research to develop advanced therapy investigational medicinal products.

This research will therefore address a clear healthcare need for several inherited diseases and chronic clinical indications. Firstly, it will provide key data to inform direct translation of the project findings into our current process for development and manufacture of clinical drug products. Secondly, it will provide proof of concept data for the application of this therapeutic approach to treat novel disease targets with limited treatment options.

What outputs do you think you will see at the end of this project?

The resulting data from this Project will be published in peer-reviewed scientific journals and presented at national and international research meetings. Findings relating to improved stem cell gene therapy will be transferred and implemented into clinical drug product manufacture.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We expect to make significant advances in the development and safety testing of novel cellular therapies for
rare inherited disease and other diseases associated with known monogenetic defects.

The optimisation of methods that result in better gene modification will significantly improve our current processes to manufacture a gene modified stem cell medicinal product. Successful use of these modifications to the current manufacturing processes will improve the therapeutic potency of the stem cell product and dramatically reduce the cost of this therapy, making it more affordable and therefore more accessible to more patients in need. As the experiments designed in this Project will use cells and materials prepared to similar specifications as clinical therapeutic HSC-gene modified drug products, the results will be readily transferable to clinical manufacture. As such the developments investigated may be translated to our cell therapy manufacture process within 2 years of completing this research.

Validation that stem cell gene therapy may be a successful approach to treat highly prevalent chronic diseases such as irritable bowel disease, will lead to continued investment in further research programs for pre-clinical and clinical evaluation.

The wider impact of successful project outcome and implementation could ultimately
contribute to

- Development of novel therapeutic approaches to chronic inflammatory disorders for which there are currently no long-term treatments available
- faster patient access to life-saving and life-changing therapies at more affordable prices

  reduced treatment costs and financial burden for payers (NHS, tax payer)

How will you maximise the outputs of your work?

Although the results of this research ultimately aim to translate the findings to clinical application, all data generated, including unsuccessful approaches for stem cell selection and enhancement of gene modification, will be published. This will ensure the outputs of this Project are maximised.

Species and numbers of animals expected to be used

- Mice: 1300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice may be weighed and experience regular (e.g. weekly) blood sampling (e.g. via tail vein nicking). Mice will receive a non-myeloablative conditioning treatment of either whole body irradiation, or up to 4 intraperitoneal injections of chemical conditioning agents administered over 4 days. Mice will then receive a graft of cells via a single intravenous injection. Mice may experience non-invasive imaging under anaesthesia after receiving a substrate tracer injection via intravenous route. Mice will be maintained for up to 6 months for study and then be killed by schedule 1 and non-schedule-1 methods.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Adverse effects that mice may experience include:

- Transient and acute pain from injections

- Acute Peritonitis as a result of intraperitoneal injections

- chronic xenogeneic Graft-versus-host disease as a result of transfer of human cells

- Up to 20% weight loss and loss of body condition as a result of myeloablation or combined impact of adverse events of protocol steps

Use of humane endpoints will limit any other potential adverse effects or any clinical symptoms as a result ofthe procedures to be performed

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mice within this Project will experience procedures with Mild or Moderate Severity. The proportions of the total mice to be used in this study that will experience each are:

Mild: up to 5% of mice

Moderate: up to 95% of mice

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We plan to use in vitro assays as much as possible to replace in vivo experiments. However, while in vitro assays provide insight into the stem cell multipotency or, the function of the therapeutic protein they are genetically modified to express, these assays cannot accurately model the multiplicity of immunological factors or networks of interactions that occur in vivo, which determine engraftment potential or functional gene expression in a physiological setting. The current gold standard assay to experimentally test the repopulating potential of human HSCs is intravenous or intra-bone injection into sublethally irradiated, genetically immune-deficient mice.

Furthermore, in order to fully understand interactions between the immune system and tissues affected by diseases related to dysregulated immunity, we need to use transgenic/genetically altered mice bearing alterations in disease-causing genes. The use of in vivo models is essential to refine existing (and develop new) cellular therapies as they allow us to detect in vivo homing and persistence of transferred cells, their efficacy in modifying/preventing disease and off target toxicities.

We will abide by the recommendations laid out in the following guidelines: (i) Refining procedures for the administration of substances [www.lasa.co.uk] and (ii) Guidance on the use of human material in

animals [https://www.gov.uk/government/publications/guidance-on-the-use-of-human-material-in-animals]

What was your strategy for searching for non-animal alternatives?

We will endeavour to use in vitro assays wherever possible to characterise and study the function of human stem cells. Although some study's use in vitro 3d culture systems to evaluate human embryonic stem cell and induced pluripotent stem cell function, these do not provide information on long-term engraftment potential and have not yet been successfully applied to primary human HSC stem cell research. We will use LTC-IC assays (long-term culture initiating cell) and CFC (colony-forming cell) assays to detect HSC early and late progenitors, to inform the planned in vivo assays.

In addition, where possible, primary clinical material and human cell lines have been sourced to conduct parallel work, to support and inform study components requiring animals.

To evaluate the impact of specific gene defects associated with disease indications, we will generate knock out human and murine cell lines for initial testing in vitro, to formulate clearer hypotheses and inform in vivo experimental plans.

Why were they not suitable?

Other than ex vivo and in vitro cellular assays, no replacements are available to assess or accurately predict human stem cell ability to migrate to the bone marrow and survive once transferred into a living organism. The humanised mouse protocols developed to study haematopoietic gene-modified stem cell function have been selected as they allow the engraftment of human stem cells, as previously demonstrated by ourselves and others. Combined with the successful engraftment of human cells and reconstitution of a functional human immune compartment, the humanised mouse model and transgenic mouse models provide an important bridge to study the therapeutic benefits or side-effects of the gene being transferred and expressed in an experimental disease model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The sizes of experimental groups and the number of repeated experiments will be kept to a minimum while ensuring that reproducible results are obtained with clear biological significance, ensuring comparable levels of data can be achieved while using fewer animals. From my previous experience using humanised mouse models described in Protocol 2, and murine bone marrow transplants in Protocol 3, the methods have been refined to maximise the number of mice that engraft with a human immune system, and to optimise the degree of engraftment and minimise the numbers of mice lost due to technical failures.

When preliminary data is available from our and others published research experience of these in vivo models, power analyses will be used to determine the minimum numbers of animals and repeated experiments that are required to meet statistical significance. All such calculations will be made in consultation with the departmental statistician.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

- Selection of experiments to be performed in the Project have been informed by in vitro data, to minimise the number of mice and experimental conditions required. For example, in Protocol 2 of this Project, initial conditions tested in vitro included evaluating the function of 8 HSC stem cell subsets (Objective 1) and over 20 different transduction enhancer compounds (Objective 2). These have been refined to evaluate only the most promising candidates for in vivo (Objective 1: 3 HSC stem cell subsets; Objective 2: 3 Transduction enhancers).
- Competitive transplant assays and the generation of mixed bone marrow chimeric mice have been included into the experimental plan where possible, as a method to provide a more robust answer of experimental vs control comparability, whilst providing an 'internal experimental control'. This further reduces the need for an independent control group.
- The NC3R's Experimental Design Assistant has also been used to review and inform the experimental plan. Establishing pilot experiments to ensure experimental, technical success, minimise failures

What other measures apart from good experimental design will you use to minimise numbers?

- Initial pilot studies will be performed to validate the experimental protocols, to ensure no unanticipated effects on animal well-being are observed and that all anticipated readouts can be achieved. This will avoid unnecessary experiment repetitions.
- Secondary bone marrow transplants of human stem cell engrafted NSG mice are frequently performed as a gold-standard test to confirm the long-term repoplulating potential of primary engrafted cells. To minimise the numbers of animals required, we will harvest bone marrow and

perform secondary transplants from mice used in other experimental series (example, use bone marrow harvested from mice transplanted with the top cell dose in a limiting dilution experiment used to determine HSC Scid Repopulating Frequency).

- Where possible, serial in-vivo imaging of individual mice will be used in order to reduce the number of animals killed for histology at various time-points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mouse models of human and mouse cell transplants will be performed to address the aims of this Project. Cells will typically be transferred by intravenous injection, into mice which are conditioned to receive cell transplant. Non-invasive imaging will be used to track cell behavior in vivo.

These procedures are minimally invasive and designed to reduce the likelihood of any adverse effects associated with toxicity or immune susceptibility as a result of conditioning treatments, or engraftment of mouse or human cells in vivo.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Adult mice are required to allow monitoring of long-term bone marrow engraftment and stem cell function, in an in vivo physiological setting that permits human and murine mouse cell growth and differentiation. Other less sentient models are not available to perform these observations.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The procedures planned are minimally invasive and refined to prevent and minimise discomfort or harm, pain and suffering:

- Use of split dose irradiation techniques to minimise potential adverse effects

- Daily monitoring of mice following cell transfer to ensure mice engraft and fully recover from the procedure

- Use of non-invasive in vivo imaging techniques

- Use of early humane study end-points using scoring charts to monitor animal health and wellbeing

- inhalation anaesthesia will be preferentially used where possible for imaging, to aid more rapid animal recovery

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We have designed the protocols that will be used within this project by consulting Best Practice Guidelines published by LASA, FRAME and NC3Rs resources. These will be annually reviewed for updates throughout the project duration.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will stay informed about potential refinements I can make and implement into the planned work in this Project, I will refer to published studies, scientific congress, and discuss with an NC3R representative. I will also conduct a mid-project review and report back to our AWERB for advice.

LASA, FRAME and NC3Rs resources will also be reviewed to update procedures and methods being used to address the Project aims throughout the study duration.

Explain the choice of species and the related life stages

Engraftment and the ability to reestablish blood cell production for the lifespan of a recipient is currently the gold standard definition of a stem cell (Rossi, CellStemCell. 2012). Critical information such as the survival of transferred immune cells in a host system, the migration of cells into disease affected tissues and impact on recipient survival can only be studied in an animal model. It is required by the UK and EU regulatory authorities (MHRA and EMEA) that advanced therapy investigational medicinal products (ATIMPs) are pre-clinically tested in animal models prior to phase I/II clinical trials in humans. The data generated in this project will inform and refine future pre-clinical studies that support regulatory requirements for ATMPs. The use of juvenile-adult mouse strains, with genetic backgrounds that permit human and mouse cell engraftment, and allow study of a single gene knock out and its restoration, are therefore the only models available to research and yield robust and highly relevant data sought in the Aims and Objectives of this Project. The choice of these models and animals will therefore provide important data to further the development of stem-cell based gene therapies for clinical use.

NON-TECHNICAL SUMMARY

196. Studying central nervous system repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, aged, embryo, pregnant
Rats	neonate, juvenile, adult, aged, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To investigate the cellular and molecular mechanisms that control central nervous system repair in order to identify new therapeutic strategies for treatment of neurological disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are currently no approved treatments aimed at repairing the central nervous system in neurological disorders, due to the lack of understanding of the mechanisms that control repair success and failure.

What outputs do you think you will see at the end of this project?

We aim to identify new targets for drugs to repair the brain following injury, more specifically to regenerate the insulation surrounding nerve fibres which is required for nerve health and function. We are achieving this by studying the contribution of immune cells in the brain which we have shown support this regeneration. At the end of this project, we will have a better understanding of the way in which the immune cells need to be stimulated in order for the brain to be repaired, which subtypes of immune cells need to be targeted, how these are involved in various neurological disorders, and what proteins can be used as a starting point for the design of new drugs to stimulate brain repair.

Our NC3Rs funded studentship also aims to develop a platform that could be widely adopted for screening in tissue explants, here focusing on screening for regenerative drugs in the context of the central nervous system using brain explants, with implications for use of these protocols in screening in either different neurological models in explants or in other organ explants. We predict that the development of this platform will reduce the number of animals needed in comparison to treatment of live animals, by 28 fold.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We anticipate that both scientists and the general public will benefit from these outputs. First, other researchers in the field will benefit from the new knowledge we generate in understanding how brain repair takes place, and how it fails. This will aid in advancing the field towards new therapies. Scientists working directly on the project will also benefit in supporting their professional advancement (e.g. in doctoral studies). Second, patient groups for neurological disorders in which brain repair fails may eventually benefit from this research, as our goal is to identify ways in which drugs could stimulate repair. This is expected to be a long-term goal.

How will you maximise the outputs of your work?

We will maximize the outputs of this work by: 1) forming international collaborations with researchers with expertise in advanced techniques (e.g. drug delivery) and with useful models to advance our research, 2) disseminating the data via presentations at conferences and publication of results, 3) public engagement via interaction with charities REDACTED and social me
4) providing information on our research on our lab's REDACTED website. All large-scale data such as gene transcriptomes are made publicly available on online databases for all researchers to access for further study.

Species and numbers of animals expected to be used

- Mice: 9500
- Rats: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Some animals will be used for breeding to generate animals that are used for subsequent experiments. Some animals are used for isolation of cells or central nervous system tissue for investigation. Some animals undergo experimentation to induce a small brain injury by injection of a substance, which normally does not lead to any signs of damage, pain, or distress, which we can then use to investigate the brain repair process. In some cases we used aged animals which show poor brain repair, and these also undergo the small focal brain injury approach. Some animals are genetically modified to allow us to visualize cells, modify gene expression, isolate RNA, or induce brain pathology. Most of our experiments are short term e.g. 1.5-3 weeks long. For experiments on aged animals, the oldest animal used is 15 months old.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We have extensive experience with inducing the small focal brain injury in animals and very rarely observe any adverse effects on the animals. Occasionally we will observe an undoing of sutures over the wound, which we can easily correct (once only). Occasionally we may observe temporary signs of pain or distress the day after surgery, at which point we consult the veterinarian and anti-inflammatory drugs may be administered or the animal culled if advised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We expect the proportion of animals to experience the following level of harm in each protocol:

Protocol 1) For both wildtype mice and rats, 75% will experience moderate severity due to exsanguination, perfusion-fixation, or use of transgenics with adverse clinical presentation.

Protocol 2) For both genetically altered mice and rats, 25% are expected to show moderate severity in clinical presentation due to elimination or overexpression of genes.

Protocol 3) For in vivo stereotaxis of mice and rats, 100% are expected to show moderate severity following surgery as all animals must undergo full anaesthesia and injection.

Protocol 4) For in vivo steretaxis of juvenile mice, 75% are expected to show moderate severity as this proportion will undergo stereotaxis and/or hypoxia.

Protocol 5) For widespread demyelination with cuprizone in mice and rats, 50% are expected to show moderate severity from demyelination as some mice are on normal diet.

Protocol 6) All transgenic mice used for neurodegenerative models are expected to have moderate severity due to neural pathology.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Using animals allows us to i) determine the mechanisms involved in brain injury and repair, ii) do precise temporal analyses of events to understand the process of injury and repair, iii) manipulate the system to understand the contribution of a specific cell or protein in injury or repair, and iv) test the efficacy of drugs in supporting brain injury. There is remarkable conservation of events, cells, and proteins in rodents and in humans, making them suitable models to progress our knowledge in the treatment of neurological disease.

What was your strategy for searching for non-animal alternatives?

We considered the use of organoids ('balls' of central nervous system tissue) and skin cell-derived brain cells/ human embryonic stem cells.

Why were they not suitable?

Although some organoids have recently been shown to recreate some parts of the central nervous system, these do not have myelin or white matter and are thus not appropriate for our studies. In addition, it is not possible to only use fixed human post-mortem tissue to address our hypotheses as it is impossible to manipulate this tissue by performing gain or loss of function experiments or to determine the role of cells or molecules in central nervous system myelin repair. Additionally, although studies in other fields are now focusing on deriving stem cells from patient skin cells (iPS cells) or human embryonic stem cells then differentiating them to cells of interest, this is not appropriate for our studies because myelin repair involves the interaction of multiple cell types (thus increasing the difficulty of reliably generating all of these cells and ensuring their physiological interaction) and it is not currently understood whether these derived cells recapitulate all of the functional and gene expression profiles of in vivo-derived counterparts. Moreover, currently human brain cells cannot be produced in large numbers, limiting experiments that can be performed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals proposed was arrived at by our previous power calculations determining that to achieve a power of >80% at a significance of <0.05, we require 6 animals per group for in vivo experiments, and 12 animals per group (1 litter) to achieve a significant number of cells or explants for tissue culture. We anticipate using more mice than rats because we use primarily mice for our brain explant and in vivo work, and rats only for a subset of experiments (less than 1 experiment per month per lab member).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will also use in vitro and ex vivo cultures for initial experiments before performing in vivo experiments, and use a shared control group between treatment groups. We also use statistical analysis of data to have statistical precision in our analyses. For live imaging, we reduce the number of animals required by a large amount due to the capacity to track the same animals over time within an experiment.

What other measures apart from good experimental design will you use to minimise numbers?

When possible, we will obtain tissue from other groups for models of interest, to avoid using additional animals. This allows us to test initial hypotheses and design pilot experiments. Pilot experiments use a small number of animals, e.g. 3, from which we use the data to perform power calculations to determine

the maximum number of animals needed to have confidence in the result. Our breeding strategies also result in either using both sexes for experiments, or using some of the mice for breeding rather than experimentation.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice will be used for in vitro, ex vivo and in vivo models due to the availability of transgenic mice that will allow us to better answer the biological question at hand, the already established protocols of brain slice generation and induction of focal brain lesions in mice, and the ability to compare our data to the literature given that the majority of experiments in the field of myelin repair are conducted with mice. We employ models of focal myelin injury to facilitate analysis of repair (known location and time of induction) and due to focal lesions being observed in both multiple sclerosis and cerebral palsy. In addition, inducing focal lesions is the most refined method to use as it induces small lesions with mild clinical effects in comparison to models with more widespread damage (such as experimental autoimmune encephalomyelitis). We will use reporter mice expressing fluorescent proteins under the control of different cell-specific promoters and these are not known to have any detrimental phenotype. Other transgenic mice expressing mutations or variants of different myelin genes, or signalling molecules thought to be involved in myelin repair, are excellent ways of studying the biological processes involved in myelin repair by altering expression of the molecules involved. These may have phenotypes, but as we are interested in improving myelin repair after injury, we hope that they will regenerate quicker and thus suffering is reduced. In some instances, the use of conditional knockouts in which immune cells (e.g. macrophages) have impaired function may be used, these may be immunocompromised therefore we will use individually ventilated isolator cages with germ-free food and water to prevent infection and suffering.

Rats will be used for the majority of the generation of in vitro cultures of central nervous system or bone marrow derived cells because we can generate higher yields of cells from these vs the mouse, and thus will reduce the number of animals required for each experiment. As with mouse studies, the protocols to isolate and maintain these cultures are already established, further reducing the need for optimization and the number of animals required.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Previous experiments have demonstrated the similarity between rodents and humans in terms of cells, cell behaviour, biological processes, and gene/protein expression.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will monitor animals regularly, provide post-operative care including pain management, heat management, and providing mash on the floor of the cage, and will consult the veterinarian if any signs of pain or distress are observed. Animals will be weighed regularly and those showing >20% weight loss will be culled.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will plan studies to ensure we can publish following ARRIVE guidelines.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I will check the NC3Rs website for any advancements in techniques available, will participate in the annual REDACTED NC3Rs day, and will send a member of my lab to the NC3Rs annual meeting in the UK.

Explain the choice ofspecies and the related life stages

We study brain repair in various models of neurological disorders across the lifespan, including developmental brain injury (e.g. leading to cerebral palsy), brain damage in young adults (e.g. multiple sclerosis) and in old age (e.g. Alzheimer's disease and neurodegenerative disease). Thus we use neonatal and juvenile animals, adult animals, and aged animals. In addition, some cell types that we study are available in larger numbers in younger animals, and we can therefore use less animals in our research if we isolate our cells from young animals. Furthermore, we can grow slices of brain in a dish which allows us to investigate brain repair more easily than in a live animal, and these slices survive better when isolated from neonatal mice. Altogether this also reduces the amount of live experimentation done in animals.

NON-TECHNICAL SUMMARY

197. Studying drivers of tumour heterogeneity and drug resistance

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To generate and demonstrate the utility of a novel transgenic mouse line, in which tumours will more closely resemble those that occur in humans than is currently achievable using existing mouse models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A significant challenge in cancer treatment is the enormous genetic variation seen within a single tumour, meaning that even if a therapy successfully kills the majority of cells in the tumour, some will be inherently resistant to that therapy. We are studying a group of genes (‘REDACTED’) whose normal function is to defend our cells against viral infection but which can go rogue, causing errors (mutations) in our DNA and driving cancer development and/or progression during treatment by generating this 'genetic heterogeneity' within tumours.

REDACTED appear to play a key role in the development of numerous cancer types, including breast and lung cancer, which between them account for approximately 100,000 cases of cancer per year in the UK. The role of REDACTED in cancer has only been revealed in the last 5 years, due to our ability to sequence DNA from tumours and to identify the mutations that have caused these tumours to develop.

While much has been learned about other important cancer genes from studying them in mice (leading to many new cancer therapies), unfortunately mice have only one REDACTED gene, while humans have seven – therefore we cannot learn very much about how these genes work, or test anti-cancer drugs that are being designed to target specific human REDACTED genes by studying normal mice. To address this problem, we have generated a ‘humanized’ mouse line, in which we have replaced the one mouse REDACTED gene with part of a human chromosome containing all seven human REDACTED genes.

We predict that this humanized REDACTED mouse will bring at least three key benefits:

1) The ability to study the biology of the REDACTED genes within the context of a whole organism; increasing our understanding of basic biology, immune response to viral infections and cancer development.

2) The mice will serve as a key model in which REDACTED inhibitors currently under development for cancer therapy can be tested prior to entering clinical trials in humans.

3) Due to the mutagenic activity of the human REDACTED genes, these mice should serve as a background in which tumours that are more 'human-like' can be modelled, therefore serving as a more refined research tool for the broad range of cancer researchers and those engaged in cancer drug development who rely on the use of mouse tumour models.

What outputs do you think you will see at the end of this project?

We will establish whether this new mouse line is a useful and improved model for studying human cancer development.

We will determine whether these mice will be useful for the preclinical testing of anti-cancer drugs targeting our genes of interest ('REDACTEDs'). If so, our collaborators in drug discovery will use these mice to help bring their drugs to the point at which they can be trialled in human cancer patients.

We will publish a paper describing this new mouse line, detailing how it can be used for studies into viral infection, inflammation and cancer.

We will present our findings at national and international cancer conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short / medium term (during the project) we will know if this mouse line is a useful tool for studying REDACTED biology during viral infection and cancer development. Once we know this, we will publish our findings and make the mice available to the wider research community.

In the longer term, we anticipate that this mouse line will become a very important tool for studying tumour development, used by many researchers and also by those in academia and industry, that are developing and testing cancer therapeutics.

How will you maximise the outputs of your work?

We are already collaborating with researchers engaged in drug discovery (REDACTED). We will publish and present our detailed characterisation of this new mouse model and make the mouse line itself widely available to the research community, through deposition with repositories (e.g. European Mutant Mouse Archive and/or Ximbio).

Species and numbers of animals expected to be used

Mice: 1400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Adult mice may be injected once with a drug and monitored for up to 48 hours before being euthanised. Only drugs that have previously been administered to mice and for which safe doses have been estabished will be used in this study.

Other mice will be kept alive until old age (up to a maximum of 2 years) and will be closely monitored to chek for signs of cancer development. Any mice displaying signs of discomfort/distress due to symptoms associated with ageing or cancer development will be euthanised immediately.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Mice injected with drug are expected to experience mild and short-lived pain at the time of injection but we don't anticipate any longer-term discomfort.

Mice that are aged to monitor for tumour development may experience symptoms associated with ageing including dry/flaky skin, possible hearing loss, problems with vision, digestive complications, problems controlling body temperature, excessive weight gain or loss, increased risk of tumours, abscesses, incontinence or problems urinating. Mice will be closely monitored for all such symptoms and will be either treated or euthanised. Mice will not suffer with any such symptoms for more than a few days at most.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most (80%) of mice will be used either for breeding or for injection and these will experience no more than mild discomfort.

The approx 20% of mice that are used for ageing / tumour development may experience discomfort of moderate severity.

What will happen to the animals at the end of the study?

Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We need to understand how tumours develop and how our genes of interest ('A3s') contribute to this process in the context of a living organism. Factors such as inflammation, disturbed sleep cycles and obesity can all increase our risk of cancer development and it is impossible to model these in cells growing in culture.

We also need to develop an animal model in which new drugs targeting the A3 genes can be tested before being trialled in humans.

What was your strategy for searching for non-animal alternatives?

We have conducted extensive analysis of the A3 genes in human clinical samples using DNA sequencing and gene expression data from The Cancer Genome Atlas project and International Cancer Genome Consortium. We have also made extensive use of human cell culture models, which form the main focus of our current research and we will continue to use human cell cultures wherever possible. We have invested a lot of effort in generating A3 knockout and A3-tagged human lines. Wherever possible we will use cells derived from our mice rather than the mice themselves for studying how the A3 genes are regulated in our new mouse line, thus sparing mice any unnecessary discomfort.

Why were they not suitable?

Human cell cultures will continue to be our primary research tool and will inform our animal experiments. However, the key questions concerning the role of A3 genes in cancer development and progression are only addressable in an animal model. Furthermore, the development of A3 inhibitors as anti-cancer agents depends upon establishment of appropriate preclinical models for testing prior to trialling in human cancer patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of our mice will be used for breeding. For the experimental mice, we have conducted power calculations to determine the minimum number needed to provide meaningful data.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We've followed guidelines detailed in the 'The Designing of Animal Experiments: Reducing the use of animals in research through better experimental design' (Festing, Overend, Borja and Berdoy; 2nd Edition).

What other measures apart from good experimental design will you use to minimise numbers?

We will use a pilot study to examine whether our ageing mice are tumour-prone. We will collect multiple tissues from euthanised mice to learn as much information as possible per mouse. We will also derive and culture cells from mice and will use those for analysis rather than performing procedures on live mice wherever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will exclusively use mice for this project. In experiments in which mice are adminstered with drugs, each mouse will only experience this once and will be kept alive for a maximum of 48 hours post-administration, so will avoid any chronic/longer term effects.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We need to study tumour development and the genes in which we are interested act in humans over many years to generate the mutations in DNA that eventually cause cancer in adults. These genes are not relevant to paediatric cancers, so we need to study tumour development in the adult mouse. For experiments in which we will measure changes in gene expression following administration of drug, we need to evaluate these changes over a period of up to 48 hours, so it is not possible to perform this under terminal anaesthesia.

While a number of cancer-relevant studies can be conducted in non-protected animals, such as nematodes or flies, modelling the complex interplay between REDACTED gene expression and inflammation and/or viral infection and cancer development requires a model as close to humans as possible, hence our use of mice. Furthermore, we anticipate using these mice as a preclinical model for REDACTED-targeted drug development; again it is desirable/essential to conduct such studies in an organism that best approximates the action of a potential drug in patients, while avoiding the use of (for example) non-human primates.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

All work will be conducted by trained personnel, who will be given further training in specific techniques where necessary. This licence contains only protocols categorised as mild or moderate and

anaesthesia and/or analgesia are used wherever appropriate. Animals will be closely monitored during all procedures and where possible we will consider refining existing techniques or incorporating new methods to minimise any suffering to the animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Ullman-Cullere et al 1999 'A Rapid and Accurate Method for Assessing Health Status in Mice' Lab Animal Science; 49(3):319-323.

Wilkinson et al 2019 'Progressing the care, husbandry and management of ageing mice used in scientific studies' Laboratory Animals 0(0):1-14.

Turner et al 2011 'Administration of Substances to Laboratory Animals: Routes of Administration and Factors to Consider' J Am Assoc for Laboratory Animal Sci 50;600-613.

Workman et al 2010 'Guidance for the welfare and use of animals in cancer research' Br J Cancer 102;1555-157.

Diehl et al, 2001 'A good practice guide to the administration of substances and removal of blood, including routes and volumes' J. Appl. Toxicol. 21, 15–23.

'The Design of Animal Experiments: Reducing the use of animals in research through better experimental design' (Festing et al 2nd Ed).

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Regular attendance at local AWERB meetings, liaising with our vet, reading the latest relevant scientific literature, attending conferences and consulting policies on animal research from our funder (Cancer Research UK) and other funding bodies.

Explain the choice ofspecies and the related life stages

We are using mice as they are a long-established and very useful model for studying cancer development in humans. The mouse is also a tractable system for conducting the complex genetic manipulation involved in introducing the human REDACTED locus.

Home Office

NON-TECHNICAL SUMMARY

198. Support procedures for Neural Repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo
Rats	juvenile, adult, neonate, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To breed normal and genetically altered animals to provide animals and tissues in a timely fashion for research into neural repair and protection, and perform initial testing of therapeutic compounds for compatibility.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The licence supports the work of a group working to develop methods to repair and protect against damage to the nervous system. The licence provides normal and genetically altered animals and tissues to support this work. The licence also allows initial testing of new therapeutic compounds to find out if they are compatible with mammals.

What outputs do you think you will see at the end of this project?

This is a licence to support the research of the group by providing animals and tissues in a timely fashion to enable research aimed at developing new treatments for damage to the nervous system. It also allows for the initial testing of new treatment compounds to assess their compatibility.

Breeding according to the principles of demand-matched supply will minimize wastage and reduce the need to obtain lines from commercial suppliers thus reducing contingent transport stress.

New potentially therapeutic substances will be tested for compatibility with animals.

The outputs will be achieved through other licences held within the group. These will be through scientific publications relevant to the repair of the protection and repair of the nervous system.

Data will be published from the *in vivo* biocompatibility tests in the licence.

Tissue from animals kept in this licence is used for *in vitro* tests whose results will be published.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The main output of the licence will be the enabling of research within the group through the timely provision of animals and tissues for research and through initial compatibility testing of compounds.

Published data from biocompatibility testing and on any new tests developed will by used by academic and pharmaceutical company groups.

The overall aims of the group are to develop new treatments for spinal cord injury, Alzheimer's disease and glaucoma.

For spinal cord injury the aim is to develop new methods to promote regeneration of axons in order to restore function.

For Alzheimer's disease the aim is to develop treatments to reactivate plasticity in the adult CNS. This enables the brain to make new circuits to bypass the damaged neurons. This restores cognitive ability and delays the onset of dementia, but does not stop the slow progression of the neuronal damage caused by the disease.

In glaucoma the aim is develop treatments that protect retinal ganglion cells from the effects of the disease and to enable damaged axons to regenerate in the optic nerve.

How will you maximise the outputs of your work?

The output of this licence will be published in papers from the group, enabling future collaborations and new models for investigation. Any new or improved methods of animal husbandry, production of transgenic animals and unsuccessful approaches will be published in papers from the group. The research group collaborates with several other research groups in various countries. Transgenic animals can be transferred from other groups or to other groups to enable research. Members of the group work closely with other groups worldwide and attend meetings with other groups working in the same area. Successful and unsuccessful methods are regularly discussed and presented.

Species and numbers of animals expected to be used

- Mice: 4740
- Rats: 1850

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Procedures are included that enable preservation of transgenic embryos and establishing transgenic lines from preserved embryos. These procedures involve minor surgery for vasectomy and implantation of embryos.

Most of the animals kept on the licence are transgenic or normal animals that are bred so as to provide the number of animals that are needed to provide cells for tissue culture, or to provide transgenic animals that will be transferred to other licences for experiments to discover new treatments for the repair and protection of the nervous system.

Some animals are used in pilot studies to test the compatibility of new potentially therapeutic compounds

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Procedures for preservation and restoration of transgenic lines. In these protocols animals receive minor surgery for vasectomy and embryo implantation. In rare cases there may be wound infection or the wound may need to be resutured once.

Maintenance and breeding of transgenic animals. The majority of transgenic animals kept under this licence have no deficits and behave like normal animals. Two lines that are models of Alzheimer's disease and Motor Neuron Disease are kept. These animals do not show any deficit until they are over 4 months old, during which time breeding is accomplished. In rare cases pregnant animals may be kept while showing adverse signs until they have delivered their litter, but in they are always killed before they become severely disabled.

Testing of compounds for compatibility. All compounds to be tested have been shown to be non-toxic and efficacious in tissue culture experiments, and past experience tells us that these compounds will be well tolerated by test animals with no adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The animals used for generation of transgenic lines receive an anaesthetic and therefore come into the moderate category; they are expected to make a rapid recovery.

Over 90% of the transgenic animals show no deficit and are therefore in the mild category.

Animal models of Alzheimer's disease and Motor Neuron Disease can show early signs of poor mobility and weight loss. They are almost always used at a time at which the deficit is very small. Occasionally pregnant animals may be allowed to survive to a greater degree of disability within the moderate severity in order to deliver their litter.

Protocol 1. Mild all animals

Protocol 2. Moderate all animals

Protocol 3. Moderate all animals

Protocol 4. Moderate approx. 30%, the rest Mild

Protocol 5. Non-recovery

Protocol 6. Mild all animals

Protocol 7. Mild all animals

Protocol 8. Mild all animals

Protocol 9. Mild all animals

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to discover new treatments to preserve and repair the nervous system, mechanisms and treatments are tested in tissue culture. Appropriate animal tissue is needed for this work. When promising treatments are identified they need to be tested in animals to show whether they can repair or protect a real nervous system with all its complexities. Tissue culture models are not yet adequate to determine whether treatments may work.

What was your strategy for searching for non-animal alternatives?

Most of the work in the group is performed in tissue culture. Only final verification is done in animal models.

Why were they not suitable?

The mammalian nervous system is extraordinarily complex, and subject to effects from the immune system and other body mechanisms. Only by testing treatments in whole animals can treatments that might be taken forward for use in human and veterinary patients be identified.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The purpose of the licence is efficient and timely supply of animals for tissue culture and work on other licences. The required number for animals for planned experiments are calculated on those licences. Numbers of transgenic lines must be sufficient to maintain a breeding population.

Numbers of animals used for establishing and preserving transgenic lines are calculated based on the likelihood of new lines being introduced, and the need to transfer or preserve lines if the lines are sent to other animal facilities.

Numbers of animals for provision of tissues is based on the current level of use of animals within the group.

Numbers of animals for testing of compatibility is based on initial testing of five new compounds during the time of the licence.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Breeding is carefully monitored so that sufficient but not excessive numbers of animals are bred for the planned experiments.

For pilot compatibility studies only 4 animals per group are planned, and animals will be dosed one at a time, so that if the first animal shows a reaction the experiment can be stopped or replanned.

What other measures apart from good experimental design will you use to minimise numbers?

In this licence efficient and timely breeding is performed. The reduction methods for the experimental work are described in the relevant licences.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Most of the animals used in this licence have no adverse phenotypes. Two transgenic lines are used to model Alzheimer's disease and Motor Neuron Disease.

In the Alzheimer animals, the genetic alteration is chosen so that animals show a deficit in memory two or more months before they become disabled. Experiments can therefore be performed on animals that appear normal.

In the Motor Neuron Disease model, animals are killed to provide cells for tissue culture before any motor deficit occurs.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Fish, insects do not give very good models of neurodegenerative disease or recovery of function compared to mammals. The tissue culture methods for which this licence provides tissue only work well with mammalian cells.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The procedures have already been highly refined based on work over many years, and very few animals show signs of harm. Tests are being further refined to allow testing of treatments at early ages, before any harmful deficit is apparent.

For compatibility testing of compounds, all compounds are screened for toxicity and efficacy in tissue culture studies. Testing begins with a low dose in a single animal and only escalates if no toxicity is seen.

When GA animals are transferred from elsewhere, where practicable germ plasm will be imported instead of live animals.

Where urine is to be collected, consideration will be given to using Lab Sand rather than collection of urine in a gridded cage.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Animal testing is constantly being upgraded in the host laboratory and elsewhere. New methods will be incorporated into our practice.

Excellent information is available on the various websites listed above which are constantly updated with new 3Rs information.

Full and updated information for licence-holders is provided under the project-holders website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The establishment offers continuous training and advice through the training facility and the animal facilities.

Excellent information is available on https://www.nc3rs.org.uk which is constantly updated with new 3Rs information. http://en.3rcenter.dk, http://www.frame.org.uk, http://3rs.ccac.ca,

http://www.ahwla.org.uk.

Excellent information on procedures is available on https://animalcare.ubc.ca

Full and updated information for licence-holders is provided under the project-holders website.

Explain the choice ofspecies and the related life stages

The main purpose of the licence is to provide transgenic and normal animals for use in experimental procedures in the laboratory. These animals are either used to provide tissue for tissue culture experiments or are transferred to other licences held in the group for experimental work.

For tissue cultures late-stage embryos or newborn animals are needed to provide nerve tissue that can survive in tissue culture

For animal experiments in the group on repair and protection of the nervous system adult animals are used, matched to behavioural and anatomical models optimised for testing repair and protection treatments.

For testing compounds for compatibility adult animals are used, because the compounds will be tested for their ability to protect and/or repair the nervous system.

Home Office

NON-TECHNICAL SUMMARY

199. Targeted immune and molecular therapies for cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, neonate, embryo, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to study the immune and molecular mechanisms associated with the development and spread of cancer and to discover and evaluate novel biological, immunological, immune cell and molecular diagnostic and therapeutic treatments, including novel antibodies and antibody-drug/inhibitor conjugates. We are particularly focusing on tissue cancers such as malignant melanoma, breast and ovarian carcinomas, especially subtypes of these diseases for which there are few effective therapies available. Our studies will help us understand how our immune system which protects us from infections, interacts with cancer cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite some promising treatments available in the clinic, tissue malignancies represent a major group of diseases for which limited effective therapies exist. Although surgery, radiotherapy, chemotherapy and adjuvant therapy have been used, tissue cancers in their advanced stages are notoriously resistant to conventional drugs and therefore present a major therapeutic challenge. Attention has recently turned to the development of novel immune and targeted therapies, including monoclonal antibodies, designed to fight tissue cancers. Immune and immune cell therapies for cancer have been the focus of many studies because tissue tumours are known to elicit immune responses resulting in immune cell activation. Several molecular pathways associated with cancer cell growth and a small number of tumour antigens have been targeted using molecular or immune therapies. Therapeutic antibodies are established in medical treatment against autoimmune diseases, transplant rejection and cancer. In cancer therapy, the high specificity of an antibody for its cellular target is expected to specifically seek out malignant cells expressing this target. This can result in cancer cell death by several mechanisms including blocking vital cancer growth functions, by immunological mechanisms or by antibodies bringing toxic payloads directly to cancer cells. Although some therapeutic interventions are already approved for clinical use in oncology, their potential for the treatment of tissue cancers is far from being realised and the mechanisms of action against tumour cells of many of these agents are not fully understood. The aim of our research is to understand the underlying mechanisms of immune responses to malignancy and to employ this knowledge to design, study and evaluate novel immune and targeted treatments that can help control cancer progression and metastasis and can ultimately benefit patients who suffer from cancer.

What outputs do you think you will see at the end of this project?

Expected Benefits

Dissecting the mechanisms of cancer pathogenesis and the recruitment and alterations of immune cell signalling in cancer will further our understanding of how tumours grow and how different components of the immune system (e.g. T cells, Dendritic Cells, monocytes and macrophages, B lymphocytes and their expressed antibodies, basophils, mast cells, cytokines, chemokines, secreted mediators of immune responses) respond to tumour antigen and inflammatory stimuli. We aim to examine ways of modulating these responses with the view of “alerting” the immune system informing novel immune therapy design. We will strive to dissect the molecular mechanisms underlying tumour growth and metastatic potential. In vivo models described herein, used in combination with in vitro, ex vivo assays and tissue and tumour organoid models, will contribute to the design and translational potential of therapeutic and biomarker approaches.

Monoclonal antibodies targeting a limited group of tumour-associated antigens and checkpoint targets provide clear survival benefits in several cancers. There is an urgent need to build and improve upon the well-documented efficacy of Rituximab, Trastuzumab, or antibody-drug conjugates (ADCs) such as Trastuzumab-DM1 (T-DM1) to benefit patients who can only receive palliative care. We are working towards developing novel antibodies for aggressive and incurable malignant diseases. An antibody generated by our team is undergoing a first-in-man clinical trial. Studies in this project licence will inform research on this and other antibodies of this class and may be pivotal in expediting and informing their path from the lab bench to the patient bedside. Research models described here are crucial to downstream evaluations for our most promising novel candidates and are required to help gain regulatory approval. If successful, our approaches are set to lead to improvements in the efficacy of a wide range of therapeutic strategies, including antibodies already in clinical use in conventional non-optimised forms.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project isfinished)?

We dissect the immunological and molecular mechanisms underlying tumour growth and immune surveillance and test these findings in vitro, ex vivo and in selected in vivo assays to evaluate their physiological significance. Our translational research teams focus on the discovery and evaluation of cancer therapeutics such as antibody and biological modalities, immune cell treatments and vaccination strategies. We also dissect the mechanisms of action of these interventions using a variety of in vitro assays and in vivo models. These studies have directly resulted in the progress of some of these strategies into pre-clinical development and clinical trials in patients. We are keen to continue and improve on our discovery and efficacy studies for cancer therapeutics. We anticipate that the findings, complemented with refined in vivo studies, will guide the discovery of more effective interventions. If our strategies prove efficacious, our research will have a significant impact on cancer care and directly lead to more effective treatments.

How will you maximise the outputs of your work?

We will strive to disseminate relevant research results to the general public in an appropriate form. REDACTED is active in public engagement initiatives and has a track record of public engagement and outreach activities through and interviews addressed to lay audiences including patient support groups, and public engagement events. She is also a member of the South East London Consumer Research

Panel for Cancer. Public engagement through these and similar formats will be pursued. Where appropriate, we will also promote new findings from this project to the wider community and lay public by communication and education such as by issuing press releases in conjunction with the REDACTED press office, which will ensure dissemination through the institutional website and in the local and national press. Our antibody discovery, cancer immunity and antibody immunotherapy research has already featured in newsletters and press releases.

To ensure that our research will benefit the academic community, any data produced from our research will be presented through oral or poster presentations at international and national conferences. Additionally, we maintain strong collaborative links with international groups working within the fields of antibody engineering, cancer immunology and immunotherapy, sharing ideas, resources and data, all instigated and supported through different consortium initiatives, dedicated meetings, conferences and original and position paper publication projects. Interaction forums include the Antibody Society, the American Association for Cancer Research (AACR), EuroMabNet, the Gordon Conferences and others. These forums will continue to provide important means for dissemination of scientific knowledge to enhance our understanding of cancer immunology and support innovation and translation of new treatments.

Species and numbers of animals expected to be used

- Mice: 5600
- Rats: 2700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, animals will receive a tumour challenge followed by treatments which may include human immune cells and therapeutic interventions. Tumour growth is monitored very closely, and animals are humanely killed at the end of the experiment or when the tumours reach a certain size. Monitoring and sampling to understand the effects of treatments is conducted during the study and at the end of the study. The most invasive procedures are those of skin tumour and normal skin transplantation and tumour transplantation in the mammary fat pad, conducted under anaesthesia. The protocols used involve least pain, suffering or distress or lasting harm for the animals.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We will establish and study rodent models of cancer and assess the effects of various treatments on helping or preventing tumours from growing. The protocols used involve least pain, suffering or distress

or lasting harm for the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

None of the intended procedures reach beyond the moderate level of severity. Procedures reaching moderate severity arise from the induction of the disease model (cancer) and are necessary to evaluate the effects of potential therapies.

What will happen to the animals at the end of the study?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We wish to study the pathways that lead to the development of cancer and by using this knowledge to develop novel immunological, molecular and biological approaches to cancer treatment, and to evaluate these as diagnostic and therapeutic tools in appropriate disease models. The in vivo studies are essential to facilitate functional and efficacy assessments for the treatment of patients with cancer. A major aspect of our research incorporates at an early stage and throughout the lifecycle of this programme, the use of in vitro screening, selection, characterisation, functional, mechanistic and efficacy assays, which serves to significantly replace, reduce and refine all proposed in vivo experimental systems.

Overall, the majority of our investigations are conducted using patient samples and human volunteer-derived cells, ex vivo and in vitro, and supplemented by genomic/transcriptomic and immunohistochemical evaluations of human specimens. When absolutely necessary to conduct experiments in vivo, we have chosen rodents as the experimental animal of choice as they have the lowest neurophysiological sensitivity while still having an immune system of comparable complexity to humans.

What was your strategy for searching for non-animal alternatives?

Our successful work conducted at REDACTED London has led to the establishment and validation of numerous assays and model systems which replace and reduce in vivo studies and are designed to elucidate the mechanisms by which therapeutics including antibodies exert their anti-tumour effects against cancer cells. Examples of some of our validated in vitro models and assays are:

• Cell culture-based studies using patient specimens

• In vitro tumour equivalent organotypic/organoid culture models

• Cancer cell viability and functional assays to evaluate the impact of potential therapies on cancer cell functions

• Assays to evaluate the ability of antibodies to activate immune cells to kill cancer cells

• Microscopy assays to study cell functions and cell-cell interactions

Why were they not suitable?

The starting point and the majority of our investigations on cancer pathogenesis, immune responses and therapeutics discovery and functions are conducted using patient samples, human-derived cells, ex vivo and in vitro culture and mechanistic assays. We utilise cell culture and cultured organ models as much as possible to develop and evaluate our therapeutic strategies. However, characterisation in live animals prior to clinical translation is essential and often a requirement by regulatory agencies to ensure that medicines are safe and efficacious. The hypotheses generated can only be further examined using in vivo models. Routinely, we precede in vivo studies by thorough in vitro culture system assessments. Data obtained from these will help select the most promising therapeutic candidates for in vivo experiments, thus minimising and refining these. Together, in vitro and in vivo studies will help to build a clearer picture of pathogenesis, spread and immune surveillance in cancer and help evaluate key molecular and biological modalities and cell-based interventions for further development and clinical testing. Some in vivo experiments may be conducted in parallel with cell analyses in order to maximise derived information.

We wish to conduct a reduced and refined set of animal studies for the following reasons:

1) Due to ethical limitations of investigations in humans we depend on the use of rodents to perform significant and scientifically valid research and pre-clinical testing of therapeutics.

2) There is no adequate in vitro model to assess the value of targeting key pathways in tissue cancers. The complexity of the mechanisms involved in carcinogenesis, (e.g. interactions of cancer cells with immune system components, molecular, biological, immune and immune cell components, cells, soluble factors and interactions between several cell types in particular microenvironments) cannot be faithfully reproduced in vitro, necessitating in vivo experiments.

3) Due to the biological complexity of our studies, animals must be used when measuring the effects of treatments and the consequences on remodelling and repair processes which result from changes in all the cell types within the body. The latter are in turn modulated by circulating agents such as cytokines, as well as circulating cells. These processes cannot, therefore, be modelled only in cell culture or in human organoid and organotypic culture systems.

4) Since molecular, chemotherapeutic and biological therapeutics (e.g. antibodies) may be sequestered in different parts of the body, it is necessary to study their effects, tissue sequestering, biodistribution, presence and retention in tumours, in various organs and excretory pathways, to assess likely function, efficacy, toxicity and dosimetry in advance of translation to clinical testing in patients.

5) Although animals must be used in this project, this research will not only lead to the design of more effective biological treatments for tissue cancers, but in the future, some of our methods such as those for generating antibodies from human tissues has the potential to eliminate the need to use further animals to generate antibodies for the treatment of many diseases, including cancer.

6) For any targeted therapies to progress to clinical development, major insights into their pre-clinical efficacy for cancer therapy can only be derived from the use of relevant animal models of local and metastatic cancers.

Therefore, while we endeavour to utilise cell culture and cultured organ models as much as possible in evaluating therapeutics, their characterisation in live animals prior to translation to the clinic is essential and often a requirement by regulatory agencies responsible for ensuring that medicines work and are acceptably safe and efficacious. Therefore, in vivo studies are a necessary step in translational research pathways, to afford a prediction of therapeutic potential before clinical trials in patients for whom limited therapeutic options are available.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimations are based on our previous experience with experimental design and on assessments by power calculations on the numbers of animals necessary to maximise the outputs of our studies, and to attain the statistical data needed. These are conducted before starting the experiments and are based on our existing work.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To ensure we use the minimum number of animals, great care is taken towards experimental design and assessment of statistical data needed before experiments. Only where necessary, pilot studies can determine optimal doses and conditions for subsequent functional and efficacy assessments. This reduces the number of animals we use. We have extensive experience with generation of relevant data sets using the minimal number of animals. Experimental data sets are usually repeated 3 times assessed for normal distribution, mean and standard deviation generated. Statistical significance of differences in data points is assessed by obtaining a p value (< 0.05 for statistical significance) using tests for independent samples such as the unpaired student's T test or the Wilcoxon-Mann-Whitney U Test for non-parametric evaluations. Our work has been discussed/designed with statisticians from the research design team at our institution and peer reviewed by funders. The statistical methods of data analysis have been published in numerous peer reviewed journals.

What other measures apart from good experimental design will you use to minimise numbers?

In our research, to develop and evaluate our therapeutic strategies we routinely utilise human samples, cell culture and cultured organ models as much as possible. This ensures that any subsequent in vivo study design is guided and optimised through these preceding data. However, the hypotheses generated with human samples and cell-based studies can only be further interrogated with experiments using in vivo models; these are deemed essential for evaluations prior to clinical translation and often a requirement by regulatory agencies to ensure that medicines are safe and efficacious.

To optimise the number of animals used, pilot studies in smaller sample groups (e.g. 3-4 animals per condition) will be implemented to determine optimal doses and conditions for subsequent functional and efficacy assessments to ascertain that data are reproducible and enable humane endpoints to be identified. The data derived from pilot studies will feed into group numbers used for definitive studies such as therapy experiments within appropriate experimental timeframes and statistically significant endpoints. These can optimise the number of animals we use overall and minimise the chance of side effects. To maximise the information from each study, samples and tissues extracted are most often used freshly (e.g. for flow cytometric analyses); less frequently, samples are also snap frozen or embedded in paraffin for downstream evaluations and these are routinely shared across users, thus maximising the information derived from each animal and experiment.

In preparation for in vivo studies, we aim to also maximise breeding efficiency by careful planning and by keeping the numbers of pairs to the minimum required through crosses and monitoring of all breeders. With these, we ensure that breeding setups are carefully maintained until the required animal cohorts are generated prior to experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Rodents have been chosen as experimental animals as they have the lowest neurophysiological sensitivity while still having an immune system of comparable complexity to the human and are therefore the most frequently used animals in studies of human pathology/immunopathology. For example, in the context of antibody (IgE/IgG) therapies, rats have immune systems with similar IgE antibody Fc receptor distribution/expression on immune effector cells that closely mirrors that of humans; they are therefore the most clinically-relevant animals in studies of antibody function, safety and efficacy.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Solid tumours such as melanoma, ovarian and breast cancers normally manifest in adults. Therefore, adult rodents have been chosen as experimental animals. Rodents have been selected as they have the lowest neurophysiological sensitivity while still having an immune system of comparable complexity to the human and are therefore the most frequently used animals in studies of human pathology/immunopathology.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The protocols used involve least pain, suffering or distress or lasting harm for the animals. None of the intended procedures reach beyond the moderate level of severity. Procedures reaching moderate severity arise from the induction of the disease model (cancer) and are thus inherent to the disease studied. The limits of tumour sizes and endpoints for tumour growth are in adherence with recommendations published by Workman et al., 2010. There are no major invasive procedures except those of skin tumour, normal skin and breast tumour transplantation. These procedures involve well-established surgical techniques. Anaesthesia and analgesia will be administered to minimise discomfort and the animals will be monitored closely during all procedures and assessed regularly for any signs of distress. In all the proposed in vivo models, if animals display signs of distress, advice will be sought from the Named Veterinary Surgeon and, if distress cannot be alleviated, the animals will be humanely euthanized.

When it is necessary to conduct in vivo studies, our protocols involve established techniques involving the minimum of suffering. Anaesthesia and analgesia are administered to minimise discomfort and the animals are monitored closely during all procedures and assessed regularly for any signs of distress. In our in vivo models, if animals display signs of distress, advice is sought from REDACTED staff, NACWOs or the NVS and, if distress cannot be alleviated, the animals are humanely euthanised. To ensure we use the minimum number of animals in our experiments, we place great care is placed on the experimental design and assessment of the statistical data needed before starting the experiments. We routinely conduct pilot studies in order to determine optimal doses and conditions for our subsequent assessments.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The limits of tumour sizes, limits of interventions and endpoints for tumour growth are all in adherence with recommendations published by Workman et al., 2010. The ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines which were developed as part of an NC3Rs (https://www.nc3rs.org.uk/the-3rs) initiative to improve the design, analysis and reporting of research using animals – maximising information published and minimising unnecessary studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The REDACTED NC3Rs Regional Programme Manager is a point of contact with regards to developments in the 3Rs. These may include Experimental Design Workshops run at REDACTED. The Experimental Design Assistant (EDA) is a free resource from NC3Rs helps to design robust experiments more likely to yield reliable and reproducible results. Additionally, researchers under this licence will be kept up to date through the NC3Rs website (https://www.nc3rs.org.uk/the-3rs).

Explain the choice ofspecies and the related life stages

Rodents have been chosen as experimental animals as they have the lowest neurophysiological sensitivity while still having an immune system of comparable complexity to the human and are therefore the most frequently used animals in studies of human pathology/immunopathology.

NON-TECHNICAL SUMMARY

200. Targeting Biotherapeutics to Arthritic Tissue

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our study's goal is to impact on the burden of musculoskeletal illness. We aim to develop improved treatment modality for arthritic conditions. We developed antibodies that specifically bind arthritic damage cartilage. We intend to use these antibodies to facilitate very early diagnosis of cartilage damage in the joints as well as to develop treatment that is designed so that drugs are specifically accumulated in the diseased joints to increase efficacy and reduce side effects.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Musculoskeletal conditions are typically characterised by pain and limitations in mobility. The most common and disabling musculoskeletal conditions are osteoarthritis and rheumatoid arthritis.

Rheumatoid arthritis characterised by long-term inflammation in the joints that leads to cartilage and bone destruction and, eventually, pain and deformation. Approximately 68% of rheumatoid arthritis patients in the UK are physically inactive creating a vicious cycle of disease progression and increased pain, thus affecting both physical and mental health. The sooner one starts treatment for rheumatoid arthritis, the more effective it's likely to be. Even though innovations in treatment strategies and monitoring are helping the patients, the high cost of drugs and limited health care budgets are restricting the treatment. Nevertheless, apart from adverse side effect of infections many patients still have partial response to treatment and 40% patients do not response to treatment. Therefore there is a need to develop new treatments that will be more effective and with less side effects.

Osteoarthritis is a disease of high incidence and prevalence worldwide and is the most frequent cause of disability worldwide. 10% of the world's population aged 60 years, or older, have significant clinical problems such as pain and reduced function that is attributed to osteoarthritis. In fact, pain is making a third of people with OA give up work or reduce hours. The only current treatment is joint replacement that is able to relieve pain.

Our study aims to develop a therapeutic that will minimise the unwanted side effect of treatments, facilitate the development of combined treatment and provide very early diagnosis for a better outcome. We will used models on mono arthritis to validate the potential therapeutic translation of our development, thus we can validate targeting to diseased arthritic tissue and compared to healthy tissue in the animal. The outputs of our study will be able to identify new therapeutic modalities for both

rheumatoid arthritis and osteoarthritis in one hand and on the other hand early diagnostic tools that are lacking.

What outputs do you think you will see at the end of this project?

Our study's goal is to develop targeted treatments that will ultimately impact on the burden of musculoskeletal illness. Our study aim to develop therapeutic that will target treatment specifically to the effected joint and minimize systemic exposure to drugs. We expect this approach to minimize the unwanted side effect of treatments, facilitate the development of combined treatment and provide very early diagnosis for better outcome. The outputs of our study will lead to publications, patents and possible licencing by big pharma. Our research will lead to identification of new tool for targeting therapeutic modalities for both rheumatoid arthritis and osteoarthritis in one hand and on the other hand early diagnostic tools that are lacking.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

a. Targeting drugs specifically to arthritic joint results in acceleration of resolution of the inflammation that is triggering the disease. Patients with rheumatoid arthritis will benefit from new drugs that will increase efficacy and reduce side effects associated with existing treatments. While several new drugs provide good results in treatment of 60-70% of rheumatoid arthritis patients, still 30-40% of patients do not benefit from these drugs. There are also safety issues due to the high risk of developing infections as a side effect of these treatments. There is therefore an unmet need to develop new strategies to improve the efficacy and the safety of these agents. The ability to direct treatment only to the effected joints will address at least some of these unmet needs

b. Our research provide early detection of joint disease, by detecting early onset of disease and before damaged of the cartilage can be detected by the classical methods such as MRI and x ray. Our study may possibly improve efficacy as early treatment before any cartilage damage, especially if treatment can be localised only in the effected joints by our developed antibody platform. This research is also relevant to animal health. For instance, horses and some breeds of dogs suffer from disabling cartilage loss and arthritis. Therefore early diagnosis and repair is also eagerly sought after, particularly for horses.

How will you maximise the outputs of your work?

The aim is to maximize output publications in scientific journals, patents, worldwide presentations (I am regularly invited to antibody meeting, and is in the scientific advisory board in the biggest antibody meetings), engagement with pharmaceuticals with the aim to enter a clinical trials for new diagnostic and treatment modalities for arthritic conditions. REDACTED

Species and numbers of animals expected to be used

- Mice: 4000
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice model of inflammatory arthritis:

To mimic arthritis inflammation will be induce in a single knee. The contralateral knee will remain healthy as control.

Most animals are expected to develop arthritis: joint erythema and swelling in the inflamed joint. Pain is anticipated due to injection and is anticipated to increase as disease progresses

At any point after induction of knee inflammation, mice will be imaged (MRI /X-ray..). This will be carried out to monitor the disease progression using minimally invasive imaging.

At any point after induction of knee inflammation, mice will be injected with therapeutic compound(s). Mice will be monitored for efficacy of treatments by measuring the degree of knee swelling and in some cases by imaging.

These compounds may interfere with the induction of arthritis, or to the end of arthritis. Appropriate vehicle controls could also be administered in cohorts of animals. If a compound has not been previously tested a safety pilot experiment will be run.

Compounds will include:

Pharmacological compounds that are made of protein drugs the so call biologics or biologics that are loaded on scaffolds or cells.

At chosen time before and after the treatment, blood samples may be collected from mice from the tail vein. Alternatively blood samples will be collected after animal were cult. Animals will not return to the cage until certain that the bleeding hasstopped.

The arthritis is typically self-limiting and its duration is usually about 7 days but varies depending on the genetic background and variability from experiment to experiment.

Mice model of osteoarthritis:

Incision will be made in the joint ligament in one knee. The contralateral knee will be operated but without knee resection or joint damage. Operation will be performed under anasthesia. All procedures will be carried out under anaesthesia and with analgesia for pain management.

The development of the disease will be followed by minimal invasive imaging animals by MRI/PET/CT/X-ray to quantify the extent of cartilage damage and localization of the antibody we developed. Imaging would be performed under anaesthesia with maximal frequency of twice a day, only at day one after injection/operation animal may undergo a maximum of 20 imaging times (GA-generally ~10min sessions max).

At any point of time in the procedure, the animals may have compounds administered. These compounds may interfere with the induction of arthritis, or to the end of arthritis. Appropriate vehicle controls could also be administered in cohorts of animals. If a compound has not been previously tested a safety pilot experiment will be run.

Compounds will include:

pharmacological compounds that are made of protein drugs the so call biologics or biologics that are loaded on scaffolds or cells.

At chosen time before and after the treatment, blood samples may be collected from mice from the tail vein. Alternatively blood samples will be collected after animal were cult. Animals will not return to the cage until certain that the bleeding hasstopped.

Duration of OA model will be up to 8 weeks.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most animals are expected to develop one knee swelling due to the induced inflammation or mild destabilization of the joint ligaments.. In both cases pain is anticipated but animals will be monitored to ensure no progression beyond moderate impairment.

The use of anaesthetics carries an associated risk due to inappropriate depth of anaesthesia (<1% incidence), however, it is expected that animals will recover uneventfully from anaesthesia.

Discomfort or infection due to injection: Animals will experience stress due to restraint and transient discomfort from needle insertion. Redness/swelling of injection sites will indicate inflammation/infection. The injection may generate a local allergic reaction, but such events will be carefully monitored and if the injection causes the animals distress (e.g. scratching lasting more than 4 hours) the animal will be humanely killed.

Some animals may developed ulcer at the site of injection

Injection into the joint or ligament cut may lead to painful joints, sore feet, lameness, disability and distress.

Animals are expected to recover uneventfully from anaesthesia and surgery. Animals are expected to resume normal mobility and started to eat and drink by the end of the working day of surgery. Frequent care and welfare monitoring will be in place to ensure appropriate pain management, and if necessary –implementation of humane endpoints.

No adverse effects are expected following the administration of drugs, many of which e.g. are already used in the clinic.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For the inflammatory model, most animals are expected to develop inflamed joint associated with swelling of the injected joint. The severity is mild to moderate depending on the developed knee inflammation. The severity of ligament disruption models in a single joint can go from hardly noticeable to moderate. Cartilage degradation is expected, with major cartilage degradation apparent at 4 weeks post-surgery. We will terminate the experiment 8 weeks after operation in order to be able to monitor sequential pathology while maintaining maximal moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In order to demonstrate an effect on the immune reaction that occurs in the human arthritic joint, this needs modelling. This requires integrative systems that comprise the fully functioning immune and inflammatory components within the joint space. In addition to this, the joint needs to be damaged by these processes in order for the antibodies to bind and target the therapeutic. This complex combination of events can only be demonstrated in autoimmune/inflammatory models of arthritis, the therapeutics being chosen to affect auto-immune and/or inflammatory cascades.

What was your strategy for searching for non-animal alternatives?

Before performing any animal studies we will perform studies using human cartilage from hip replacement spares to make sure that the antibody and antibody-drug conjugate bind and penetrate the arthritic cartilage. We might employ organ culture for further tests as well.

Why were they not suitable?

Human post operation cartilage explants experiments can demonstrate specific binding but are not able to demonstrate specific accumulation of drugs that are injected systemically as well as not suitable to check drug efficacy of disease progression. Arthritic diseases are complex and involve interactions between cells leading to the disease manifestations that cannot be assembled in the test tube. Only animal models can reflect some of the complex pathology in human disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Most of our experiments will be performed in mice models of arthritis. This will include models of rheumatoid arthritis and models of osteoarthritis. Based on our previous studies, we have estimated around 40 mice for each experiment: usually we use 6 animals per treatment group to observe significant difference between treated and non-treated control group. We usually reach to 30 animal per experiments: 6 mice treated with antibody fused to compound 1; 6 mice treated with antibody fused to treatment 2; 6 mice treated with non relevant antibody fragment fused to compound 1; 6 mice treated with antibody fragment fused to treatment 1 and 2; 6 non treated control group. Rat will be used only for the osteoarthritis model to confirm results obtain in the mice and thus the expected number is small.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To spare animal numbers, we will primarily use models where we induce the disease in one joint and use the contralateral joint as a healthy joint control. Hence, to save further animals use, most of our experiments will be carried out using one model of rheumatoid arthritis-namely induce inflammation in one joint. For osteoarthritis we will also use mostly a single model of osteoarthritis. A second model for bot diseases will be used for small group of animals to confirm the translatable nature of the results at the end point.

We will develop an imaging approach where we use our developed antibodies to longitudinally follow disease progression and response to treatment. This will save a large number of animals, as the same animal will be used for several time points and will improve reproducibility and reduce numbers. This is in contrast to current studies where animals are killed at each time point for disease/response validation.

In addition, to avoid excessive use of animals we will perform power calculations to ensure that we use the minimum number of animals needed to obtain statistically significant results. This will avoid excessive use of animals, whilst retaining statistical power. We will use a significance level of 5% and a power of 80% group sizes which are typically 6 animals per group. We will ensure randomisation of animals to different treatment groups and analyse outcome blindly as recommended in the ARRIVE

guidelines. Experiment designing, calculations and analysis of data will be performed in consultation with statisticians.

What other measures apart from good experimental design will you use to minimise numbers?

We have already a wealth of pilot data from our current experiments that will assists us in optimising the animal usage. We also plan to use human explant tissue to minimize the use of animal tissue for histology experiments. In our institute we have other groups that are working on these models and we can share some of the tissues from mice for additional histology study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The arthritis model that will be used in this study is the least severe model and the majority of our experiment will be done in this model. Once we see potent treatment efficacy of one of our candidate we will test it in a second model in a small group of animals which is also moderate. In both models, inflammation is only in one knee of mice. Similarly for the osteoarthritis studies most of our experiments will be performed using a single model which is a mild model of osteoarthritis which will follow by a second model in only small number of rat to confirm efficacy in a second model of osteoarthritis.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Joint diseases are complex and involve a great number of interactions between cells leading to the disease manifestations that cannot be assembled in the test tube or terminally anesthetized mice. We therefore use live animals to look at how disease progress in the whole organism, and how they may be corrected to stop the progression of the disease. No similar joints to humans are present in less sentient species.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be monitored regularly for signs of adverse effects including unexpected inflammation/infection, body weight, along with a body condition score will be monitored to ensure food intake is maintained. Behaviour and overall condition indicative of health status (activity,

responsiveness, condition of coat, posture) will be assessed. Injection sites will be monitored for signs of redness, swelling and infection.

Imaging of diseased-induced knee will also be another indicator for degree of cartilage erosion which will allows us better predictability of disease progression and better management of clinical signs and thus animal suffering.

To minimize distress in arthritic mice we will follow the measures that include the provision of soft sawdust litter to reduce pain on walking, the use of non-tangling nesting material or long nozzles on drinking bottles.

To minimise stress animals will be carefully restrained and procedures will be conducted by trained and competent individuals.

A soft diet will be provided if there are concerns over the animal's ability to feed.

Inflammation at injection sites will be treated as advised with appropriate local analgesic and/or anti-inflammatory agents.

To minimize the risk of infection, animals of the cleanest health status should be used and held within barrier protection at all times. Analgesia will be used as advised by the NVS.

Animals will be monitored daily. Animals displaying diarrhoea will be supported via administration of fluids and/or an enriched diet for the first 48 hours to give them the opportunity to recover. After these treatments animals will be assessed to confirm they are fit to undergo further procedures.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

To minimize distress in arthritic mice we will follow the measures outlined in the publication “Applying refinement to the use of mice and rats in rheumatoid arthritis research” by Hawkins et al 2015.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Yes, keep updated by reading papers and attend expert conferences

Explain the choice ofspecies and the related life stages

Our project aims at understanding the causes underlying the development of long lasting (chronic) arthritic diseases. In vivo studies, using animal ‘models’ of arthritis , are currently part of the research and development process for new or improved therapies and treatments. The rodent models we are using are very relevant to our study to test new treatment modalities as well as to validate the potential of our newly developed antibody to detect the onset of the disease at a very early stage and to monitor it longitudinally.

We are primarily, but not exclusively focusing in our research on Rheumatoid arthritis (RA- arthritis associated to inflammation of joints) and Osteoarthritis (OA-generally more associated with physical overuse or direct damage in the joint cartilage). We have been researching how each of these conditions occurs and finding new methods for treating them.

We plan to investigate and develop new drugs capable of switch off inflammation and cartilage damage thus to achieve long-term cure.

NON-TECHNICAL SUMMARY

201. Targeting Relapse Initiating Mechanisms in Adult Acute Lymphoblastic Leukaemia

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall goals of this project are to understand more about the pathogenesis of acute lymphoblastic leukaemia (ALL) in adults, in particular to deliver major insights into relapse associated mechanisms (self-renewal, dormancy and increased survival) and to use this knowledge to develop novel therapeutics for ALL.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Adult ALL is an aggressive haematological malignancy and treatment consists of intensive induction chemotherapy followed by cycles of highly toxic drugs given in intensive inpatient cycles for 1-2 years. Despite the robust approach to treatment, long-term survival is achieved in only approximately 50% of adults. After relapse, few (<7%) survive. **An improved understanding of relapse-initiating mechanisms together with novel treatment approaches are therefore urgently needed.**

What outputs do you think you will see at the end of this project?

This project will produce new understanding of leukaemia initiating cell biology which will in turn lead to new treatment strategies that can be developed further in clinical trials. The outputs of the project will be published in the scientific literature and disseminated at scientific conferences.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

It is intended that the ultimate beneficiaries of the outputs from this project will be patients with ALL through clinical trial implementation however the timescales for such an achievement will be medium/long. However, my role as a clinical academic and active clinical trialist in the field of adult ALL would lend optimal positioning to facilitate full clinical translation. A rather more short/medium term output from the project will be to generate new knowledge and innovation in a previously unexplored area, with potential for cross-disciplinary feeds since concepts conceived under this project may have wider implications for the field of leukaemia biology or indeed solid cancer and normal haematopoiesis.

How will you maximise the outputs of your work?

We follow the principals of research data sharing. Our data will be disseminated though conferences/workshops and publications in open-access journals. After publication, data will be deposited in an open access digital repository. Published materials/reagents/mice will be available upon request to allow for collaboration and dissemination of new knowledge.

We operate within both clinical and scientific professional local, regional and national networks. For example, REDACTED, National Cancer clinical subgroups and other similar forums. This allows for further collaborative working, sharing and efficient dissemination of results.

Raw data of potential use to others will be shared in public repositories, such as NCBI Gene Expression Omnibus, and experiential methods will be shared in detail.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be housed in protective conditions, usually in groups of 5, with sufficient space to ensure best husbandry practice. Once they are acclimatised to our animal unit they will be injected with tumour cells and then monitored for both their welfare and also the development of the model of leukaemia. In some cases mice will be given a low dose of radiotherapy or chemotherapy prior to injecting the tumour cells to prevent rejection.

Mice selected for testing of new drugs will be given pre-specified courses of treatment and during this time their welfare will continually be monitored as well as the effects of the treatment on the burden of leukaemia. If mice at any stage are seen to suffer they will be killed in a humane manner; to achieve this we have a strict, objective scoring system to assess mouse welfare with a prespecified cut-off to prompt such action. We also pioneer a more sensitive method of measuring tumour burden in the mice and this allows for early start and endpoints to our experiments. At the end of the experiment the mice are killed and this allows us to collect the material used to analyse the experiment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals will suffer only minor impacts from procedures such as handling, ear marking and blood taking. The impacts from other procedures such as preparatory radiotherapy/chemotherapy tumour injections, treatment regimes and bone marrow sampling are more significant and may include pain, weight loss, dehydration and lethargy.

However, through experimental design, driven by our experience with these models, the mice usually tolerate the procedures very well. We also have a comprehensive system of work including with supportive care throughout the experimental procedures to minimise the harmful effects to animals so

that they are very rarely, if ever, distressed. Of specific note is that we try to use tumour samples that do not require the mice to undergo preparatory radiotherapy or chemotherapy but where this is necessary we use very low doses which minimise adverse effects.

We have very strict protocols for responding to mice who appear to be suffering to allow for swift interventions to prevent unnecessary levels of suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Our animals are expected to have moderate severities during our experiences.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Murine models are a key part of this work for two reasons:

First, the work concerns identification of leukaemia initiating (stem) cells and with current technology it is not possible to properly culture them in glass - these type of cells quickly die and/or lose their potential when they are plated out in dishes.

Next, the self-renewal hallmark of leukaemia stem cells can only be confirmed through serial transplantation in murine models.
That is, the leukaemia stem cells can only be identified properly by their ability to regenerate leukaemia, and this does not happen when they are kept in glass as opposed to in animal models.

What was your strategy for searching for non-animal alternatives?

A combined cell culture system that mimics some of the effects of the bone marrow environment on leukaemia cells has been developed and is utilised for initial experiments in which initial theories are tested before using mouse models.

Why were they not suitable?

The models described above are only suitable for some of the work; they are unable to recapitulate the biology of leukaemia initiating cells because of limited proliferation and survival of primary ALL cells outside of a living body. To be able to study the biology of these cells in close enough detail to be able to find mechanisms by which they can be treated we must use mouse models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our animal number estimation comes from careful planning of our experiments based on our own experience as well as that from other researchers. We ensure we use the minimum amount of animals to generate meaningful data which can then inform the basis for translation of our results to benefit humans with ALL.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Our experience and that of others has allowed us to design experiments in which the number of mice used is minimised and in which the duration and severity of the experiments are reduced as much as possible. Where relevant in the project design we have performed power analysis to determine the minimum number of animals required to robustly determine our defined experimental endpoint. We also incorporate "future proofing" measures into our experiments, e.g. by preserving DNA from the animals, so that it can be processed again without having to use more animals.

What other measures apart from good experimental design will you use to minimise numbers?

In vitro studies where feasible allow for minimisation of animals required for in vivo experiments.

Using engraftment pilot studies we avoid exposing a full cohort of mice to a leukaemia graft which is destined to not work and therefore give no usable outputs.

The experience of animal handling and interventions held by my research team is invaluable for the purpose of reduction. We have an exemplary record on mice welfare meaning that no mice our wasted, evidenced by our record of 0 found dead over the last year.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

During this project we will use immunodeficient mouse models.

I have extensive experience working with these animals to investigated the biology of ALL. During this time I have refined the steps involved in this type of research continually.

A refinement which I am leading on is the use of intratibial bone marrow sampling which allows for greater sensitivity in tumour assessment and this therefore allows for advanced detection of scientific endpoints prior to any clinical deterioration of the mice, when compared to more traditional blood sampling which we find to be less sensitive and less robust. The technique is performed with a very short general anaesthetic which allows for the minimum of suffering and a very rapid return to normal post-procedure.

These mouse models are the accepted standard for this type of research and are used across ALL research groups worldwide. We share methods via the scientific literature to ensure we are working with equal or improved welfare standards to our colleagues elsewhere.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice and humans share many biological similarities which makes it possible to human leukaemia in mouse models. It is possible to study certain "highly conserved" biological mechanisms in less sentient animals, such as fish, flies or worms, but this does not extend to studying human leukaemia initiating cell biology. This means that data we gather from mice are applicable to humans and can potentially be quickly translated into human medicine; something which is would not be possible from models generated in less sentient animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We use the least invasive method of tumour seeding possible in the least immunodeficient strain to allow the most efficient engraftment. For primary human tumour cell engraftment, our previous work has shown that intra bone marrow injection into NSG mice produces the most efficient tumour engraftment although intravenous methods may have a specific role in certain experimental contexts and for certain ALL subsets alternative routes, such as subcutaneous, may be required. Mice are anaesthetised during the procedure which proceeds quickly (<5 minutes) with minimal effect on the mouse.

All procedures performed by members of the team are done with strict supervision and after competence assessment by our NACWO/NTCO.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We observe both the PREPARE and ARRIVE guidelines for planning and reporting our work.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Professional development activities, organised locally throughout our REDACTED and collaborating institutions, such as the recent *REDACTED*.

We work closely with our NACWO and NVS team and all members of the team will periodically go to events and training organised by NC3Rs. We are continually looking to refine our models and reduce the amount of mice we use and so would quickly incorporate any new processes that are relevant to our research.

Explain the choice ofspecies and the related life stages

We will use adult immunodeficient mice in our experiments, since a mouse with an immune system would quickly reject transplant cancer cells. Immunodeficient mice that allow the tumours to develop are the only option available for successfully creating models of ALL that allow us to further understand how these tumours grow and relapse. Likewise it also enables us to test new therapies targeted at these mechanisms. Previous mouse types for generating human leukaemia models were prone to developing mouse lymphoma but we are avoiding this by using a newer breed.

Where possible we are performing experiments in glass dishes or using computational models to avoid using more mice than necessary but for a detailed understanding of ALL growth and relapse the mouse del is required

NON-TECHNICAL SUMMARY

202. Targeting RNA metabolism to expand normal blood stem cells and eradicate cancer stem cells in acute myeloid leukaemia

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, adult, neonate, juvenile, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to identify regulators of normal blood functions and provide mechanisms through which stem cells undergo leukaemic transformation and become leukaemic stem cells (LSCs). This research will allow us to therapeutically target LSCs/cancer stem cells while enhancing normal blood cell functions.

A retrospective assessment of these aims will be due by 04 August 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake thiswork?

Lifelong blood production critically depends on blood stem cells, also called haematopoietic stem cells (HSCs), which possess the unique ability to generate all types of blood cells. Due to these properties, stem cell transplantation, in which blood stem cells are sourced from adult donors or cord blood, offers optimal treatment for many diseases, including severe autoimmunity disorders, immunodeficiencies, bone marrow failure syndromes and blood cancers. Given the shortage of suitable donors and low numbers of stem cells from cord blood tissue, **it is essential to efficiently expand blood stem cells in a dish for widespread clinical applications.**

Acute myeloid leukaemia (AML) is a blood cancer in which stem cells acquire mutations and form treatment-resistant leukaemic stem cells (LSCs), which initiate and propagate the disease. Since current therapies often fail to eliminate LSCs, the surviving LSCs cause severe disease relapses. **It is therefore essential to identify efficient means of LSC elimination.**

What outputs do you think you will see at the end of this project?

This project aims to investigate the effect of inhibiting specific proteins involved in a process known as RNA metabolism on normal and leukaemic stem cells. RNA acts as a messenger, relaying instructions from DNA to help coordinate the production of proteins. This process is crucial as proteins are responsible for nearly every task in the cell. RNA metabolism, where proteins regulate the synthesis and degradation of RNA, is therefore fundamental for the function of cells. We hope to establish the therapeutic potential of inhibiting specific proteins involved in RNA metabolism in order to expand blood stem cells and target LSCs in different subtypes of AML.

Given the shortage of blood stem cells donors, we aim to identify drugs which will efficiently expand blood stem cells in a dish for multiple clinical applications, such as stem cell transplantation. Importantly, these drugs will also be used to eliminate LSCs in different blood cancers, providing an essential new therapy for AML patients. Bearing in mind that LSCs share similarities with other cancer stem cells, we will work with our collaborators to explore the broader applications of our findings in other cancers. At the end of this project we expect to publish multiple high-impact papers in the stem cell, cancer and leukaemia biology fields.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Understanding leukaemic/cancer stem cell biology is incredibly important as it has broad ramifications for several fields including oncology, haematology, and drug discovery. Eradication of leukaemic/cancer stem cells is essential to develop effective new treatments in blood and other cancers. Furthermore, due to the shortage of blood stem cells from donors, the expansion of blood stem cells for multiple clinical applications including transplantation remains an important research goal. Our research is therefore of an immense strategic importance and addresses key areas of unmet clinical needs.

The key beneficiaries are:

AML patients: We aim to achieve efficient eradication of AML leukaemic stem cells thus providing curative treatments for patients. Patient benefit will depend on the efficient translation of our work to the clinic. We have strong links with the pharmaceutical industry, as well as clinical haematologists around the UK and will work closely with them to achieve this as rapidly as possible.

Patients with other blood malignancies: Once we provide a proof of concept in AML treatments, we will test whether similar therapies can be applied to other blood malignancies (e.g. chronic myeloid leukaemia, myeloma, lymphomas).

Cancer patients: In the longer term, we will collaborate with our colleagues focusing on different cancers to test whether our treatment strategies can be employed in other cancers, creating new treatment options.

Patients requiring stem cell transplantation: Achieving blood stem cell expansion in a dish will be a breakthrough for patients who require a stem cell transplantation. This includes patients with many disorders including severe autoimmunity disorders, immunodeficiencies or bone marrow failure syndromes.

How will you maximise the outputs of your work?

We will strictly adhere and support our funders' policy for research data sharing and management. Our data will be presented during multiple conferences/workshops and published in open-access high quality journals. After publication, data will be deposited in an open access digital repository. Published materials/reagents/mice will be available upon request to allow for collaboration and dissemination of new knowledge. Together, our data will be safely stored to ensure their longevity and that they can easily be shared, uploaded or reanalysed by everyone.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most of our mice will be used for breeding to generate cells, tissues and organs lacking genes of interest. The mice will be humanely culled to obtain this research material, typically at the age of 8-12 weeks. We will also breed our recipient mice which will undergo bone marrow or stem cell transplantation. In this procedure, recipient mice undergo an irradiation procedure to remove their bone marrow cells, and are then injected with new stem cells or bone marrow cells. These recipient mice will be kept for 16 weeks after transplantation. In some occasions, we will cull these mice, collect the bone marrow and re-transplant the cells into other recipient mice, which will be also kept for 16 weeks. This experiment, known as a secondary transplant, is required to test the self-renewal capacity of blood stem cells, i.e. their ability to continually generate all types of blood cells. Some of our transplanted mice may develop blood cancers. All mice will be very carefully monitored and those showing unexpected side

effects will be culled. However, a very small percentage of sudden deaths may happen (despite an intensive program of care and welfare). All mice will be humanely killed at the end of each experiment.

In some cases, we will need to withdraw small quantities of blood from both non-transplanted and transplanted mice by inserting a fine needle into a vein. This causes short-lasting discomfort, similarly to patients who give a blood samples for testing.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The expected impacts and adverse effects for animals in this project vary depending on their use. In the majority of cases, breeding involves no adverse effects, pain or suffering. In some rare cases we may have to breed healthy mice that are susceptible to leukaemia. These mice will be carefully monitored on a daily basis, so their suffering will be minimised.

In transplantation experiments, after irradiation, animals may experience weakness, modest weight loss and some abnormal behaviour, such as withdrawal from the group. Animals may also experience some pain, and may be given pain killers by veterinary staff. These adverse effects, caused by the irradiation itself, normally last for several days and then the animals fully recover. During this period (5-14 days after irradiation), mice will be scored every day according to the scoring system we have developed and refined. This system gives us an objective way of assessing animal health, and also allows us to clearly identify and apply a humane killing point at the earliest opportunity, both to achieve our scientific goals and to minimise suffering.

Some of our transplanted mice may develop blood cancers. Mice will be very carefully monitored and evaluated, and any animals showing the earliest clinical side effects will be culled. However, due to the nature of the disease, a very small percentage of sudden deaths may happen.
All mice will be humanely killed at the end of each experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

A large number of our mice will be used for breeding, where we expect to see no adverse effects. When breeding mice susceptible to leukaemia (which covers approximately 4,000 of our mice for the period of 5 years), approximately 10-20% of mice will experience adverse effects such as weakness, modest weight loss and some abnormal behaviour, such as withdrawal from the group.

We plan to use approximately 5000 mice to investigate the functions of normal and leukaemic stem cells following gene deletion. Some mice in these experiments will develop leukaemia, but due to close monitoring, the vast majority of mice will be culled before they develop significant adverse effects. We estimate that 10-25% of mice may experience adverse effects as a result of leukaemic disease.

Approximately 10000 mice will be used for transplantation assays to study functions of normal and leukaemic stem cells. Of these experiments, approximately 50% will be injected with leukaemic cells, and we expect 20-80% of those to suffer adverse effects. Deaths related to leukaemia will be less than 5% of all mice in these experiments.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 04 August 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In some instances, the use of animals is currently unavoidable as many facets of stem cell and leukaemia biology can only able to be studied in animals, such as mice, where these cells and diseases naturally occur. For example, the current knowledge does not allow us to properly culture blood stem cells in a dish – once plated into a dish they die and lose their potential. Current culture conditions also do not allow us to test many key properties of leukaemic cells, including their ability to cause leukaemic disease. Therefore, at the moment, many important experiments need to be conducted in mice. Additionally, given that our ultimate plan is to take our research into clinical trials, where new treatments are tested in human patients, appropriate validation of the therapeutic targets we investigate has to first be done in mouse models.

What was your strategy for searching for non-animal alternatives?

Where possible, we strive to use non-animal alternatives in our research. We often use stem cells from human cord blood tissue instead of mice. We also use human bone marrow-derived cell lines in dish-

based tissue culture experiments to obtain information about human leukaemic disease and to test the role of genes of interest in AML, and we will continue to do so.

Notably, we are very active in developing techniques that would improve our ability to study aspects of leukaemia in a dish. In a recent publication, we have developed machine learning algorithms and a high-throughput tissue culture-based screen for drugs against leukaemia, involving the testing of various drugs against leukaemic cells in a dish.

Transplantations of blood stem cells or leukaemic stem cells into recipient mice are essential experiments for the study of stem cell and leukaemia biology. However, these experiments require large numbers of mice, both mouse donors, from which blood cells are derived, and mouse recipients, into which blood cells are injected. Whenever possible, we replace mouse transplantation with dish-based tissue culture experiments, so called long-term culture-initiating cell or colony-forming cell assays which require very few animals.

Moreover, to study genetic pathways in stem cells, whenever possible, we perform predictions using computational software instead of using animals. We have a dedicated bioinformatician (specialist computer scientist) in our group whose role is to study sequencing data from leukaemia patients to obtain maximal information about the biology of the disease. While these are strong predictions, our findings need to be validated in animals before we can move our research into clinical trials with human patients.

Why were they not suitable?

Blood stem cells and leukaemia stem cells reside in bone marrow niches, very specialised pockets within the bone marrow which provide stem cells with a specific microenvironment composed of multiple biological factors that support their functions. Culture conditions in the dish fail to reproduce this complex microenvironment. Indeed, when exposed to culture, stem cells lose their activity and adopt characteristics of non-stem cell types, making them unusable for research. As such, non-animal alternatives are sometimes unsuitable and we must use animals to accurately study stem cell and leukaemia biology in a whole animal context.

A retrospective assessment of replacement will be due by 04 August 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of mice are carefully planned based on our long-term experience and consultations with our expert collaborators. An experienced statistician in our group performed careful estimations to ensure that the number of animals used in our experiments is the minimum number required to generate statistically significant results (i.e. statistically convincing results). Designing animal experiments to produce statistically significant results means that we can generate more powerful data. This data can then be translated into clinical applications, such as curative AML therapies, as quickly as possible.

We plan to breed and generate 20,000 mice for this project for the period of 5 years. 5,000 of these mice will be used for cell-based tissue culture assays. 5,000 will be used to study stem cells functions, and 10,000 will be employed to examine stem cell functions upon transplantation. In all experiments we will use mice of both sexes to avoid having to cull a surplus of mice of a particular sex.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

As key means of achieving reduction we have and will continue to carefully design our experiments and mindfully estimate the number of animals required in order for the results of our experiments to be statistically convincing. To minimise the number of animals used in each experiment, we will use power calculations, calculations that allow us to gauge how statistically convincing a given result is. For example, in preliminary studies where we are trying to determine the most effective number of cells, or drug dosage to use, no more than 3 animals per group will be used when possible. Experiments will be carefully planned to maximise the information obtained per animal and thus limit the subsequent use of additional animals. Experiments requiring cells from animals will be carefully optimised in order to minimise the number of animal cells required.

What other measures apart from good experimental design will you use to minimise numbers?

An important means of achieving reduction is to apply the most efficient breeding strategies. My group has extensive expertise with mouse colony management (i.e. monitoring large cohorts of mice) and we will strive to employ the best breeding schemes. We will replace breeders before their reproductive performance declines, and non-productive breeders will also be replaced.

My group is fully aware of the ARRIVE guidelines and experimental design tools provided from NC3Rs. As such, we employ the optimal experimental designs to implement the 3Rs and optimise the number of mice for each experiment.

Importantly, experiments will be carefully planned to maximise the information obtained per animal and thus limit the subsequent use of additional animals. For example, haematopoietic organs, i.e. organs involved in the blood system, including bone marrow, lymph node and spleen cells will be stored and used for multiple experimental purposes. All experiments requiring cells from animals will be carefully optimised in order to minimise the number of animal cells required.

A retrospective assessment of reduction will be due by 04 August 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In the majority of our experiments we will study mice lacking genes of interest specifically within the blood system. These 8-12-week old mice will be analysed to study the haematopoietic organs (bone marrow, spleens, thymi and lymph nodes), which can also be used for tissue culture or transplantation experiments. In some cases, we will age these mice for 60 weeks to study the role of genes of interest in the ageing of the blood system. These experiments do not involve any invasive procedures and therefore any pain, suffering or distress will be minimal.

Given that the major goal of our work is to study leukaemia, in some cases we will need to inject leukaemic cells into recipient mice. Following this, these mice will develop leukaemia. In 50% of cases they will be analysed before they develop clinical symptoms of leukaemia. In another 50% of cases, when the progression of leukaemia is of scientific interest, mice will be monitored and culled at a point such that our scientific research is achieved, but pain, suffering and distress is minimised.

All these models are the current state-of-the-art and the gold standard in cancer and stem cell research. If/when other improved models become available, we will immediately implement them in our research. We are very active in trying to refine our procedures. For instance, at the moment bone marrow imaging techniques are not developed sufficiently. However, we are working with key experts in the field to try to optimise these approaches to be able to non-invasively image cells in the bone marrow and monitor stem cells without having to sample blood or bone marrow from mice.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Given that our aim is to target human cancer stem cells in leukaemia or expand adult stem cells, we will need to employ mice for these purposes. Mice and humans share the same genes of interest and the cellular processes involved in stem cell biology and leukaemia are very similar. As such, mice are ideally suited for our work as they allow us to gain insight into human stem cells and leukaemia biology without having to work on human patients. Furthermore, all the reagents necessary for our research are mostly developed for the mouse and human systems. Other less sentient animal models (e.g. flies, fish or worms) are excellent model systems to study some conserved biochemical pathways, but do not replicate complex human or mouse blood stem cell and leukaemia biology. In fact, there are no models of leukaemia in these species. However, we do collaborate with several experts around the world to obtain maximum relevant information from less sentient animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To ensure technical competence, all staff will be directly supervised by the project license holder. To minimise infections of mice with impaired immune systems, the animals will be housed in barrier caging under sterile conditions and handled in a sterile environment. Whenever appropriate, in order to prevent pain, pain killers will be given as directed by veterinary staff. Genetically modified animals exhibiting any unexpected pain or suffering will be humanely culled. For protocols involving bone marrow transplantation and leukaemia experiments, we have developed and successfully used a stringent scoring system which allows immediate identification of mice displaying adverse effects. This system gives us an objective way of assessing animal health, and also allows us to clearly identify and apply a humane killing point at the earliest opportunity, both to achieve our scientific goals and to minimise suffering.

Over the last 10 years we have optimised and refined many procedures. For instance, as mentioned above, we have optimised a clinical scoring sheet allowing us to rapidly identify any animals which are likely to develop clinical symptoms of leukaemia or post-irradiation sickness, and cull them humanely before they start suffering. Importantly, to further refine transplantation procedures using human AML cells or cord blood stem cells, we are in the process of optimising transplantation procedures using mice lacking aspects of their immune system, so-called immunodeficient mice.

Notably, our current transplantation experimental protocol requires that the recipient animals undergo an irradiation procedure. Without irradiation, the immune system of the recipient mice would reject all donor cells, rendering the experiment ineffective. Irradiation procedures allow us to preform successful transplantation experiments, generating important data. However, irradiation can have unwanted health effects on animals, which is why we are seeking to replace irradiated recipients with immunodeficient mice in our transplantation experiments. Due to their impaired immune system, immunodeficient mice

will already not reject donor cells, and so do not require irradiation. Optimising transplantation experiments using immunodeficient mice will reduce pain and suffering, and so will be a major refinement to our procedures.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Our experimental designs are based on our long-term experience in this field (we have already refined many protocols and experimental designs) and peer-reviewed high-quality literature. We always seek to apply the most refined methods which are published in the field. We also base our knowledge on ample literature disseminated by NC3R and interactions with many expert colleagues and collaborators. We will always continue to refine our protocols based on the literature and knowledge exchanged with skilled collaborators and we are very proactive in this area.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Many advances in cancer research, including advances in mouse cancer models, are disseminated during scientific conferences and seminars, which we frequently attend. Further, members of my group frequently attend 3Rs events organised by NC3R, and we continue to update our knowledge through the literature NC3R disseminates. We also have an extensive network of local and international collaborators who use similar state-of-the-art models, and by frequent exchange of information we will always stay informed about the best advances in the field. Given that our group is extremely committed to the implementation of the 3Rs, we will utilise any useful knowledge learned during these events and the literature to improve mouse procedures, apply petri dish-based models where possible, improve statistical methods, and minimise pain and suffering of our experimental mice.

Explain the choice ofspecies and the related life stages

Many dish-based or computational-based experiments are unsuitable to study human blood stem cells or cancer stem cells in leukaemia. As such, we need to employ mice to recapitulate these complex biological processes. Our lab uses mice for research because mice and humans share the same genes of interest as well as the cellular processes involved in stem cell biology and leukaemia.

In general, we will use 2 types of mice.

Firstly, in the majority of our experiments we will study genetically altered mice - mice lacking genes of interest specifically within the blood system. In our preliminary experiments, we found that removal of these genes results in the expansion of normal stem cells and elimination of cancer stem cells. To further explore these results, and prepare our data for publication and translation into clinical trials, we plan to examine the impact of removing these genes from mice. Typically, 8-12 week-old mice will be culled to obtain haematopoietic organs, which will be used for analyses, dish-based tissue culture or transplantation experiments. In some cases, we will age these mice for 60 weeks to study the role of genes of interest in the ageing of the blood system.

Secondly, we will use non genetically altered mice as recipients of bone marrow or stem cell transplantation. Transplantation of blood cells into recipient mice is the gold standard way to analyse the activity of normal stem cells or leukaemic/cancer stem cells. These experiments allow us to study how normal stem cells regenerate blood or how leukaemic/cancer stem cells generate leukaemia.

A retrospective assessment of refinement will be due by 04 August 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

203. Targeting the molecular mechanisms of neurodegeneration

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo, aged
Rats	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our work in this project licence aims to first understand the molecular mechanisms of neurodegenerative diseases, such as Parkinson's disease, Alzheimer's disease and motor neuron disease, and then to develop and test new treatments in rodent models of disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Degenerative disorders of the brain, such as Alzheimer's and Parkinson's, resulting in deficits in cognition and movement, are becoming more common as the population gets older, as age is the greatest risk factor. The national census in 2011 revealed that there are more people over 60 than under 16 in the UK for the first time. The UK Government has responded to this through the Prime Minister's Dementia Challenge and the UK Dementias Platform. Neurodegeneration is not only a disease of ageing western societies, but a world-wide problem: there predicted to be more people in China with dementia by 2040 than the rest of the developed world put together. There are currently 850,000 people with dementia in the UK, with numbers set to rise to over 1 million by 2025 and soar to 2 million by 2051. Currently another 140,000 suffer from Parkinson's disease, a number which will also rise with our ageing population. Work such as ours, starting in cellular models and moving to rodent models, is essential to develop and test new treatments.

What outputs do you think you will see at the end of this project?

Outputs from our work will include a new understanding of the mechanisms of neurodegeneration, new publications in leading scientific journals, and ultimately the development of new neuroprotective therapies.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Those in the scientific research community working on better understanding the mechanisms of neurodegeneration will be the first to benefit as new tools, models and exprimental approaches are published in the short-term. We have published rodent models for Parkinson's (alpha-synuclein transgenic mice and LRRK2 transgenic rats), Alzheimer's (MAPT transgenic mice) and motor neuron disease (TDP-43 transgenic mice). All the rodent models we have generated and characterised are made available for all to access, for example our alpha-synuclein transgenic mouse models are made

available through the REDACTED and have been taken up by several laboratories in academia and the pharma industry worldwide.

Longer-term beneficaries will be the patients, carers and families of those with neurodegeneration who will benefit from improved neuroprotective therapies. In neurodegenerative diseases specific neuronal populations die which we aim to preserve. We are working on distinct approaches to develop novel therapies to preserve either dopamine neurons (lost in Parkinson's), cortical neurons (lost in Alzheimer's), motor neurons (lost in motor neuron disease) or sensory neurons (lost in Friedreich's ataxia). We work in close partnership with a number of industrial partners from pharma to discover and develop new therapies. Such partnerships will be powerful in ultimately bringing new treatments to the clinic. Treatment of several diseases in the clinic is made more difficult because the clinical symptoms of each disease only become apparent when the underlying neuronal changes are well underway. We liaise closely with colleagues working in the clinic who are developing methods for detecting pre-symptomatic phases of disease in patients using genetic markers of susceptibility, biomarkers and brain imaging. Once those prodromal phase individuals can be identified they will be targeted as most likely to benefit from future neuroprotective therapies. Prodromal disease includes mild cognitive impairment (MCI) as a prodrome for Alzheimer's and REM sleep behaviour disorder (RBD) for Parkinson's.

How will you maximise the outputs of your work?

Several different approaches will be used to maximise output of this work. In the first instance, we will disseminate new work through presentations of posters and talks at national and international conferences and then publish our work in academic journals. We aim to publish all our work, including those generating negative results. We also present our work to lay audiences through travelling to local interest groups, holding events and Open Days or though online resources, such as podcasts. We establish national and international collaborations which may form the basis of future funding opportunities. Finally, we engage with industry which can be a means of further developing or funding translational work.

Species and numbers of animals expected to be used

- Mice: 34000
- Rats: 14000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be bred as part of the project and checked shortly after birth for the presence of a human gene which causes disease. Some animals will be then taken forward for experimental work and some

will kept as breeding stock to generate new experimental animals. As we study diseases of the ageing brain, we often keep experimental animals to "old age", about 2-3 years in rat or mouse years. The studies we do are of two types. In some cases we age the animals over time to study behaviour or brain imaging before taking brain tissue to understand how a brain with a disease functions, or dysfunctions, differently from a healthy brain. We may inject substances, such as a disease protein, to see how how that affects disease progression. In the second type of study we perform we treat the animals with new drugs to try to correct the deficits we have seen, for example by using a drug to remove the disease protein or protect the cells from dying.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Because we study diseases of the ageing brain, a proportion of the animals (about 1/3) will be allowed to grow old and develop symptoms reminiscent of a neurodegenerative disease of old-age, such as motor deficits and memory loss. Animals may also be treated with compounds to model the disease. Animals will experience the usual signs of ageing and some may develop difficulties with memory, gait balance and posture. Once we have identified disease-relevant changes in our mice and rats we will then test new therapeutics delivered orally, or injected into the body, or injected directly into the brain using surgery, to attempt to cure the disease. Animals will be very closely monitored following the onset of any symptoms and the disease will only be allowed to progress to a limited degree. All animals will be humanely killed at the end of the experiment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Overall, we expect 60% of the animals (rats and mice) used in this project to experience a Mild severity and 40% to experience a Moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Diseases like Parkinson’s disease and Alzheimer’s disease affect how the whole brain functions and dysfunctions as the diseases develop. In order to be able to, first, understand how the mechanisms which drive the diseases to develop in the brain, and then to be able to test potential new therapies, we need to work with animals which show signs of the disease. We have chosen to work with mice and rats because of the shared similarity of the brains of rats and mice, as mammals, to humans, incuding

the way brain cells are wired together into circuits, the way in which the brain is protected by a “blood brain barrier” and the way the immune systems changes as disease develops. We use genetically altered mice which develop early stage forms of the disease as this is the stage of disease we wish to study, and ultimately treat.

Although the use of less sentient animals (such as flies, fish or worms) can be informative in biology there are a number of advantages of using rodent models to study progressive neurodegenerative diseases. The most common risk factor by far for developing a neurodegenerative disease is age and therefore it is essential to use a model in which the development of the disease pathology can be studied over a prolonged period, ideally years. A second important consideration is the presence of important disease genes in the animal we work with. For example, we know that the gene for alpha-synuclein, a key pathological protein in Parkinson’s, is not present in invertebrates, such as flies and worms. Finally, there is a very high degree of similarity between rodent and human genes and a conservation of structure, function and connectivity in the mammalian brain shared between rodents and humans. Overall, this makes rodents the best animals to model diseases of the brain in to understand the mechanisms and seek cures.

What was your strategy for searching for non-animal alternatives?

The animal work we do runs in parallel with other complementary approaches in our laboratory. First, we study diseases using neuronal cells cultured in dishes which is useful for generating preliminary data on disease processes. In particular, we work with patient-derived stem cells which can be used to generate different neurons of interest, such as dopaminergic, cortical and motor neurons. This cutting-edge stem-cell technology represents a powerful platform both to investigate mechanisms of disease and screen for novel molecular therapies which impact on cellular disease processes and may have therapeutic value. Second, we study human post-mortem brain tissue donated by patients who have died from neurodegenerative disease. This more traditional approach remains very useful as it gives information on the real brains of patients who died with diseases such as Alzheimer's or Parkinson's.

Why were they not suitable?

Both the work in human stem cell-derived neurons and patient post-mortem tissue are very useful but have certain limitations. The work in cultured cells tells you how neurons may die but not how the brain as a "wired circuit" will respond to disease. Human patient post-mortem brain material is very valuable to study, but it does only represent the end-stage of the neurodegeneration, and provides limited information on the mechanism of disease progression over time. The human brain is an inaccessible and highly complex organ which makes it almost impossible to obtain patient "brain samples" during life. We therefore need to use animals in our project but only after we have obtained as much information as possible from those experiments which do not require animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices

that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use animals for a range of experiments to study the clinical and pathological signs as the diseases develop. Previous experience and statistical power calculations allow us to define the number of animals we need in each experiment to observe alterations in behaviour, or to detect biochemical or pathological changes. Approximately 10-20 animals per strain are allowed to grow into old age for each experiment and to develop symptoms, which in rat and mouse terms is about 2-3 years old. We will test behaviour, co-ordination and memory of the ageing rodents, perform imaging studies, and finally, analyse the brain in detail when they die. By performing many tests on each animal, we will minimise the numbers of animals we need to use.

We use mice which have been genetically altered to develop an early stage of disease, such as Parkinson's or Alzheimer's. We breed ourselves all the mice which we need and most of the mice we use are required for breeding only and will not be allowed to age, or to develop any disease symptoms or used for testing therapies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We take extensive statistical advice from experienced researchers in the field, combined with our own previous experience of working for over 15 years in the field, and statistical power calculations to define the number of animals we need in each experiment to observe alterations in behaviour, or to detect biochemical or pathological changes. Approximately 10-20 animals per strain are allowed to grow into old age for each experiment and to develop symptoms, which in rat and mouse terms is about 2-3 years old.

We are able to take multiple samples from one brain to be able to reduce numbers. For example, the brain has two halves which are essentially identical. So, for example, we are able to treat each half of the brain differently and collect different information and samples, allowing to collect more information and samples per animal.

What other measures apart from good experimental design will you use to minimise numbers?

We monitor very actively the breeding strategies we use which are all optimised for animal use. All breeding animals are followed individually and all schemes are recorded on a computer to follow animals pedigrees. Optimising the breeding numbers is important to ensure neither too few, or too many animals, are generated. Tissues are collected from animals and shared across project to make best use of all material. Pilot studies may be used to estimate the effect size of a drug treatment, or to confirm a drug is not toxic, before full-scale test are performed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In our work we use mice and rats genetically altered to carry genes which, in humans, lead to developing a genetic form of diseases of the ageing brain, such as Alzheimer's or Parkinson's. We study the effect of disease genes on the brain of rats and mice to understand how the disease develops in human, and then test new ways of how to treat it. Mice and rats carrying disease genes are aged to mimic age-related diseases and monitored carefully over time. Our work aims to study and treat the very earliest forms of disease which also causes the least pain, suffering distress or lasting harm to the animals we use.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

As mammals like us, mice and rats conserve many of the brain structures found in humans affected by disease which we need to study and represent the simplest mammal we can work with. Other animals sometimes used in research, such as flies and worms do not have the same brain structure nor do they carry the same disease genes found in humans. We do use embryos or new-born pups to provide tissue to generate neurons to grow in the laboratory which provides a useful additonal means to study the disease and also to test new drugs.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We have extensively refined the methods that we use to generate rodent models of neurodegenerative disease. Modern accurate genetic techniques act as a refinement and allow us to manipulate genes in ats and mice and express human disease genes in the right part of the brain at the right time to lead to disease processes and symptoms highly reminiscent of the human disease being studied. We focus on studying the early stages of disease because that is the key therapeutic window which we would want to treat patients in the clinic. As a results, we study and treat animals with generally only a mild form of disease. Animals are handled and trained carefully for behavioural tests to ensure the best most reliable and reproducible data are obtained. Animals are very closely monitored following the onset of any symptoms and the disease will only be allowed to progress to a limited degree.

hat published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow advances as publicised on the NC3R website which provides information on the most refined techniques, such as new guidelines on non-aversive methods of picking up mice, single-use of

needles and blood sampling. We will adhere to updated ARRIVE guidelines on reporting work with animals as now required by many journals.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will follow advances as publicised on the NC3R website which provides information on the most refined techniques, such as new guidelines on non-aversive methods of picking up mice, single-use of needles and blood sampling. We will adhere to updated ARRIVE guidelines on reporting work with animals as now required by many journals.

Explain the choice ofspecies and the related life stages

We will study strains of rats and mice carrying forms of human genes involved in neurodegenerative disease, such as Parkinson's, Alzheimer's and motor neuron disease. We use rats and mice as they have a similar brain structure to humans and share almost all the same genes. Most of the animals we will use will be young breeding animals used to maintain the strains. As neurodegenerative diseases generally affect old people a proportion of the animals (about 1/3) will therefore be allowed to grow old (which in rat and mouse terms is about 2-3 years old) and develop symptoms reminiscent of a neurodegenerative disease of old-age, such as motor deficits and memory loss.

NON-TECHNICAL SUMMARY

204. Technical developments in imaging for in vivo application and use in cancer detection and therapy.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This license will allow us to continue our developments in imaging technology and to apply these to cancer imaging and therapy. In addition, it will allow us to make these new developments available to the wider imaging community as we will apply them to other disease areas, not just cancer.

Improvements in imaging technology will enhance measurements of disease, promote translation between animals and man, and contribute to the 3Rs in animal research.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Imaging is the method-of-choice for diagnosing, understanding, and monitoring a variety of disease. Since measurements can be non-invasive, the development of disease and the effects of intervention can be assessed using a wide range of anatomic and functional measures in the same subject.

Imaging is a very powerful technique as it:

- enables detailed, fast and accurate visualisation, characterisation, and quantification of biological processes in vivo

- provides time-resolved, repeated measurements in the same subject resulting in improved analysis, increased experimental quality and great reductions in animal numbers.

- can operate non-invasively, enabling measurements that cannot be achieved using more conventional methods such as histology or biopsy where tissues are removed for examination by a pathologist.

- can simultaneously assess changes in both structure and function of organs and tissues, providing a more comprehensive characterisation of the disease.

- can be used to plan and to measure the effects of therapeutic intervention and define windows-of-opportunity for successful treatment.

However, all imaging techniques require skilled interpretation with defined rules of reporting. Through development of new imaging techniques, optimisation of existing imaging techniques and validation against gold standards, we will:

- minimise ambiguity in image interpretation and reduce the possibility of false positive/negative findings

- lower the detection limits of disease

- refine the imaging experience for the animal

Through the combination of imaging with therapeutic techniques, we will be able to deliver more accurate and precise therapies, and monitor disease progression and the response to treatment significantly better than before.

What outputs do you think you will see at the end of this project?

The outputs will include new and better animal handling apparatus, scanning methods and data analysis tools, with dissemination through presentation, publication and distribution of techniques to other groups and imaging centres.

The developments made will include: improved animal handling aparatus that is easier for the operator to use and decreasingly invasive or intrusive to the animal; faster and more sensitive scan modes that reduce the anaesthetic burden upon the animal and relate directly to Objectives 1 and 4. More comprehensive, increasingly clinically relevant and increasingly easily translatable studies that willl advance treatment protocols in the clinic, most probably during the lifetime of this licence, result from Objectives 2, 3 and 4.

Many of the engineering developments resulting from these works will be applicable in a range of disease areas, for us most notably in cardiology and neurolgy as we have ongoing collaborations centred around the use of our developments in other centres' works.

Hardware and softwre developments will be described in the scientific literature and distributed to other groups, in some cases via inclusion in instrument manufacturers' products. Discoveries resulting from he increasingly well characterised disease progression are and will continue to be disseminated via the scientific meetings and literature and by inclusion in our disease-focussed collaborators' works.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The combination of less invasive animal handling apparatus and workflows, coupled with faster and more sensitive imaging techniques will both refine the animal experience and reduce the number of animals required for study. These benefits will be realised with each deployment of a better technique.

Faster and more robust scanning techniques reduce the cost of and training requirement for imaging, thus lowering the barrier to replacing conventional, invasive measurements such as histology. Proof-of-concept studies demonstrating this will be possible and will benefit those currently not practising imaging works in a range of disease areas. These benefits will be realised over the course of this project.

The demonstration of better imaging and collaboration with scanning manufacturers will help deploy some of the imaging developments on an international scale, again reducing the barriers-to-imaging and increasing uptake of this non-invasive technology. These benefits are realised on an ongoing basis as suppliers increase the range of functionality in their systems.

Finally, the availability of the improved measurement performance naturally leads to use of the incorporation of these technologies into imaging and biological research programs. More robust examinations of cancer progression and treatments will result and applications in disease areas unrelated to those we study are expected. These benefits are realised on an ongoing basis.

How will you maximise the outputs of your work?

Output from these works will be measured in terms of publishable output in journals of International repute (both by our group and our collaborators), by integration of our imaging developments into commercial imaging systems and by distribution of our techniques to other imaging groups
.

Apart from publishing in internationally renowned peer-reviewed journals, we will also submit our reports on validation of the technology and scientific and welfare findings to scientific conferences held at national and international levels. Once validated, our new imaging developments, including image-guided therapies, will be handed over to our user groups to enable their research programmes which will further enable distribution our technologies.

Furthermore, we developed an extensive network of users for the imaging technology developed previously and we will continue doing so during this project. To aid dissemination of our knowledge to other groups, we are developing a website for facilitated distribution of the technical (software and hardware) aspects of our new developed imaging techniques. As such, future users can then assemble and deploy our technologies, ensuring sustainability of our technologies as it moves into more routine usage and allowing for dissemination beyond the existing collaborative networks of the team.

Species and numbers of animals expected to be used

- Mice: 2000
- Rats: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

A staged approach will be used to develop new imaging techniques; methods are only tested *in vivo* once it is confirmed that the technique works in non-living systems, and methods using tumour models and/or recovery anaesthesia will only take place once basic *in vivo* demonstration has been achieved.

Basic in vivo demonstration typically consists of:

General anaesthesia using isoflurane in oxygen-enriched air for < 1 hour during which the following techniques will be performed:

- Fluid replacement using subcutaneous injection of saline is used to ensure physiological stability

- Placement (non-surgical) of a tail vein cannula for reliable compound delivery.

- Placement of physiological monitoring apparatus to ensure animal welfare during imaging; a rectal temperature probe, subcutaneously-implanted ECG needles or topical ECG gel electrodes and/or topical respiration monitor will be used to monitor the animals' vital signs.

- Intravenous dosing of contrast agents to improve the sensitivity of the imaging.

- Imaging of anatomical structures or functional activity

- Schedule 1 kill.

Advanced *in vivo* demonstration typically consists of:

A subcutaneous tumour is implanted whilst the mouse is under a brief period of general anaesthesia. Such tumours typically grow from palpable tumours at 1 week post innoculation) to 1000 mm^3 tumours within 3-4 weeks.

Local, fractionated radiotherapy, replicating clinical practise is performed. Multiple low, rather than a single high, doses of radiation are delivered to the tumour on consecutive days, under general anaesthesia once the tumour reaches 100 mm^3.

Imaging is then performed under general anaesthesia for <60 min per session, and repeated 3x/week for 3 weeks. During each anaesthetic session, the following techniques will be performed:

- Fluid replacement using subcutaneous injection of saline is used to to ensure physiological stability and aid recovery times

- Placement (non-surgical) of a tail vein cannula for reliable compound delivery

- Placement of physiological monitoring apparatus to ensure animal welfare during imaging; a rectal temperature probe, subcutaneously-implanted ECG needles or topical ECG gel electrodes, and/or topical respiration monitor will be used to monitor the animals' vital signs.

- Intravenous dosing of contrast agents to improve the sensitivity of the imaging

- Imaging of anatomical structures or functional activity

Additional procedures to be performed under terminal anaesthesia at the end point of the study:

- Intraperitoneal dosing of histological markers for validation against a gold standard

- Cardiac blood sampling for e.g. confirmation of the health status of the animal or for quality control of the contrast agent (e.g. metabolite concentrations)

Schedule 1 kill.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Tumour innoculation will only be performed under general anaesthesia which may induce transient pain at the site of injection, expected to be of short duration (hours).

Most animals will experience effects of gas anaesthetic as they recover. Good temperature control and rehydration protocols, including the availability of ingestable hydrogels post recovery is used to minimise this. Durations of anaesthesia and repeat intervals are set to minimise cumulative effects which, where they occur, would be of short duration (hours to days).

Transient pain may be expected consequent to the use of subcutaneously, intraperitoneally, intramuscularly and intravenously positioned needles for dosing, and for subcutaneously implanted needles for ECG measurement. These are positioned and removed whilst the animal is under general anaesthesia and the effects, where they occur, are likely to be of short duration (hours). Where intramuscular dosing is performed analgesia will be applied, and where any behaviours indicating pain are present analgesic and/or emollient cream will be applied.

Following radio-, photodynamic and ultrasonic therapies transient wounding to the skin may occur. In this case analgesic cream will be applied and emollients may be applied. Where the skin is broken it must repair within 24 hours, where the skin is bruised it must be repairing within 72 hours or the animal will advance to Schedule 1.

Food deprivation, as required for some PET imaging, may induce a transient weight loss, and will last no more than 6 days. Weight loss may also be a result of cumulative exposure to anaesthesia and/or treatment, and is expected to be of short duration (days).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

For both mice and rats we expect:

Non-recovery: 50%

Mild: 20%

Moderate: 30%

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The live animal is required because many of the phenomena and features we need to image only exist in the living body. Some of these, such as tissue volume or constitution, are the target of measurement whilst some of them, such as the involuntary muscle jerks, cardiac and respiratory cycles and peristalsis, are confounds which corrupt the imaging process. We aim to develop imaging techniques that are insensitive to these confounds whilst being maximally sensitive to the measurements required.

Our primary disease focus is cancer. Some aspects of tumour development is currently too complicated a task for computational or cell-culture biology to model at the whole-body level as the development of tumou requires host-tumour interactions that only occur in the intact living body.

What was your strategy for searching for non-animal alternatives?

Basic and prototype developments are performed using computer, mechanical and electronic simulations, with progression to in vivo taking place only after successful demonstration of the development in a direct preplicate of the in vivo experiment.

Why were they not suitable?

As this licence is specifically aimed at technology development that will benefit others who have already committed to in vivo experimentation we need to apply and validate the resulting technology in the live animal before making the said technology available to the community.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have gained extensive experience through the use of our predecessor PPLs and we have used this past experience to estimate our numbers of animals for this project.

Most of our statistical analysis is very straightforward as we tend to be examining a binary question; is the new imaging technique better than an existing technique (*yes* or *no*)? Typically, small sample sizes and numbers of animals (often <20 per development) satisfy this need. Validation may require a further 20 mice and ongoing quality controls over the term of the project double this.

Using this approach we can expect to complete >20 developments for mouse and 1 development for rat over the term of this project.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We will minimise the number of animals required by developing techniques using test objects, computer, mechanical and electronic simulations wherever possible, and only advancing to *in vivo* once techniques are demonstrated to work. Demonstration of techniques (as opposed to, say, evaluation of drug efficacy) usually requires small numbers of animals as the measures of success tend to be binary (does the technique work or not). For more complicated questions, we will liaise with the the Statistics Unit for advice on statistical experiment design and for performing power calculations to obtain meaningful data.

It is well established that repeated *in vivo* imaging allows a significant reduction in the sample size required to achieve a particular level of statistical significance.
The aim of this project is to develop techniques that enable better measurements of disease progression and response to treatment, using imaging techniques. These improvements may offer better imaging data, better imaging data collection efficiency, and/or better animal welfare compliance. All three of these provide opportunities for minimising the number of animals required.

Tools such as the NC3Rs' Experimental Design Assistant will be used wherever possible and we will make every attempt to incorporate the ARRIVE guidelines into the design of our studies.

What other measures apart from good experimental design will you use to minimise numbers?

Methods are only tested *in vivo* once confirmation that the underlying technique works in a preplicate simulation of an in vivo experiment.

Works in tumour models and/or with recovery will only take place once the techniques work in naive animals and where the tumour or recovery is required for the validation.

We will compare our newly-developed methods with existing techniques and quantify the benefits with additional functionality introduced in a stepwise fashion. Developments stop, and methods are made available to the community, as soon as the technique is validated.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mouse and rat and are chosen as these are industry standard for use in preclinical imaging development works. The rat will only be used where the physical size of the animal to be imaged or treated dictates.
All imaging techniques and related measurements will be developed, evaluated and validated in stages so we can control as many variables as possible at the same time to make techniaue developement as effiecient and successful as possible. This approach is also reflected in the use of the different animal models.

During the inititial stages of development, no disease will be introduced and all procedures will be performed under terminal anaesthesia during which the animal remains insentient. Only when the new development works for the normal animal without causing any welfare issues, we will proceed with models of disease and/or with recovery anaesthesia.

Superficial xenografts will be considered for the next stage of the develoment pipeline. They offer us a simple means to introduce the disease variables whilst we still control the growth kinetics and the location of the tumour. Tumours will be generated by injecting tumour cells subcutaneously under a very brief period of general anaesthesia. We may implant cells in up to two sites in order to enable us to use one tumour as the internal control for the other. We typically co-inject the cells with materials to promote tumour growth; for example the basement membrane preparation Matrigel. The tumour remains localised to the site of injection and no metastasis occurs. Therefore the animals do not

generally suffer adverse effects. We employ humane euthanasia before combined tumour volume reaches 250 mm^3 (mammary fat pad) or 900 mm^3 (s.c. xenografts) to avoid any impairment of mobility. Measuring superficial tumours is conducted in conscious animals using callipers or will be image-derived.

It is sometimes needed to use more complex models of disease as differences in tumour heterogeneity, perfusion, microenvironment and host tissue involvement will affect the image presentation and/or measurement. In these cases we need to generate the tumour within the organ of interest; breast, lung or pancreas cancer cells grown in the mammary fat pad, lung or pancreas, respectively. Injection into the mammary fat pad or lungs will typically take place under a brief period of general anaesthesia, in a similar manner to the generation of subcutaneous tumours. As with the subcutaneous models, we may implant cells with biomaterials such as Matrigel to promote growth or to make sure the cells stay in the intended site (percutaneous lung model). Currently, orthotopic pancreas tumours require abdominal surgery, conducted in accordance with the LASA 'Guiding Principles for Preparing for and Undertaking Aseptic Surgery'. Surgeries will be carried out early in the working day to allow sufficient time for assessment of animal recovery prior to the overnight period. Animals will be given pre- and post-operative analgesia, and replacement fluids. The tumour cells will be co-injected into the tail of the pancreas (as opposed to the head) with matrigel in order to limit adverse effects and improve chances of successful tumour growth. The humane endpoints relating to the post-surgery period and the burden of pancreatic tumour growth are fully detailed in the relevant protocols. We will employ humane euthanasia if the pancreatic tumour reaches 900 mm3. There have been some publications in the scientific literature relating to ultrasound guided injection of tumour cells into the pancreas and this is being trialled by other groups in the department. This would represent a significant refinement to the animal. Seen our extensive expertise in imaging technique development, we will further develop this technique as a suitable alternative to abdominal surgery.

A substantial part of our planned work is the development of improved imaging techniques for the early-detection of lung metastasis. A similar staged approach will be followed; the percutaneous model, described above, will be used as the subcutenous xenograft alternative for the lung. Although a carcinogen (urethane) will be used to induce the autochtonous lung model, the doses used are non-toxic and the tumours are slow growing with pre-determined groth kinetics. We will perform imaging to determine the tumour volume and employ humane euthanasia at an overall tumour volume of 200 mm3.

Wherever possible substances will be administered as isotonic aqueous solutions and in the smallest volume that can be accurately/safely administered. We will adhere to the limits on number and frequency of doses set out in the Protocols. Injections may be administered to conscious mice that are competently restrained, or to animals under gaseous anaesthesia. The intravenous cannulation route will be used where possible, in order to reduce the number of interventions the animal is subjected to and to make sure the injection route is clear. Oral administrations will be made to conscious restrained animals where possible, and formulations will be flavoured or sweetened where possible to render them palatable to the animals. In occasional cases we will administer injections directly to the tumour. Drugs will be administered in doses and formulations shown to be non-toxic and well tolerated; either from the experience of colleagues or collaborators or the scientific literature.

Radiation beams, photodynamic treatments and biomedical ultrsonics will be applied to tissues and tumours. This will be conducted under gaseous anaesthesia. Radiation dose to regions other than the target is minimised either by shielding with lead or the use of a focused image-guided micro-irradiator.

From experience we know that a single dose not exceeding 30 Gy or fractionated dosing (up to 5 Gy/day, and not exceeding a total dose of 50 Gy) is well tolerated. For irradiation of orthotopic pancreatic and lung tumours, igRT will be used. PDT treatment consists of a single dose of PDT-drug at non-toxic concentrations prior to a non-thermal illumination light dose. Damage to non-target tissue and surrounding skin is minimised by the use of small diameter laser beams and precise positioning of the laser beam. Biomedical ultrasound therapeutic delivery protocols will only be used when optimised by other research groups. Humane endpoints for any therapeutic delivery are stated in the Protocols and humane euthanasia will be applied when desquamation of the skin, reddened skin, weeping skin or ulcer development occurs over an area larger than 110% of the treated target area.

Anaesthesia is often required for subject immobilisation during imaging developments. Animal physiology will be monitored by core temperature (e.g. subcutaneous or rectal temperature probe), respiration rate (e.g. pneumatic or piezoelectric detector) or ECG (e.g. subcutaneous electrodes). Temperature will be maintained using a thermostatically controlled heating pad. For non-terminal anaesthesia, animals will be monitored until they have fully recovered from general anaesthesia. We are developing alternatives for non-invasive ECG monitoring. The duration and repetition rates of anaesthesia are set to allow measurement of parameters of interest whilst maintaining adequate health and welfare status of the animals.
For extended durations of anaesthesia (>200 minutes), a 72 hour minimum recovery period will be invoked and confirmation (by NACWO) that the animal is sound will be required before repeating anaesthesia.
In a limited number of cases where the aim of this work is to allow examination of the time-dependent processes/alterations in for example vascular function, then highly-repeated anaesthesia will be performed. If so, the repate rates will be limited to 10 times in 20 days with a maximum duration of 90 minutes per session.

We seek to develop minimally invasive techniques that can be applied without introducing significant harm to the animals and without altering the progression of the disease to be studied. The use of image-guided and image-monitored therapy offers the opportunity to maximise on-target delivery of treatment whilst minimising stray tissue damage. This along with the high-resolution and fast imaging that is available to us enables highly efficient deployment of these techniques for use in other research programmes.

The most invasive techniques will be performed under terminal conditions during which the animal will remain insentient. Protocol 4 is restricted to procedures to be performed under terminal anaesthesia to allow translation of our methods to other disease models so the wider scientific community can benefit from our most refined imaging techniques.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mouse and rat are chosen as they are the industry standard for use in preclinical imaging development works and methods will be, as far as is possible, scalable to use in larger species and man. Dedicated small animal imaging systems, that replicate those in clinical practice, have been optimised for use in mice and rats, the species most abundantly used for the study of human disease.

Moreover, the mouse is the most studied animal model in the field of oncology and other disease areas, and therefore there is a wealth of literature available to guide experimental design. This is mainly because the mouse shares similarities to humans that do not exist in lower species, and they develop tumours as a result of mutations in genes known to cause cancer in humans.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We seek to develop minimally invasive techniques that can be applied without inducing significant harm to the animal and without altering the progression of the disease to be studied.

We operate programs of developments in animal handling apparatus, physiological signal monitoring, scan control and system integration methods. This forces a highly structured and standardised approach to in vivo imaging with standardisation aimed at the highest level of performance. As a direct result of this holistic approach animals are physiologically monitored using minimally invasive techniques and imaged with the shortest possible scan times. Minimum necessary anaesthetic durations are, therefore short.

Application of the techniques developed offer scope for significant refinements especially for use under the authority of other biologically-oriented PPLs. MR-image guided radiotherapy (MR-igRT), as previously developed by our group, allows a directly clinically translatable technology to be used with a level of robust performance that is scientifically sound, economical and highly refined. With MR-igRT, abdominal tumours are accurately and precisely treated during short anaesthetic periods that are repeated over several days. This protocol, favoured in the clinic, maximises treatment of the tumour whilst minimising side effects elsewhere, thus providing a major refinement.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Experiments will be based on the Guidelines for the welfare and use of animals in cancer research (Workman P et al. Br J Cancer 2010, 102: 1555-1577).

Recommendations from NC3Rs will be followed where possible; e.g. tunnel handling, single use of needles.

In addition, we will keep up to date with the literature and implement new recommendations as they are published; e.g. FASEB J. 2019 Mar; 33(3): 3097–3111.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are already liaising with the NC3Rs regional officer. NC3Rs news letters (both at local level through the REDACTED and at national level through NC3Rs) will be consulted.

Furthermore, we routinely attend and present at animal welfare conferences and symposia such as IAT, NC3Rs, American Association for Laboratory Animal Science - AALAS.

Explain the choice ofspecies and the related life stages

Adult mouse and rat and are chosen as these are industry standard for use in preclinical imaging development works, and rat will only be used where the physical size of the animal to be imaged or treated dictates.

The mouse is also chosen because of availability of genetically altered mice which often provide the best mechanistic model of various pathological mechanisms.
Well-characterised, genetic alterations to animals will be used where these are essential for the generation of image contrast or where the development of pathology requires this.

Home Office

NON-TECHNICAL SUMMARY

205. Testing of Veterinary Immunologicals

Project duration

5 years 0 months

Project purpose

- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult
Guinea pigs	juvenile, adult
Rabbits	juvenile, adult
Domestic fowl	neonate, juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Quality Control testing of in-process and final product (vaccine) test samples to ensure they meet set specifications and requirements before they are released for sale. These tests ensure the products are safe, have the right quality and are efficacious.

A retrospective assessment of these aims will be due by 06 July 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vaccines protect animals against serious and potentially fatal diseases. The vaccine formulations have been used for several decades and reliably provide excellent protection from disease. Use of these products worldwide is established veterinary practice and enhances the welfare of animals by controlling animal disease or human food poisoning. Laboratory testing is a legal requirement to ensure consistency of the vaccine and ensures that any substandard product is not released for use.

Over 1.93 Billion chickens, sheep, pigs and cattle will be protected from disease by the vaccines tested under this project.

What outputs do you think you will see at the end of this project?

The manufacture and marketing of several different farm-animal vaccines that are consistent, safe and reliable. Use of these vaccines will enhance animal welfare due to reduced disease incidence and contribute to food safety by reducing transmission of Salmonella in eggs.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Vaccines protect animals against serious and potentially fatal diseases. The vaccine formulations have been used for several decades and reliably provide excellent protection from disease. Use of these products worldwide is established veterinary practice and enhances the welfare of animals by controlling animal disease or human food poisoning. Laboratory testing is required to ensure consistency of the vaccine and ensures that any substandard product is not released for use.

It is estimated that over 1.9 billion farmed animals will be protected from disease by the vaccines tested and manufactured under this project, equivalent to protecting greater than 20,000 animals for each animal used in the five-year project

How will you maximise the outputs of your work?

Due to the unique business and confidential nature of this work it is difficult to share experiences apart from collaboration with other company production sites.

Species and numbers of animals expected to be used

- Mice: 74500
- Guinea pigs: 9100
- Rabbits: 8600
- Domestic fowl: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Injections of vaccinal components and final vaccine products with a result being obtained by measuring antibody responses and/or absence of any adverse side-effects.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most animals may experience short-term discomfort following injection. Analgesia will be given if discomfort is expected to be of longer duration

Possible signs of clinical disease. These animals are euthanased at the onset of clinical signs to prevent any suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Domestic fowl: Mild procedure.

Rabbits: Mild procedure.

Guinea Pig:

- 1.2 % Mild procedure.
- All other Guinea Pigs will show moderate to severe clinical signs. These animals will be supported with analgesia and close monitoring. A significant majority are euthanised as soon as the clinical signs are displayed.

Mice: 50% are expected to show moderate to severe clinical signs, however, with close monitoring a significant majority are euthanised as soon as these signs are displayed.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 06 July 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal tests will only be used where it is a legal requirement to ensure the final released products are efficacious and safe. Where legislation permits and there are alternative non-animal tests available they will always be used.

What was your strategy for searching for non-animal alternatives?

Laboratory tests, e.g. ELISAs are used for quantification of many of the in-process and final components of the vaccines produced. Over recent times animal tests have been replaced by laboratory methods (for example cell line assays and Antigen mass assays) and further research is ongoing in these areas.

Why were they not suitable?

Alternatives are suitable and are used for several of the tests but some vaccinal components have proven difficult to identify and their assay using in-vitro models is not currently feasible. We are actively pursuing replacement of the remaining animal tests for the future.

A retrospective assessment of replacement will be due by 06 July 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on what will be required for legal and regulatory testing of the products that are planned to be manufactured and tested over the next five years. These numbers include all stability work that is scheduled.

The estimated number of mice to be used under Protocol 1 is 55000. The testing performed under this protocol includes all work performed on in-process antigen toxoids and toxins (4 different tests are performed on 15 different species of antigen - each test uses upto 10 mice per sample as well as control mice which are typically shared between samples) to determine the overall yield of the sample and ensure that the antigens have fully detoxified before they are used in the blending of final vaccines.

These toxoid antigens have a long shelf life which ensures that all samples produced and tested are utilised and none are discarded.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The numbers of animals involved are primarily dictated by testing regulatory standards but there may be areas where less animals could be used in the future by a process of statistical and scientific analysis of data and this is an avenue that is currently being actively pursued.

What other measures apart from good experimental design will you use to minimise numbers?

The number of animals is prescribed by regulatory requirements and future reduction using in-vivo replacement or statistical and scientific arguments will be investigated.

A retrospective assessment of reduction will be due by 06 July 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Animals are used for some of the testing to ensure that batches of veterinary medicines are efficacious, safe and consistent, as dictated by legal regulatory requirements.

Some tests may cause animals to develop significant clinical symptoms. By regular clinical monitoring performed at critical periods by experienced, trained and competent personnel, any suffering will be minimised by prompt euthanasia.

Where relevant, early recognition of a Humane Endpoint (HEP) is essential to the conduct of this work and any animal approaching a recognised HEP for the specific test will be promptly euthanased.

If a test is predicted to cause some discomfort, suitable analgesia will be given prior to procedures being performed.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Legal regulatory requirements dictate the species used.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Some tests may cause cause animals to develop significant clinical symptoms. By regular clinical monitoring performed at critical periods by experienced, trained and competent personnel, any suffering will be minimised by prompt euthanasia.

Where relevant, early recognition of a Humane Endpoint (HEP) is essential to the conduct of this work and any animal approaching a recognised HEP for the specific test will be promptly euthanased.

If a test is predicted to cause some discomfort, suitable analgesia will be given prior to procedures being performed.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

- The support network, including Named Persons actively disseminate information posted from bodies such as the IAT, Home Office, NC3R's, RSPCA, LASA etc.

- The NVS and his support team are members of the VOLE e-mail network and the NVS is a council member of the Laboratory Animals Veterinary Association (LAVA). The veterinary care team have the ability to consult with an extensive network with close connections with the relevant and experienced colleagues.

- The NACWO and the animal care team actively pursue exploring and applying new initiatives for refinement and the well-being of the animals they care for.

- All staff are keen to attend events where there is opportunity for education and networking to enhance the high standard of care for animals.

- Frequent updates are effectively disseminated within our organisation by the HOLC, and by all present at regular AWERB meetings.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Active involvement and discussion with Animal Technology resources on an ongoing basis.

A continuing active dialogue regarding animal welfare and experimental refinement between the animal care staff, Project Licence holder and Named Persons.

The AWERB is regularly informed and kept up to date with any developments and any concerns are actively discussed.

Explain the choice ofspecies and the related life stages

Small laboratory species are used to evaluate the safety and efficacy of vaccines for farm species.

A retrospective assessment of refinement will be due by 06 July 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

206. The aetiology of diabetic neuropathy

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Diabetes, neuropathy, nerve, regeneration, sensory

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim for this programme of work is understand the mechanisms underlying the key functional changes that take place in the nervous system in diabetes and develop treatment strategies to reverse or prevent these changes

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Diabetes mellitus affects 9% of the population (an estimated 463 million people worldwide) and the incidence is ever increasing. Approximately 50% of people with type 1 or type 2 diabetes will develop some degree of diabetic neuropathy (damage to nerves) which may be accompanied by tingling and burning sensations, heightened sensitivity, or numbness and loss of sensation. This can lead to tissue damage, infection and an increased risk of limb amputation.
Diabetic neuropathy can also affect internal organs, for example causing gut and bladder problems. It is a debilitating condition which impacts on patient's health and quality of life.
There is currently no treatment for diabetic neuropathy, other than managing blood sugar levels or treating symptoms, and this is an urgent unmet clinical need.

From our studies we hope a greater understanding of the mechanisms underlying diabetic neuropathy will enable a realistic prospect of development of novel targeted therapies.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We use rodent (rat/mouse) models of diabetes and have estimated 1500 animals over a 5 year period.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

We use rodent models of Type 1 and Type 2 diabetes to study the development and progression of diabetic neuropathy. With both models, animals will develop raised blood sugar levels, eat and drink more and urinate more frequently than non-diabetic rodents. Animals are regularly checked and their condition monitored. Cages are changed daily, and animals have unlimited access to drinking water and food, which are provided in extra amounts. Animals with Type 1 diabetes do lose weight, so weights and condition are carefully monitored. The severity of diabetes is controlled by implantation of a low-dose insulin delivery pellet under the skin (conducted under anaesthesia and with post-operative analgesia) this ensures that animals develop raised blood glucose (at levels that might be seen in poorly-controlled clinical diabetes) and neuropathy, but prevents morbidity due to the diabetes. Animals with Type 2 diabetes, become obese and may develop skin irritation, again conditions and weights are carefully monitored. We assess sensory, motor and cognitive function over the timecourse of the study using tests that do not cause fear, pain discomfort or any tissue damage, and do not expect any adverse

effects from any tests selected.
Then, at the end of the study, animals are terminally anesthesised to assess nerve conduction speeds and bladder function. Animals are euthanased at the end of the protocol and tissues collected for molecular and biochemical analysis

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

In our laboratory we routinely use cell culture to both complement and help us design our in vivo work. However diabetes is a whole body disease, affecting the hormonal, immune, cardiovascular and nervous systems which all play a role in progression of the disease, and it is impossible to wholly mimic in a culture dish. The complications of diabetes are progressive and take time to develop and are the product of several consequences of poorly controlled diabetes. Hence there is a need for animal models of diabetes. The similarities between diabetes in humans, mice and rats justifies the use of animal models of diabetes to elucidate the mechanisms of the disease process, in characterising the changes in the nervous system and assessing the efficacy of therapeutic agents.

If any relevant non-animal alternatives become available during the course of the project, we will incorporate these in our studies.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Experiments are designed on the basis of previous work and published data and we refer to the ARRIVE guidelines. Full evaluation of previous/pilot data and power calculations are performed, such that the minimum number of animals required to provide valid data are used (typically 14 per group for therapeutic studies).

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The animal of choice for this work is a lower order mammal, typically the rat, although mice may also be used. We typically use the streptozotocin Type I model of diabetes and are familiar with its advantages and limitations as well as the specific requirements for animal welfare. Our results can be integrated with the continuously expanding body of research conducted on these species and model, and contribute to comprehensive understanding of the pathogenesis of diabetic neuropathy.

Numerous strategies are in place to minimize animal suffering, we use appropriate anaesthetics and analgesia for any surgery. Sensory and cognitive testing do not cause tissue damage or pain and animals are handled and acclimitised to minimise any undue stress, and we study innate behaviours.

Home Office

NON-TECHNICAL SUMMARY

207. The benefits of sleep and the cost of wakefulness

Project duration

5 years 0 months

Project purpose

None selected

Key words

Sleep, wakefulness, brain, sensory stimulation, neurodevelopment

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The project aims at improving our knowledge about the functions of sleep. It centres on three interrelated questions: 1) How sleep is regulated? 2) What are the consequences of inadequate sleep? 3) Can we take advantage of the beneficial functions of sleep to improve our health?

1. Sleep is a complex behaviour and is tightly regulated. We have all experienced that undeniable drive to sleep. Staying up much later than usual or rising after only a few hours of sleep and then attempting to stay alert and functional throughout the day, serve as unpleasant reminders of the power of sleep drive. Even when we feel alert and are unaware of our sleep drive, it is always present and growing while we are awake. In fact, the only true way to reduce rather than mask sleep drive is to sleep. What is the sleep drive made of and what are the mechanisms regulating it? These questions will be addressed by quantifying the cellular changes in the brain in conditions with high sleep drive (e.g. after a long period of wake) and low sleep drive (e.g. after a long period of sleep).

2. In modern society, chronic insufficient sleep (defined as gaining less sleep than required) has become epidemic worldwide, in particular among adolescents, and represents a serious health risk. Insufficient sleep is associated with higher risk of developing neuropsychiatric and behavioural disorders, such as anxiety and depression, that are the primary drivers of disability worldwide. This project will help clarify the consequences of sleep loss by measuring the short and long-term responses of brain cells to insufficient sleep. By gaining insight into the underlying biological mechanisms linking chronic insufficient sleep to altered brain function I aim to identify potential therapeutic targets to improve mental health.

Recent research has demonstrated that boosting some cardinal features of sleep (e.g. sleep intensity and efficiency) is possible by delivering sensory stimulation during sleep. Both acoustic and vestibular (i.e. rocking) stimuli have been effective in enhancing sleep. In this project, I will apply this approach to rodents to understand whether some brain functions can be promoted by enhancing sleep. This research will help clarify why sleep is beneficial to our health and whether sleep can be manipulated to enhance the capability of our brain to perform better, particularly in the pathological context of debilitating neuropsychiatric diseases, such as Alzheimer's.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The proposed project will improve our understanding of the mechanisms and functions of sleep. It will shed light on the detrimental consequences of sleep loss on cognition and mental health, in particular during sensitive periods of brain development. Finally, it will clarify the effects of sleep enhancement on brain functioning.

The acquired knowledge will benefit other scientists (e.g. clinical researchers in neurology and clinical sleep scientists) in the short term and clinicians in the medium/long-term, in light of the prevalence of sleep disorders in modern society (20-30% of adults report sleep problems). Finally, a better understanding of the impact of insufficient sleep will help inform society and policy makers of the risks posed by chronic sleep deprivation.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Approximately 2320 mice and 910 rats over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The kind of investigations that are proposed require healthy rodents. Therefore, housing and handling conditions are designed to optimise welfare and any surgical procedures make use of full anaesthesia, health monitoring and analgesic regimens recommended by veterinarians. In the sleep deprivation/restriction experiments, rodents will experience tiredness and desire to sleep. Experiments are designed in such a way that animals will never experience physical exhaustion due to these procedures. Animals may sometimes have controlled access to food to motivate task performance, but they will be given highly palatable and nutritious rewards during behavioural tests that tap into to rodents' natural preferences (e.g. exploring mazes, poking their noses in holes). This range of experiments will cause mild to moderate discomfort. Once experiments are complete, animals will be humanely killed, and brain tissue collected to support further data analyses.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Sleep is a behavioural state and as such it can only

be defined and investigated in animals. The consequences of sleep deprivation involve the entire organism and can only be studied in animals. In order to study sleep as a global phenomenon, there are no alternatives but using a freely behaving animal. Non-animal alternatives such as in vitro or computer models do not replicate the complex neuronal mechanisms that underlie sleep and its manifold disturbances.

Humans cannot be used to study changes at the circuit or cellular level due to the invasive procedures necessary, as well as the inability to collect tissue.

Reduction

Explain how you will assure the use of minimum numbers of animals.

When possible, a within-subject design will be adopted, meaning that the number of individual rats and mice used is kept to the absolute minimum required to allow statistically robust conclusions.

Experiments will be planned carefully to optimise data collection by addressing multiple objectives during a single procedure (for example by performing histological analysis in the same animals used for behavioural/electrophysiological experiments).

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The rodent (rats or mice) has been chosen as the experimental animal because the physiological changes during the 24-hour waking cycle and the response to forced waking induced by sleep deprivation have been extensively studied in this species. However, the transgenic approach needed to visualize or manipulate the activity of individual brain cells is currently available mostly in mice. Therefore, mice will be preferentially used for these experiments. Rats, on the other hand, have more complex behaviour and bigger brains, therefore will be preferred to investigate the effects of sleep loss on behavioural tasks.

NON-TECHNICAL SUMMARY

208. REDACTED

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Using mice as a model, the goal of this project is to investigate if the supplementation of resveratrol or vitamin D can be used as effective nutritional strategies to treat and prevent the decline in skeletal muscle contractile function induced by the consumption of a high fat diet (HFD).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Literature in recent years has established that high calorific diets and more specifically adipose tissue accumulation, will negatively influence contractile function of skeletal muscle. Despite this, there has been very little literature on the reversibility on such negative effects. The limited research which has considered such has reported that dietary intervention alone is insufficient in reversing the decline in muscle function brought about by a high fat diet.

An emerging body of literature has begun to examine the possible anti-obesogenic effects of supplements resveratrol and vitamin D. Whilst both have displayed to reduce adiposity accumulation when given as part of a high fat diet. Current literature has not considered the therapeutic effects of vitamin D and resveratrol supplementation on contractile function when used in conjunction with or following a high fat diet. As such, the current work will uniquely examine if supplementation of vitamin D and resveratrol can be used as a therapeutic strategy to reverse or prevent a decline in muscle function associated with consumption of a high fat diet

As the prevalence of obesity has quickly become a global epidemic, effecting upward of 30% of adults in the United Kingdom, which is ultimately costing the National Health Service an estimated £6.1 billion per year, it is important to begin to establish possible therapeutic methods to mitigate such declines in the contractile function of skeletal muscle. Without such scientific research a negative obesity cycle may continue, whereby poor contractile performance and inhibited muscle function lead to greater inactivity and subsequent weight gain, which exacerbate the declines in contractile performance. Undertaking this work will help progress current scientific knowledge on the therapeutic effects of both resveratrol and vitamin D on the contractile performance of isolated muscle and potential anti-obesogenic effects. Furthermore, this work may be used as a starting point in establishing the direct effects of the chosen supplements before progressing into a human model

What outputs do you think you will see at the end of this project?

We hope to identify possible avenues to treat or prevent a decline in contractile function associated with consumption of a high fat diet with resveratrol and vitamin D. Following completion of the study we hope to submit this work for publication (e.g., the International Journal of Obesity, or similar) and present the findings at conferences (e.g. European Congress on Obesity, or similar). The findings from the study will also be included as part of a Doctor of Philosophy thesis. If, as hypothesised, supplementation of nutritional supplements alleviates detrimental effects of a high fat diet on contractile performance of skeletal muscle, this work will used as part of future grant funding applications to further scientific knowledge on the chosen supplements and development into a human model.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short term the proposed study will be the first step in establishing the direct effect of resveratrol and vitamin D on muscle function, and understanding if the proposed strategies have a direct effect on the intrinsic force producing capacity of skeletal muscle. This work is not only important in developing our scientific understanding of the effects of both resveratrol and vitamin D short term, but it may also be a foundation for longer term future studies to implement nutritional strategies in a human population in order to negate the detrimental effects of obesity on muscle function. Obesity is at epidemic proportions globally, substantially impacting on health, reducing quality of life and is strongly related to mortality. Obesity also has substantial financial implications for health care providers, costing the UK's National Health Service upward of £6.1B per year. Therefore, the current study may help in the development of future therapeutic strategies for weight management, which subsequently helps in reducing obesity related costs to health care providers.

How will you maximise the outputs of your work?

We hope to maximise the outputs from this work by submitting for publication and presenting the work at national and international conferences, irrespective of the success of the nutritional strategy. By submitting for publication we further hope to develop the scientific understanding of the effects of both resveratrol and vitamin D. Furthermore, it may also be a foundation for future studies to implement nutritional strategies in a human population in order to negate the detrimental effects of obesity on muscle function. The study may also lead to future research grant funding, probably with existing or new external collaborators, as we develop a plan to extend this work based on these findings. Alternatively, if there were to be no effects of selected nutritional supplements on the contractile performance, publishing such results will still influence future work as they may consider alternative doses, durations or different nutritional supplementation before progressing into a human population.

To ensure effective and rigorous reporting of our results, we shall write papers according to the ARRIVE guidelines which are recognised as providing excellent transparent standards for reporting of research using animals and were developed by the NC3Rs.

Species and numbers of animals expected to be used

Mice: 840

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice will be fed one of the following altered diets ad libtum for up to 16 weeks;

High fat diet (e.g 60%Kcal fat)

Standard laboratory diet

Resveratrol or vitamin D enriched High fat diet

Resveratrol or vitamin D enriched standard diet

Mice will be schedule 1 culled at the end of the 16 week altered feeding regimen

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The nutritional supplements have no previously reported adverse effects. The use of the supplements is to promote positive effects such as decreased weight and fat gain and mitigate the decline in muscle function normally seen in high fat diets.

Whilst unlikely, if the animal finds their altered diet unpalatable they will be removed from the study. Weight loss/gain will be monitored regularly to ensure each animal is sufficiently nourished.

In the high fat diet groups a difference in body mass of up to 31% has been reported in groups who receive a high fat diet when compared to animals who receive standard lab chow. This work and other literature which has reported a similar increase in body mass in mice have reported no adverse effects for the animals. As such, we aim to evoke a similar change in body mass in a maximum of 16 weeks. However we expect this cut off point to be achieved at an earlier point as previous work has indicated such changes occur between 12 and 16 weeks. Animals will be regularly monitored by trained staff and veterinarians using an AWERB approved score sheet (weekly weight and health monitoring) to establish humane end points for the animals e.g. weight gain is affecting cage density thus effecting the ability of the animals within the cage to ambulate or is causing pain/distress to the animal. In the event an animal is in pain or distress or find the diet unpalatable they will be immediately removed from the study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

approximately 80% animals will experience mild severities as the only changes the animal will experience is a change in diet. The remaining animals will receive a standard laboratory diets, as such, no severities are expected.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst there has been an increase in human studies examining the effects of obesity on muscle function, an isolated animal muscle model offers a direct approach to assess the contractile performance of skeletal muscle, as outlined in a recent review article. Using relatively small isolated muscles allows for a greater understanding of the direct effect of obesity and nutritional strategies on whole muscle function and muscle quality. This form of assessment allows for tighter control of potential confounding variables related to the environment the animal lives in, including diet. Previous work which has isolated non-human muscle to establish effects of a HFD on contractile performance have identified muscle, fibre type and contractile specific responses. As such, isolated muscle is extremely valuable in understanding these specific responses and changes which may be brought about by supplementation of resveratrol and vitamin D during consumption of a HFD. There are also many variables during in vivo testing, such as adherence to dietary changes or ability to produce maximal contractions, which limit our ability to understand the direct effects of nutritional supplements on muscle function. In vitro testing is also a valuable first step in establishing direct responses of treatments, which has the potential to be the foundation for future studies which look to use such treatments in a human model.

What was your strategy for searching for non-animal alternatives?

Due to the current knowledge in the area of nutritional supplementation as a method to prevent or alleviate the effects of a high fat diet, non-animal alternatives cannot currently provide comparable detailed and robust information on the effects of such supplements on muscle function.

Why were they not suitable?

There are many cofounding variables of an in vivo experimental design which will substantially impact the outcome of our understanding of nutritional interventions on muscle function. For example adherence to dietary changes and ability or willingness of participants to perform maximal contractions will limit our ability to accurately identify the effects of the chosen supplements on the function of skeletal muscle. Furthermore, in vivo experiments limit our ability to understand the direct effects of supplementation on muscle quality (force per unit of muscle) due to difficulties in isolating human muscle. Using isolated muscle allows for a greater understanding of the direct effect of obesity and nutritional strategies on muscle function and muscle quality. This form of assessment allows for tighter control of potential confounding variables related to the environment the animal lives in, including diet. As such in vitro testing can be used as a valuable first step in establishing direct responses of treatments and can be the foundation for future studies which transition into a human model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Ten years of experience for the lead researcher in this field has shown that 10 animals per experimental group provides sufficient statistical power in studies of this nature.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The study design is cross sectional manipulation as we are looking at the same population (female mice, age matched) with modified diet. Where possible, factorial experimental designs will be used (i.e. each unique diet will be tested against each other possible condition) followed by appropriate statistical analysis (e.g. ANOVA, MANOVA, etc.). This minimises the number of animals that would otherwise be required if simple paired comparisons were used instead. Thus, the same statistical power can be achieved using the fewest number of animals.

What other measures apart from good experimental design will you use to minimise numbers?

We will minimise the number of animals required by electing to harvest two muscles per animal. Previous work has required a greater number of animals as they have often only harvest one muscle per animal. However, we are reducing the number of animals needed by half and we are confident that this is achievable based on other published work where we have used two muscles from an animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Female mice will be used, similar to previously published literature from our laboratory, allowing us to make direct comparisons between previous work, which will increase the outputs from the work without the need to sacrifice a greater number of animals. Furthermore, using female mice only ensures that sex does not cause any variability in responses to treatments.

As stated previously we expect there to be no harm toward the animal as they will only receive a modified diet, opposed to alternative methods which may induce stress through handling i.e. oral gavage. The nutritional supplements provided have not only reported np adverse effects, they have also show to evoke positive responses such as improved contractile function and potential anti obesogenic effects. In the unlikely circumstance they find the modified diet unpalatable they will be removed from the study. Animals will also be regularly monitored by trained staff and a veterinarian, where an AWERB approved score sheet will be used to ensure welfare of the animals throughout.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The life stage of the animals is used to represent physiological maturity and peak muscle performance. The treatment is of mild severity and should therefore cause non or limited pain or distress. Long term anaesthesia during dietary treatment would be impractical and unnecessary.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Animals will be regularly monitored i.e. weight gain, by trained staff and veterinarians to ensure animal welfare. If the animal displays signs of discomfort, malnutrition or weight gain is affecting cage density, they will be immediately removed from the study. An AWERB approved score sheet will be used for weekly weights and health monitoring checks.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The ARRIVE guidelines will be followed to ensure scientific rigor of the research, to maximise the research outputs and minimise and reduce the number of animals used and the severity they will

experience. Furthermore, the most refined methodology and protocols will be taken from reputable journals and research groups which have experience in high fat diets, dietary nutritional supplementation and measuring contractile performance of isolated skeletal muscle in rodent models.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

REDACTED

Explain the choice ofspecies and the related life stages

Female mice will be used, similar to previously published literature from our laboratory, allowing us to make direct comparisons between previous work, which will increase the outputs from the work without the need to sacrifice a greater number of animals. Furthermore, using female mice only ensures that sex does not cause any variability in responses to treatments.

The life stage of the animals is used to represent physiological maturity and peak muscle performance. The treatment is of mild severity and should therefore cause non or limited pain or distress. Long term anaesthesia during dietary treatment would be impractical and unnecessary.

  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim is to obtain evidence that blocking HCN2 channels with specific pharmacological agents in our guinea pig models of tinnitus will lead to a significant reduction in tinnitus related symptoms.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is estimated that over four million prescriptions a year (in the USA and Europe) are for drugs to treat problems associated with the presence of tinnitus, such as anxiety, stress and sleeplessness. Tinnitus generally becomes much more noticeable and potentially annoying when experienced in a quiet bedroom at night. This may make it more difficult to get to sleep and can produce disturbed sleep and increased levels of stress and anxiety. Currently there are no pharmacologically effective treatments for the symptom of tinnitus itself, and no drug has been approved for its treatment (Langguth et al., 2019; Ann Rev Pharmacol Toxicol 59:291-313). The current healthcare bill, for treating the problems associated with tinnitus on the NHS, is estimated to be 750 million pounds per year (Stockdale et al., 2017; BMC Health Services Research 17:577). Thus there is a huge market for a drug to reduce the tinnitus percept directly (Elgoyhen and Languth, 2011). Tinnitus is a symptom produced by a wide variety of aetiologies and there is clear evidence that more than one mechanism underlies tinnitus. Fundamentally we do not fully understand tinnitus and have no broadly effective way to treat it (McFerran et al., 2019; Front. Neurosci. 13:802. doi: 10.3389/fnins.2019.00802 . We are hoping to identify a treatment, involving an oral medication, which would be easy to prescribe and of potentially wide use probably for the form of tinnitus that is comorbid with hearing impairment.

What outputs do you think you will see at the end of this project?

The drugs we will be using in this project have been produced by a commercial company as experimental drugs to try and target HCN2 receptors in different body systems such as the cardiovascular. The drugs have already undergone extensive testing in these systems and REDACTED is now interested in potentially repurposing them if we can obtain reliable evidence that one or both of them are effective in our guinea pig model of tinnitus. The drugs are nearing the end of their patent protection and we do not expect any delay being placed on the publication of papers based on our data.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The drug company will receive information about whether or not there is evidence that these particular drugs may be effective against tinnitus. This will also be of more general use because other more

specific HCN2 blocking drugs, that have higher binding constants, have recently been developed and are awaiting patent protection. If our less-specific drugs are effective against tinnitus then these new drugs are also likely to be effective against tinnitus. By using the older drugs we will be able to publish our results and thereby update other scientists about our results. Many previous attempts have been made to find a drug that is effective against tinnitus but these have all been unsuccessful. If we can obtain positive results and publish them then this will encourage other groups to investigate this class of drugs for treating tinnitus. This should speed up the identification of a drug that can treat tinnitus even if these two particular drugs are not considered to be a sufficient solution.

How will you maximise the outputs of your work?

This work involves collaboration with a drug company. Obtaining reliable results about the effectiveness of these drugs against tinnitus should encourage REDACTED to start to develop these or even more effective drugs as a treatment for tinnitus. As the two drugs are nearing the end of their patent protection there is no bar to publishing the results in high impact journals and presenting the results at international meetings and this is what we intend to do. We will also present the results to patient's organizations such as the British Tinnitus Association.

Species and numbers of animals expected to be used

- Guinea pigs: 130

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

We have two models of tinnitus:

1) is a rapid onset, reversible form of acute tinnitus that involves the subcutaneous (s.c.) injection of a high dose of sodium salicylate (the active form of aspirin). This form occurs in human patients who receive high doses of salicylate to treat certain types of advanced cancer. It reliably produces tinnitus in 95% of animals and its effect peaks after about two hours. We can then administer our test drug, again by subcutaneous injection and half an hour later, when it has taken effect start behavioural testing to measure our tinnitus marker. This testing involves playing sounds to the animal and measuring ear flick responses using a system of infrared cameras that track the ear movements in 3D space. After an hour of testing we have sufficient data to determine if the animal has tinnitus and the animal is killed by a painless overdose of pentobarbitone.

2) is a chronic model of tinnitus that takes about 8 weeks to develop and involves an hour long period of loud noise exposure applied to one ear using a sealed loudspeaker while the animal is deeply

anaesthetised. Before and after noise exposure, while the animal is anaesthetised, we record auditory brainstem responses (ABRs) using subcutaneous needles. These needles pick up tiny brain potentials that we can use to measure hearing thresholds, before and after the the noise exposure, to confirm the degree of hearing loss. Anaesthesia is induced by an intraperitoneal injection of anaesthetic mixture followed by intramuscular injections to maintain anaesthesia at a constant deep level. Animals are anaesthetised for about three hours and then recover over the following two hours. The animals all demonstrate hearing loss in one ear and are left for the next eight weeks before behavioural testing is started. About 40% of the noise exposed animals will have developed tinnitus and these can then be used to test the drugs. As it is chronic tinnitus a range of drug doses can be used on each animal followed by an hour of behavioural testing after each dose. Each dose of drug would be repeated twice in a week and a maximum of ten doses given over a period of five weeks. Some non-tinnitus animals (20% of original group) would also be given the drugs to act as controls. No animal would be tested with drugs for more than five weeks in total.

Some (60%) of the noise exposed and drug treated animals would then be prepared for terminal electrophysiology experiments. In these the animal is given a long-lasting liquid anaesthetic injected intraperitoneally followed by top ups of additional anaesthetic as required (approximately once an hour by intramuscular route). Once deep surgical anaesthesia is achieved the trachea is cannulated and the animal placed on a respiratory pump. It is then placed in a head-holder and soft tissue reflected so that holes can be drilled in the skull that will allow the placement of electrodes on the surface of the cochlea or in the cochlear nucleus. These experiments can last for up to 12 hours and at the end all animals will be killed by an overdose ofpentobarbitone.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

High concentrations of salicylate cause tissue breakdown around the site where they are injected. Initially this is not too irritating because the salicylate is also an effective pain-killer and anti-inflammatory agent. However as the salicylate is absorbed into the blood stream and excreted by the kidneys these effects begin to wear off and will be much reduced after 8 hours. The tissue damage and associated pain still remain and will become more distressing as the analgesic effects wear off. The exact degree of pain can be difficult to assess but we know from previous work with i.p. injections that some animals can move into the severe category after one or two days. Thus we will kill all our animals within five hours of administering salicylate.

The unilateral noise loss used to induce tinnitus is a non-invasive procedure that does not seem to be associated with any appreciable pain. However the long period of anaesthesia (three hours) can be associated with complications because of the long period during which the animal is unable to adequately regulate its breathing, blood pressure or temperature. Less than 5% of animals are expected to develop problems that would cause them more than moderate distress and would require them to be killed by a schedule 1 method. The remaining animals should mostly (90%) only show mild distress, as they recover over a period of two hours following the anaesthetic, while a few (5%) may take longer to recover and or show a moderate level of distress for an hour or two during recovery.

The baseline behavioural testing does not distress the animals any more than being picked up for any other purpose. However after noise exposure some animals develop a hypersensitivity to loud sounds (hyperacusis) and this can lead to threatening or flight behaviour during the behavioural testing to

determine if they have tinnitus. These animals become calm again when returned to their home cage but they have to be withdrawn from the study and are killed by a Schedule 1 method. This is expected to apply to less than 10% of the animals.

The subcutaneous injections of experimental drugs is mildly unpleasant but no animal will be given more than 10 doses of blocker drug over a period of five weeks and this will minimise any cumulative effects. At the end of the dosing regime and testing the animals will be deeply anaesthetised for electrophysiological recording and at this point they can no longer feel any pain or distress. Anaesthesia levels are constantly monitored and there are always at least two staff present to ensure the animal never recovers consciousness.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

With the salicylate animals, all are expected to enter the moderate category but none will remain in this state for more than five hours.

With the noise exposed animals no more than 10% would be expected to show moderate symptoms of distress and the rest should only be in the mild category.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are trying to identify drugs that would be effective in alleviating tinnitus but before beginning clinical trials we need to obtain preliminary evidence of their efficacy using an animal model. There have been a number of studies validating the rodent behavioural model of tinnitus using human subjects - eg Fournier and Hebert (2016) The gap-startle paradigm to assess auditory temporal processing: bridging animal and human research. Psychophysiology 53: 759-766. Others have been able to demonstrate pre-pulse inhibition (PPI) using the small muscle potentials associated with the vestigial pinna reflex and have found similar changes to (PPI) in tinnitus patients as we see in our guinea pigs. We also know that tinnitus is a good measure of salicylate toxicity in the clinic (Samlan et al. 2008; https://www.ncbi.nlm.nih.gov/pmc/articles/PMC2672263/). This reassures us that our guinea pig models are closely analogous to human tinnitus. Currently there are still no drugs that have been approved for specifically treating tinnitus in either America or Europe and the clinical trials to date have still not found any drug that is broadly effective (Langguth et al., 2019; Annual Review of Pharmacology and Toxicology Volume 59: 291-313).

What was your strategy for searching for non-animal alternatives?

Computer modelling of the effects of the drugs on the firing rates of nerve fibres in the cochlear nerve.

Why were they not suitable?

The cause of tinnitus is still not properly understood and the mechanisms that cause its development have still not been worked out. We do not know enough about the neural mechanisms producing tinnitus in order to model the effect of altered firing rates on its development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Effects of HCN2 blockers on behaviour following salicylate

In protocol 1 we will initially try a wide range of drug concentrations to estimate the optimal range over which a small change in drug concentration will produce a large change in the effect on behaviour. We should have one dose where there is no effect, one dose at maximum effect and then two where the effects are intermediate. Depending on the exact results the optimal range should be either between or to one side of the two intermediate doses. We will use two animals at each dose to reduce the expected variability and this means that for two drugs we will need 16 (2X4X2) animals treated with salicylate for the initial study. Once we have determined the optimal range of the curve then we will use six animals at two points on the steepest part of the dose response curve to get an accurate idea of the slope of the curve. Thus we will optimise our acquisition of dose response data as recommended in recent studies http://people.csail.mit.edu/mrosenblum/Teaching/adaptive_designs_2011/BerryMuellerGrieve.pdf This will require a further 12 animals for each drug. This will mean that we require 40 animals specifically for protocol 1: (16 +12+12).

Effects of HCN2 blockers on behaviour following noise exposure

The numbers required for the noise exposure model are estimated based upon the number of treatment groups and the incidence of tinnitus generated by noise exposure. In our guinea pigs about 40% of animals are expected to develop tinnitus following noise exposure. As it takes about 8 weeks for the noise induced tinnitus to develop we use 5 animals at a time and there is little risk of us using more animals than will be required to show a significant effect. Based on our previous experiments we expect that 6 animals in the tinnitus group would be sufficient and this would leave 9 in the non-tinnitus group. We estimate that we will need 15 animals for each of the two drugs to be used in the noise exposure studies. If all of these animals are noise exposed (protocol 2), then we would expect 12/30 to develop tinnitus and these would be split into two groups of 6 to test HCN2 channel blockers. We also need to

confirm that the two new channel blocker drugs enter the cochlear nerve but are excluded from the brain. This will involve injections of blocker drugs, in non-tinnitus animals so that tissue can be removed at postmortem (blood, brain and nerve) to quantify the amount of blocker drug present 30 min. after administration. This will provide partition constants for each drug in the different tissues but will not require any new animals.

Effects of HCN2 blockers on neuronal spontaneous firing rate following noise exposure

Most neurophysiological measures are robust across animals and it is statistically valid to consider multiple neurons from one individual as independent, and aggregate across animals. In deciding on the number of neurons to record from we consider a response feature (spontaneous firing rate) which we predict would be higher in animals with tinnitus. If we are recording in the cochlear nucleus after the induction of tinnitus we would like to be able to detect a small change in the mean firing rate. To do this our previous calculations indicated we would need to record from about 300 neurons. In electrophysiological studies of this sort we would expect to record from at least 20 neurons per experiment. As we want to compare the tinnitus (T) and non-tinnitus (NT) animals we estimate that we will need about 15 animals in each group.
In order to obtain 15 tinnitus animals for electrophysiology, we want permission to noise expose 60 animals in case only 25% (instead of the 40% expected) of the animals develop tinnitus (15 T + 45 NT = 60) but will stop noise exposures once we have obtained the required number of tinnitus animals (15 T). Thus for all three protocols we will need a total of 130 animals (40 salicylate, 30 drug effects and 60 electrophysiology = 130).

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

By undertaking the behavioural studies first we should be able to identify which of the HCN2 blocker drugs is more effective and just use this one in the electrophysiological studies, rather than trying to compare two drugs. We have also learnt from recently published studies about how to reduce the numbers of animals required for dose response studies by minimising the numbers used to measure ineffective doses and those where the response has saturated. We have also taken advice from our local statistician about power calculations and have used the NC3Rs website to incorporate blinding into our dosing regime.

What other measures apart from good experimental design will you use to minimise numbers?

Rather than breeding our own animals, as we have done in the past, we will now only use animals, brought in from a supplier, at a specified weight. This will minimise animal wastage and reduce variability in the age of the animals that we administer drugs to. We have also undertaken extensive pilot studies using a non-specific HCN channel blocker (ivabradine) to optimise our experimental methods and routes for drug administration.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Choice of animal

Guinea pigs are placid herbivores that thrive in safe, well-maintained animal units and their sociable nature means they are very suitable for maintaining in small colonies. They have a large, easily accessible cochlea and this means that they have been a preferred model for studying the auditory system for more than 50 years. Their brains show typical mammalian characteristics that make them a good model for the human brain as they contain the same central structures and use identical neurotransmitters and modulators as humans. Additionally, there is a large amount of electrophysiological data obtained in guinea pig, and available in the literature, much of which might have to be replicated if a different animal were used (contradicting reduction). None of our protocols is rated as causing more than moderate distress and most will not produce more than mild distress.

Methods for inducing tinnitus

Tinnitus can be induced rapidly and reliably by injecting a single high dose of sodium salicylate (300 or 350 mg/kg). This causes less overall distress to the animal than noise exposure as it avoids the prolonged period of anaesthesia and subsequent recovery as well as the gradual onset of tinnitus over a number of weeks. In the past we injected salicylate i.p. and this was associated with irritation and damage to the wall of the gut that developed over the subsequent 24 hours. We will now administer the HCN2 channel blocker two hours after the salicylate and then perform all the behavioural testing within the next two hours. This means that the animal can be sacrificed within five hours of the salicylate being administered and the pain associated with local tissue breakdown is minimised. We have made some pilot studies injecting the salicylate by the s.c. route and they did not show any signs of moderate pain. There was no vocalising during the injection or a subsequent hunched posture, immobility or piloerection of the sort we have previously observed in a few animals one day after i.p. injections. The s.c. route should be safer and cause less irritation. Salicylate injection in mice by the s.c. route has already been shown to be safer than by i.p. injection as the dose at which half the animals die (LD50) for i.p. injections is 500 mg/kg but for s.c. injections it is 550 mg/kg
https://www.nwmissouri.edu/naturalsciences/sds/s/Sodium%20salicylate.pdf
Salicylate is absorbed by passive diffusion and rapidly distributed in most body tissues and so the s.c. route has been shown to be effective
www.vmd.defra.gov.uk/productinformationdatabase/SPC.../SPC_261932.DOC

Identifying tinnitus in noise exposed animals requires a behavioural test and we have been successfully using a method that involves studying pre-pulse inhibition of the acoustic startle reflex. Initially we tried measuring the whole body startle which is widely used in testing small active rodents such as rats and mice. However after about the first five startle presentations the guinea pigs stopped giving reliable body movements. They still gave an involuntary ear flick and so we now use a system involving the ear flick reflex to measure changes in pre-pulse inhibition that are characteristic of tinnitus.

This is a simple procedure that allows the animal to sit quietly in a sound booth, while its ear flicks are monitored with a motion tracking system in response to startling clicks, with or without a preceding gap in the background noise that can act as a cue to indicate the imminent presentation of a startling sound. Initially we used sessions of 40 min. to monitor the ear flick responses but because of their reliability we have been able to reduce this to 20 min. sessions and still acquire valid data.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Acute recording experiments under terminal anaesthesia

All of our electrophysiology experiments will be made under deep terminal anaesthesia so that there should be no chance of the animal suffering any distress. Anaesthesia will be carefully monitored to make sure there is no chance of the animal recovering consciousness.

Guinea pigs are precocious and are born with their ears and eyes open and are fully conscious shortly after birth. There is no opportunity to use a less sentient state without the use of a general anaesthetic.

This project is designed to test the effect of drugs on tinnitus and as tinnitus is only experienced when awake the behavioural testing can only be performed on alert animals. Guinea pigs are an excellent model for human hearing because they have a similar range of hearing thresholds for low-frequency sounds and being mammals they have an auditory system and brain that are organised in a very similar way.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Induction of tinnitus by salicylate injection

High doses of salicylate can lead to irritation of the stomach or gut wall and we will be particularly careful to avoid this problem. We now intend to use s.c. injections to reduce the risk of damaging the stomach. Each dose of salicylate will be injected at two or more different locations in the loose skin at the back of the neck to avoid direct irritation of the gut. Animals will be carefully restrained and injections performed by trained and competent staff in accordance with LASA guidelines. The condition of the animals will be checked every half hour immediately after the injection to check for unusual sensitivity.

Recovery anaesthesia for noise exposure

The main risk of adverse effects are related to the prolonged anaesthesia required to record the ABRs and expose to loud noise in one ear. Some guinea pigs are particularly prone to the respiratory depressant effects of anaesthetics and may stop breathing even before a surgical depth of anaesthesia has been reached. By careful observation using a camera and monitor it is possible to check for a rapid decrease in the amplitude or rate of breathing just before it stops and this should allow remedial action (two drops of sublingual Dopram). Similarly the skin colour and rate of capillary perfusion can usually be checked on the fore or hind-paws either directly or with a pulse oximeter to give an indication of

falling blood pressure. (This will be made easier by using albino guinea pigs rather than the pigmented ones used previously). Falls in blood pressure can be reversed by an injection of adrenaline (i.m.). Animals recovering from anaesthesia often urinate and to keep them dry and prevent any chance of local hotspots on the elements of the blanket burning them, while they are still unable to initiate movement, half a nappy will be placed under the animal. After recording the post-deafening auditory brainstem response a reversing agent such as atipamezole (1 mg) may be injected (i.m.) if appropriate and as recommended by the NVS to aid recovery. Administering a general anaesthetic may lead to mild distress due to the physical restraint or needle damage. This will be minimised by making sure staff are fully trained and monitored for competence before making injections with an assistant who will restrain the animal. After the second period of ABR recording is finished the rectal thermometer is removed and monitoring becomes more intermittent. During this time, there is the possibility that the animal will not be able to regulate temperature, or may have difficulty breathing. To protect against this, we will place the animal in a warmed recovery cage and ensure a good posture conducive to easy breathing.

Behavioural testing

Occasionally animals (< 10%) become very restless and try to bite the loudspeaker or repeatedly climb out of the cage in the sound booth during testing. This may be partly due to them experiencing increased sensitivity to sounds so that loud sounds distress them. The first time this happens testing will be stopped and the animal returned to its home cage. If it happens three times in a row the animal will be removed from the experimental group and either used in a terminal procedure or killed by an S1 method. Animals are never restrained during behavioural testing and will not experience more than a mild level of stress from being placed in the test booth. They will never be left in the booth unattended or for more than an hour in any one day. The booth has a glass window in its side so that the animal can be continuously observed.

Surgery

The respiration rate, CO2 levels and ECG are routinely monitored to maintain a healthy physiological state. The core temperature is monitored and thermostatically maintained with a heating blanket. Some experiments have to be terminated early because of respiratory problems which we are unable to resolve. Guinea pigs are particularly prone to respiratory problems which reduce their lung capacity. Thus although varying numbers of our animals may have respiratory problems that manifest after about four hours of general anaesthesia we should still manage to acquire good data from >85% of animals. All animals will be closely monitored throughout the period of terminal anaesthesia and will not be left until death has been confirmed either by exsanguination or by monitoring heart rate and end-expired carbon dioxide levels.

Dehydration under anaesthesia will occur and we have measured that our animals lose about 1 ml of water per hour. Supplementary fluids will be administered by by i.p injection of warm sterile saline as advised by the NVS.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

All non-recovery experiments involving surgery are now performed using aseptic precautions as outlined in the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery http://www.lasa.co.uk/pdf/lasa_guiding_principles_aseptic_surgery_2010.2.pdf). This means that at least two people are present during the periods of surgery with one undertaking the sterile procedures and the other providing assistance.
These aseptic precautions include use of surgical gown, hat, gloves and sterile drapes. All instruments and drapes will have been autoclaved. A hot bead steriliser is available to re-sterilise instruments during the day if necessary but we try to avoid using it as it is no longer recommended. Procedures are in place so that the animal is never left unattended. If the fire alarm sounds (except when it is known to be a false alarm) the animal will immediately be killed by an overdose of pentobarbitone which has been placed in a syringe at the beginning of the experiment.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will rely on guidance about improved methods from the Named persons who will provide detailed oversight and assistance with all aspects of the work. They have already been working with us intensively over the last few years to help us improve our experimental methods and this will continue. We will also consult the NC3Rs website and keep informed by the relevant literature.

Explain the choice ofspecies and the related life stages

Tinnitus does occur in children but it is more common in adults and its incidence peaks in the population decile aged from 60 - 70 years old. There is no known direct genetic link and in many people the aetiology is unknown. Thus the most appropriate animal model for drug testing is a mature mammal. Guinea pigs are a traditional and widely used model of the human auditory system. Guinea pigs have a more similar audiogram to humans than rats or mice as these small rodents have poor hearing at the low fundamental frequencies present in human speech. We have developed a behavioural test for tinnitus in guinea pigs that is relatively quick and easy to implement and that is designed to allow us to test the effects of drugs that may alleviate the symptoms of tinnitus.

Home Office

NON-TECHNICAL SUMMARY

210. The health and therapeutic potential of in vitro derived oocytes using an ovine model

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Sheep	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To test the implantation and pregnancy potential of embryos derived from oocytes that have undergone complete in vitro growth and maturation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Premature ovarian insufficiency (POI) or total sterility can occur in girls and young women as a result of genetic defects, surgery, abdominal trauma, or more commonly as a side effect of radiation or chemotherapy treatment for cancers or haematological disease. POI has adverse clinical and psychological effects on women's health. Ovarian cryopreservation can now be used to safeguard the fertility of girls and young women at high risk of sterility or POI. Primordial follicles, containing primordial oocytes, can be cryopreserved in ovarian cortex and stored long-term at -196^{o}C. When the patient wishes to start her family, the stored tissue is autografted back at an orthotopic or heterotopic site to restore fertility. However, for girls and women with blood-born leukaemias or cancers with a high risk of ovarian metastasis, ovarian autografting risks reseeding the cancer through the transplant. For these individuals fertility restoration can only be safely achieved in the laboratory by the complete in vitro growth and maturation (IVGM) of cryopreserved primordial oocytes into fertile metaphase II (MII) oocytes. Following in vitro fertilisation, a healthy embryo can be transferred to the patient to produce a pregnancy. The therapeutic potential of IVGM is huge but the technology is extremely challenging. Never-the-less significant advances in IVGM have recently been made to the extent that we can now derive MII oocytes from primordial follicles totally in vitro. This project will examine embryos created from these oocytes and their ability to form a pregnancy that develops normally into healthy offspring. Translation into women would have major therapeutic potential for the restoration of female fertility and the treatment of infertility. These studies will be conducted in sheep as a proven, physiologically and clinically relevant model for fertility preservation and restoration in women.

What outputs do you think you will see at the end of this project?

This research is ultimately designed to improve health outcomes. Our goal is to engage with the academic community through general meetings and academic publications, to the IVF industry, and to patient groups. Results of this research will be published in academic journals such as Nature Medicine and more specific Reproductive journals such as Human Reproduction and Fertility and Sterility. This study will impact the wider scientific community as it will provide a validated model system to study ovarian/oocyte development. With our network of scientists and clinicians we are well placed to facilitate potential impacts and prepare for the next stage of implementation. These meetings and transfer of information will effectively inform the scientific/clinical community in the area of reproductive biology and medicine. All applicants are involved in meetings that are clinically orientated

and so will reach a wider audience of clinicians and embryologists and therefore potential beneficiaries.

Successful completion of this study will provide proof of concept data that will underpin the submission of an application for an HFEA research license to allow us to test the safety and efficacy of IVGM in human oocytes and embryos. Following license approval, we plan to submit a follow-up, 2-year grant application to fund safety testing of the optimised human IVGM system. Ultimately, if successful we aim to apply for NIHR efficacy and mechanism evaluation (EME) funding to test the efficacy of IVGM oocytes in a small embryo transfer trial in women.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Normal ovarian function underpins lifelong health and wellbeing in women. When it is disrupted there is a significant burden for women, their families and healthcare providers. Normal ovarian function can be compromised in girls and young women as a result of genetic defects, abdominal trauma, or more commonly as a side effect of radiation or chemotherapy treatment for cancers or blood diseases. If there is a reduction in the number of eggs formed or an increase in the number of eggs used there will be fewer eggs in the ovary and the woman will be at risk of premature ovarian insufficiency (POI) or total sterility that may have adverse clinical and psychological effects on health. Ovarian cryopreservation followed by the complete in vitro growth and maturation (IVGM) of eggs can now be proposed as a means to safeguard the fertility of girls and young women at high risk of sterility or POI. Significant recent advances have been made in both IVGM technology and in our abilities to test the health and normality of eggs grown in the laboratory. The stage is now set to use these advances to test the therapeutic potential of in vitro derived eggs for fertility restoration. The proposed project is vital to enable selection of the best IVGM method and to ensure that the technology is both efficient and safe before it is used to treat patients.

The research project will have a direct impact on key STAKEHOLDERS that include patients who suffer from POI. The legacy of this project will also impact on academics, reproductive and developmental scientists and clinicians as well as the wider scientific community including biomedical scientists, computational biologists, and healthcare professionals. The team of applicants have established extensive communication networks in these areas that will be used to discuss and distribute the findings of the proposed studies to both the scientific and clinical communities and to the public. The unique collaborative network established for this project will impact on the MRC through realization of the potential of past, publicly funded research investments, as well as additional analyses of existing research tissue and data banks.

THE ACADEMIC COMMUNITY working on Fertility Preservation and infertility treatments shall benefit in the short term. The proposed work will also benefit young researchers and graduate students by opening up new areas of study in silico for computational biologists and will ultimately provide data which can be used by researchers in the wider scientific community to study ovarian biology and oocyte development so helping to reduce the reliance on mouse as a model system for human. Our development and use of bioinformatic tools for quality validation of transcriptome metadata will be of broad interest to other bioinformaticians, data wranglers and computational biologists who use similar

approaches to analyse big data sets. The information and skill sets generated will be of value to support training provision in the analysis of RNAseq data which will enhance UK skills in the area.

ANIMAL CONSERVATION will also benefit. This project could also impact on the use of assisted reproduction techniques for endangered species. We have contacts with scientists involved in reproduction of endangrered species in zoos and research institutions, both within the UK and internationally involved in reproduction of endagrered species. Through these contacts our research can be disseminated to zoos and reach those interested in animal conservation management.

HEALTH CARE PROVIDERS and all those involved in Assisted Reproductive Technologies (ART) will benefit in the longer term. The results obtained could have a range of potential applications and significant commercial advantage over existing ART treatment methods. If the results of this project are positive then we will be in a position to develop methodologies for novel approaches for assisted reproduction. These could potentially a) negate the need for hormonal stimulation of the patient, b) avoid multiple surgical procedures to harvest the resultant eggs, c) implement a series of quality control measures to optimise egg selection for subsequent fertilisation and d) most importantly provide options for fertility preservation/restoration to women who have no options currently available. All these are highly desirable outcomes for improving the treatment and management of infertile women. A significant application of results obtained from this proposal would be in the area of fertility preservation. An in vitro growth system that supports the safe and complete oocyte growth and development from the earliest primordial stage to maturity could provide this patient group with sufficient numbers of viable oocytes for the restoration of their fertility in conjunction with other assisted reproduction technologies. Similar considerations may also apply to the significant number of women with premature ovarian insufficiency, for whom a cause often cannot be found and for whom at present the only option for their infertility treatment is egg donation.

THE UK GOVERNMENT and NHS will benefit in the medium to long-term from the proposed research through: improved health and wellbeing of cancer survivors; the development of new infertility therapies; and expansion of its research base.

HEALTH POLICY MAKERS in the UK and beyond will benefit from this research in the median term through the generation of increased understanding of the ramifications of- and treatment options for- ovarian dysfunction and its contribution to lifelong health. In the long term this will positively impact on the health and wealth of the UK in terms of better health and fertility for subsequent generations, and has the potential to lessen the burden of infertility treatment costs upon the healthcare services.

THE GENERAL PUBLIC will benefit in the medium term, as we aim to disseminate our findings beyond the academic community to increase awareness of ovarian dysfunction and the need for fertility preservation for key groups of patients. By interfacing with the clinical community the project will impact directly upon health professionals through the development of new therapeutic paradigms. We will disseminate our findings beyond the academic community to increase awareness of fertility preservation strategies and by interfacing with the clinical community this knowledge will impact directly upon health professionals.

THE COMMERCIAL SECTOR will benefit in the medium term as a key driver in this application is realization of the potential of a novel therapeutic pathway as well as core and platform culture technologies and associated intellectual property. In addition to patient treatment, the core IVGM

technology underpinning this application may impact on animal breeding and conservation programmes.

How will you maximise the outputs of your work?

We are regular speakers at international meetings (European Society for Human Reproduction and Embryology, World Congress in Fertility Preservation, Society for the Study of Reproduction , Society for Reproduction and Fertility, British Fertility Society etc. We have roles in organisation of meetings are invited as speakers at many basic and clinical workshops. We are members of an international expert panel who are evaluating the pathway to clinical application of in vitro derived oocytes. Project progress will be communicated directly with this international group.

We are experienced in commenting and interacting with the media (TV, Radio and newspapers) to explain research in our area of specialism and have worked with the UK Science Media Centre. We interact with our media offices to publicise research by issuing press releases for appropriate findings/publications and being available to comment on other work. All applicants are actively involved in public understanding of Science programmes, including school visits, Science festivals and informal events such as "Pint of Science". We have spoken at Progress in Educational Trust events on the impact of reproductive technologies as well as contributing to local public lecture series. We will produce web pages supporting hard copy material highlighting the research in a publicly accessible format, and will produce a video-cast of research highlight key features of the research and its potential. REDACTED

This project will lead to the development of a data package that the business development team will use for commercial liaison.

Species and numbers of animals expected to be used

- Sheep: This will use up to 110 adult ewes and, if all embryos implanted create an offspring, up to 150 offspring

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will have blood samples taken and have tests that are commonly done on patients when they attend the doctor. They will sometimes be given treatments by injection or pessary similar to those that are used in women during infertility treatment.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Animals undergo standard animal husbandry techniques. They will have some blood tests and measurements and be given substances in common clinical use that will cause mild transient discomfort and no lasting harm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity experienced by animals in this project is classified as moderate for the adult ewes and mild for their offspring.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This is the step before transfer of this technology into women. It builds of work using mammalian cells and tissues collected in vitro. This project is looking at pregnancy potential which cannot be examined in a non-animal model.

What was your strategy for searching for non-animal alternatives?

There are no non-animal alternatives as we are looking at pregnancy potential and this can only be assessed in vivo. While using cells can help refine parts of the project we need to study animals to assess the cells developmental potential in vivo.

Why were they not suitable?

We need to study animal pregnancy where multiple cellular systems interact in complex ways.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

It is important that we use just enough animals to allow us to get accurate results with minimal numbers. We look at our experience and the results from other researchers in the UK and internationally to ensure that we accurately calculate the numbers required to show changes that are clinically important. These calculations are fully displayed and reviewed during funding applications. We have planned for the minimum amount of ewes to show enough clinically significant data to facilitate transfer of the technology into women.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The project was carefully powered by a biostatistician and the calculations were reviewed internally and externally as part of the funding application.

What other measures apart from good experimental design will you use to minimise numbers?

We use a three stage experimental model where we only progress to the next stage when the previous stage has been successful. One of the stages in a pilot phase. That means we only use animals when we have evidence that the experiments will succeed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We use clinically realistic fertility treatments and assessments that cause minimal distress and suffering without lasting harm to the animals.

We are using commercial breaders with expertise in insemination, uterine flushing and embryo transfer and all the techniques we are using for pregnancy generation and used in commercial breeding programmes. These techniques are designed to produce good quality offspring with the least pain, suffering and distress to the animals.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The ovine model has a long history of research in ovarian biology and fertility preservation. Indeed ovarian cryopreservation, which is currently in common clinical practice was developed using an ovine model. This is because sheep ovarian function and intrauterine development is very similar to that of humans.

We are studying pregnancy and the outcomes of pregnancy and as such have to use adult animals capable of becoming pregnant and being monitored through pregnancy.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We ensure that all the tissues are carefully labelled and stored at the end of the study so that ourselves and others can design new laboratory studies with already collected tissue to ensure that experiments do not need to be repeated.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We follow detailed local guidance from the LAS and national guidance from the NC3Rs and Home Office to ensure that experiments are conducted in the most refined way.

We utilise the concepts in the PREPARE guidelines: Planning Research and Experimental Procedures on Animals: Recommendations for Excellence. PREPARE covers the three broad areas which determine the quality of the preparation for animal studies: formulation, dialogue between scientists and the animal facility, and quality control of the various components in the study. We utilise the adapted PREPARE checklist.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

REDACTED has regular newsletters and meetings, at least annually, to ensure that all researchers are up to date and can implement advances appropriately. There are annual 3R competitions that facilitate sharing of best practice.

Explain the choice of species and the related life stages

We are studying the ability of the most immature eggs in the ovary to be grown in the laboratory to form eggs that are suitable for fertilisation and able to generate a pregnancy. We are looking at the health of the offspring produced. The sheep ovary is very similar to humans and the sheep has a long history in fertility research that has translated into clinical treatments for women. The size and development of sheep means that we can use the techniques and tests that are used in humans.

NON-TECHNICAL SUMMARY

211. The impact of ageing and diet on connective tissue chemistry

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand how the chemistry of connective tissue changes with age and also how diet might impact this process. We are particularly interested in the chemical changes which occur in collagen and elastin.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is unclear from the literature what the most important chemical and biological changes that occur in ageing tissue are (chemical changes are ones that occur spontaneously when two reactive molecules come into close proximity to each other, biological changes are ones driven by the biological conditions/environment, for example an enzymatically catalysed reaction which only occurs when a specific enzyme is produced). It is self-evident that changes occur with age which alter the characteristics of tissues, we can all see and feel these changes, but there is a surprising lack of clarity in the description of what chemical and biological changes are actually occurring at a molecular level.

We have shown in our own research (submitted for publication) that tendon collagen chemistry is much more dynamic than previously thought, changing in response to stretching, and that the chemistry that underlines this also changes with age. We have found that circulating glucose levels can impact the chemistry and physical properties of tendon which has led to an interest in whether diet also impacts the ageing process. Different tissues have different chemical profiles which reflect the different functions required from the tissue, for example tendon has a quite different function to bone or the wall of the aorta which is seen in the chemistry found in these tissues. In the work we plan to carry out under this licence we wish to continue to study connective tissues to understand how the changes in the chemical properties seen as the result of ageing and diet impact the normal functioning of the tissue. Understanding this may lead to improvements in treating diseases such as diabetes and cystic fibrosis, as well as potentially providing a rationale for strategies for healthy ageing or tissue repair.

What outputs do you think you will see at the end of this project?

We will publish the results of our animal work in respected peer reviewed journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

A better understanding of the processes involved in ageing could ultimately help in both treatment and prophylaxis of diseases associated with normal ageing. It is expected that this project will lead to the development of methods to study ageing tissues and identify the important changes which occur as we age. Ultimately we aim to transfer the methods developed here to study the ageing of tissues in humans.

It is likely that changes in connective tissue chemistry impact many disease processes. For example, changes in crosslinking and glycation in the collagen of arterial walls are expected to lead to increased stiffening leading to increased blood pressure, an increased incidence of aneurisms and arterial valve stenosis. With respect to ageing, the stiffening of joints and tendons would also be expected as a consequence of increased collagen crosslinking and glycation. The treatment of aspects of diseases not necessarily liked to ageing, such as lung damage in cystic fibrosis and poor wound healing and tendon ruptures in diabetes may also benefit from this research.

The tissues generated in this project will be stored and made available to other researchers interested in the ageing of connective tissue, providing a valuable and unique resource of isotopically labelled and chemically profiled tissues of different ages. This will be done through personal contact with other researchers in this field of research. It is reasonable to expect that other researchers studying normal ageing processes would find this resource valuable. We also try and time our experiments so that other researchers within the organisation can make use of fresh tissues when we kill aged animals, such as lymph nodes, bone marrow etc.

How will you maximise the outputs of your work?

We collaborate with other researchers on the ageing of connective tissue and give presentations on our latest results when appropriate. This is the best way to disseminate information on approaches that do not work.

Species and numbers of animals expected to be used

- Mice: 650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The mice will be kept for up to an age of 130 weeks and fed balanced diets. In some cases mice will be put under a light general anaesthesia so that ultrasound measurements can be made to determine the stiffness of the cardiovascular system. These cardiovascular measurements may be carried out up to 4 times with a minimum period of 4 weeks between each measurement.

Mice will be kept under standard animal house conditions up to an age of 130 weeks.

db/db mice and Nrf2-/- mice will be purchased at various ages and kept for the minimum period of time to allow a single cardiovascular ultrasound measurement to be obtained from each animal. This will be no longer than 1 month.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are no specific impacts or adverse effects expected on wild type mice ageing healthily during this project. The majority of the animals used on this project will be wild type. Animals that are developing irreversible ill health conditions will be killed before they exceed a mild threshold because we are interested in healthy ageing and not the ageing of diseased or unhealthy animals.

We have kept mice routinely to 98 weeks with an upper limit of 104 weeks and found that these animals have been remarkably healthy and could have been kept longer without causing harm.

Two standard genetically altered strains from commercial sources will be used in addition to the wild type animals. One strain (db/db) is diabetic and the other (Nrf2-/-) has a poorer immune system linked to a mutation that causes reduced levels of glutathione. These will be monitored closely and kept for the minimum time required to made a single cardiovascular ultrasound measurement, and no longer than 1 month. These animals will only be fed a normal standard diet typically used in the animal unit.

The animal house staff are trained and experienced in the recognition of signs of ill health found in ageing animals.

Animals are inspected during routine cage cleaning with in hand inspection weekly for mice over 52 weeks old.

The staff will be looking particularly for eye abnormalities, malocclusion, over grooming, ulcerative dermatitis, abscesses, rectal prolapse, weight loss (a potential sign of other underlying problems), neurogenic symptoms (fits / seizures / spinning / head tilt), abdominal swelling. These are conditions that could develop as a result of old age and diseases expected to be found in old age.

Any animals showing signs of illness which, in the opinion of the NVS, cannot be ameliorated with minor interventions will be killed using a Schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The mice are not expected to exceed a severity of Mild.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The ageing of tissues is a complex process involving a multitude of cell types and factors. For example, a blood vessel like the aorta is a complex highly organised structure of cells, collagen, elastin and other connective tissue components. The blood vessel wall is not believed to have a fixed composition at a molecular level, changing with age and in response to factors such as blood pressure. Similarly, the structure of other tissues such as tendons and bone respond to stresses and age related factors which it is not yet possible to reproduce in culture.

What was your strategy for searching for non-animal alternatives?

There are no alternatives that I am aware of that could be used to study changes to the chemistry of connective tissue during ageing.

Why were they not suitable?

There is no alternative model that has the complexity of the interacting biological processes found in animals during ageing.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on the experience of running a project over the last 5 years and typical animal usage from our records. We involve a professional biostatistician in the design of experiments to minimise the use of animals wherever possible. Many of the animals used are to provide fresh aged tissues for study after they have been killed.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We typically start experiments with a small number (5 to 10) animals in each group, collect the required data and then collaborate with a statistician to decide if we need to increase the number of animals used. We then collect data from additional animals and add this to the original data set, if appropriate.

What other measures apart from good experimental design will you use to minimise numbers?

Where possible we keep the carcasses of the animals that we use so that we can sample tissue from different organs. This helps to minimise animal usage and allows us to build up a picture of changes in the connective tissue across the whole body of individual animals. For example, this potentially will allow us to correlate changes seen in skin with changes in the aorta, tendon or bone.

Where old and young animals are killed by other researches for tissues and the carcasses are unwanted, we often take these and keep the remaining tissues that could be of use in our own experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mice are allowed to age normally under this project and so they should not experience anything that a normal healthy mouse would not.

Where we require cardiovascular ultrasound measurements the mice will be put under general anaesthesia.

We have limited the time that commercially available genetically modified animals can be kept to minimise the potential for suffering or distress. The genetically modified strains required are extensively

used by others and the phenotypes characterised.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We are trying to understand why connective tissue ages and relate these changes to those seen in humans. The animals chosen are required to have a biology that is as close to human biology as possible. Mice fit this requirement.

The extracellular matrix found in non-mammalian species is chemically different to that of mammals which makes them unsuitable as an alternative. The physiological environment within the extracellular matrix, organ structure and diet also effect the chemistry of the matrix. These are too dissimilar in non-mammalian species.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The mice should not experience any harm.

In this project we use two strains of commercially available genetically modified animals. One strain is diabetic (db/db) and the other has reduced glutathione levels (Nrf2-/-) with increased risk of infection. These two strains of mice will be kept for less than 1 month to enable the required measurements to be made and minimise the potential for harm to the animals.

Neither the db/db mice nor the Nrf2-/- mice will be fed altered diets. The db/db mice will not be fed diets containing raised levels of sugars.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The NC3Rs website contains a wealth of information on best practices, experimental design and animal welfare.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Through reading of literature and listening to presentations on advances in the 3Rs.

Explain the choice of species and the related life stages

We are studying the chemical changes which occur in connective tissues (primarily to collagen and elastin) with age. As such we require mice of all ages. Ageing mice are extensively used as a model for

human ageing because they show the same attributes of ageing as seen in humans, but over a shorter time frame.

We have shown previously in tissue from db/db mice that higher levels of glycation are seen without increases in other crosslinking. This is required to understand the mechanism and impact of collagen glycation on function without the complication of other increases in crosslinking typically associated with changes in tissue function.

Nrf2-/- mice are required to test a hypothesis that glutathione levels play a role in crosslink reduction in elastin found within the extracellular matrix.

Home Office

NON-TECHNICAL SUMMARY

212. The importance of gut microbes in health and disease

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to understand how the populations of microorganisms resident in the gut (the microbiota), contribute to health and disease, and to use the knowledge gained to develop the means of altering the microbiota to improve or restore health and to treat diseases affecting the gut and other organs, such as the brain.

The key objectives are:

1. To determine how gut microbes and their products communicate with the cells in our body to influence their behaviour and function.

2. To determine the most effective means of changing gut microbe populations to promote or restore gut health and treat disorders affecting the gut and other organ systems.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The expected benefit of this programme of work is to provide an increased understanding the role that gut microbes play in promoting healthy ageing that will lead to new interventions to promote or boost gut health in at risk (elderly) individuals.

One such anticipated intervention and benefit from our research is the development of new vaccines. There are currently only a handful of licensed vaccines able to protect the major sites of pathogen entry to the body - the gut and lungs. New vaccines are desperately needed in order to prevent infection by respiratory and gut transmitted pathogens that collectively account for more than 8 million deaths annually worldwide. In particular, there is an urget need to develop new prevention and treatment strategies for viruses such as influenza and cornonavirus that can cause pandemics (i.e. COVID-19). The young and elderly are at particular high risk from these infections due to their weakened immune systems that have an major impact on the NHS and social care expenditure. By genetically engineering a major bacterium that resides in the human gut to express virus vaccine antigens in its' microvesicles (outer membrane vesicles; OMV) that are shed from its surface we have generated OMV containing vaccine antigens and therapeutic proteins for oral and nasal administration. This project will enable us to further optimise and refine OMV formulations and test their effectiveness in providing increased resistance to infection and disease prior to their use in humans and in veterinary medicine.

Another anticipated impact of our programme of work relates to manipulating gut microbes to prevent or treat age-associated decline in immune function and mental health (cognitive function). Events taking place in the gut play a central role in the ageing process and in the functional decline and senescence of various organ systems including the immune and cardiovascular system, and the brain. This makes gut microbes a realistic target for interventions to positively impact on the ageing process. As part of this project therefore, we will further refine and develop microbiota replacement therapy (faecal microbiota transplantation; FMT) by determining its mechanism(s) of action and optimising its effectiveness. We will also investigate other approaches to manipulating gut microbes including the use of single or defined mixtures of microbes or microbial products such as OMV. We anticipate that this new knowledge and data will during the lifetime of the project be used to develop evidence based protocols

that can be used in clinical trials to assess the efficacy of FMT or others forms of microbe-based therapies to overcome immunosenescence and boost immunity in elderly individuals.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mouse, approximately 10,500 over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The germfree or GA strains we will use are not expected to develop any adverse clinical or psychological signs. However, in the they show any deviation from normal health or wellbeing will be immediately killed by schedule 1. Aged animals (>20 months) are expected to show signs of frailty and immunosenescence that is a hallmark feature of aged mammals. Frailty is assessed and scored by monitoring an individual animals weight and its movement over a fixed period of time. Those that do not remain in good health and display generally accepted end of life signs (e.g. slow or laboured respiration, hunched body position with matted fur, failure to eat and drink determined by food hopper weights and degree of dehydration or, poor body condition score) will be killed by schedule 1. Clinical presentations for aged mice include rectal prolapse, alopecia and dermatitis, ocular lesions and palpable masses although the presentation and severity of these signs can be varied making it difficult to predict the expected incidence. However, any animals displaying any of these signs may after consultation with the NVO be killed by schedule 1.

We will administer substances that include harmful and harmless microorganisms and/or their products or antigens, chemicals, and drugs such as antibiotics and steroids to induce inflammation and colitis that replicates key features of intestinal inflammation and inflammatory bowel disease in patients. These substances will result in no lasting harm in the majority of animals (>90%) using the minimum dose consistent with the scientific objectives. Doses will be no more than the maximum tolerated dose (MTD - defined as that associated with weight loss of no more than 20% of the animal’s initial bodyweight). All mice receiving these substances will be inspected and weighed daily. Mice will be promptly and humanely killed if they are approaching 20% weight loss and/or display signs of pain, distress or of significant ill health such as abnormal posture/positioning, abnormal breathing, decreased food/water consumption, dehydration, muscle rigidity, twitching/trembling or pilo-erection.

The treatment regimens used to prevent and/or treat inflammatory disorders affecting the GIT and its microbiota, the immune system and the CNS are expected to improve overall physical and/or mental

health and we do not expect them to exacerbate or worsen any pre-existing symptoms or illness. In the unlikely event they do, animals will be promptly killed by schedule 1.

Behavioural tests are used to assess motor, cognition and motivational skills and have been chosen over more aversive tests as they have been extensively employed to assess the impact of genetic modification on brain function without requiring the traditional motivational constraints of shock or food deprivation. None of the tests to be used are expected to cause any pain, suffering, distress or lasting harm in well habituated animals. Aged and frail animals may however exhibit excessive signs of distress during these tests in which case they will be immediately withdrawn. If the signs persist they will be killed by schedule 1.

Withdrawing food and/or water for short periods of time and up to a maximum of 12 h for food withdrawal and 4 h for the withdrawal of water should result in no discernible adverse effects. Since rodents consume most of their daily food intake during the dark phase we would fast them during the day to minimise distress. Any animal showing any deviation from normal health or wellbeing will be immediately killed by schedule 1. The administration of modified diets is designed to test the ability of the animals to resist obesogenic diets and some will therefore gain excess weight over the study period. However, a 12 week study period is sufficient to detect an effect of the diet on metabolism and the development of metabolic syndrome, but not long enough for excessive weight gain to cause distress or significant ill health.

Insulin and glucose resistance testing is a well-established method for assessing metabolic status and diagnosing metabolic syndrome. It is not expected that any mice will experience any adverse effects as a result of insulin or glucose administration. However, blood glucose levels will be monitored (at least every 30 minutes) for 2 hours after administration, by which point blood glucose should return to baseline levels. If levels do not return to baseline within 2 hours or if at any time animals display significant clinical or psychological signs of ill health they will be immediately killed by schedule 1.

All animals anaesthetised for imaging purposes are expected to make a full recovery. The interval of repeated general anaesthesia (a minimum of 24 hours) enables animals to make a full recovery as determined by exhibiting normal behaviour, eating and drinking normally and socialising with cage-mates. Any animals failing to fully recovery or that develop signs of significant ill-health such as breathing difficulties, inappetence, hunching, crouching or pilo-erection, will be promptly killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The reasons why this project cannot be undertaken without using protected animals are:

1. Computer modelling and systems biology is not sophisticated enough currently to account for the complex multi-organ interactions or the dynamic activity of multiple cell types within an individual tissue the function of which is determined by their spatial organisation within complex tissue architecture.

2. Laboratory-based assays cannot faithfully replicate or model the complexity of tissues and cell types present in the GI-tract that is integral to its normal function.

2. Laboratory-based assays cannot faithfully replicate or model the interactions involving gut microbes and the myriad of cell types that reside in gut.

3. Many different types of cells in the gut cannot be kept alive outside of the body and cannot be kept alive in the laboratory.

4. A significant proportion of gut microbes cannot be kept alive outside the body and in the laboratory.

5. The gut contains cells comprising the immune system, the nervous system, the endocrine system and multiple types of barrier epithelial cells each of which has their own specific requirements and conditions for growth making it very difficult to study them combined in laboratory-based cell culture systems.

6. The intervention studies proposed in this project cannot be performed in humans due to ethical constraints.

As part of this project we will evaluate the use of newly emerging technologies that might overcome or minimise the factors identified above that would allow us to reduce our animal use. This will include the use of intestinal organoids, organ (gut/brain)-on-a-chip technology, and advanced fermentations systems for culturing intact complex microbial communities.

Reduction

Explain how you will assure the use of minimum numbers of animals.

When designing experiments we rely on 30years past experience, literature searches, consulting the institute statistician and statistical analyses to ensure the minimum number of mice per group that will be informative are used. The exact numbers of animals required will for example vary with the particular experimental design, the estimate of variation in response, and other factors. For qualitative experiments, the amount of material required will be the minimum necessary to provide an adequate description.

To reduce the number of breeding pairs, genetically altered (GA)-mice expressing the mutant gene will be kept wherever possible, provided they remain healthy and able to breed. Breeding schemes will be designed to use the minimum number of breeders to obtain sufficient numbers of age and sexed matched animals of each of the required genotype (wild type, heterozygote, homozygote)

To maximize the information from a single animal and to minimize suffering, we will aim to collect samples post mortem, we will share tissues with other appropriate scientific colleagues for use in their work.

We will as part of this project evaluate the use of newly emerging technologies that would allow us to reduce our animal use. This will include the use of intestinal organoids, organ (gut/brain)-on-a-chip technology, and advanced fermentations systems for culturing intact complex microbial communities.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse is an appropriate and extensively validated model for gut biology and disease and is the species in which reliable genetic engineering technology and germfree experiments is best established. Also, mice are our model species of choice based upon our 30years personal experience of undertaking these experiments. They are also the standard species for producing genetically altered-animals and are the de facto standard for this work globally.

Prior to embarking on animal experiments we will collect as much evidence as possible to determine whether a candidate gene or microorganism is likely to effect gut health and immunity. This will involve collaborating with colleagues that have expertise in gut microorganisms and intestinal organ, and isolated epithelial cell culture. While these techniques hold considerable promise they cannot reproduce the interactions of more than two cell types.

Ageing is major focus of this project and requires the use of aged animals (>20 months). Aged mice will be closely monitored for signs of ill health and any displaying generally accepted end of life signs including non-responsiveness to being touched, cold body temperature to the touch, slow or laboured respiration, hunched body position with matted fur, failure to eat and drink (determined by food hopper weights and degree of dehydration) or, poor body condition score or approaching 20% loss of body weight relative to baseline will immediately be killed by a schedule 1.

Wherever necessary local and general anaesthesia will be used to minimise animal suffering. In all long-term experiments, animals will be promptly killed if they are approaching 20% weight loss and/or if they show any signs of ill health during experiments such as hunching, lack of group behaviour or breathing difficulties.

Microorganisms will be administered at doses known to induce an appropriate inflammatory response. Where the outcome of infection is unknown, dosage will be carefully titrated using small-scale trial studies to minimise any adverse unknown effect.

NON-TECHNICAL SUMMARY

213. The influence of metabolic disturbances on platelet function, thrombosis and vascular inflammation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Blood platelets play critical roles in the prevention of blood loss, termed haemostasis, but also participate in pathological thrombosis, cancer and cardiometabolic diseases. This project aims to dissect the molecular mechanisms unpinning platelet driven disease processes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood platelets are cells that become sticky and clump together to form blood clots to stop us from bleeding after injury. However, in some people platelets also form blood clots inside intact blood vessels leading to heart attacks and strokes. The formation of these blood clots, called thrombi, account for large numbers of deaths in the UK. We know that people at risk of these diseases often have increased levels of fat and sugar in their blood, and that raised fat and sugar concentrations may cause platelets to form clots more readily in the blood stream. However, we do not know how these fats and sugars cause excessive blood clotting. If we can identify the proteins on platelets that respond to fats and sugars it will help doctors understand the causes of blood clots and to develop new medicines to prevent thrombotic disease. The only way we can really examine the importance of these proteins is to increase the amounts of fat or sugar in blood of mice and then determine how blocking or deleting them affects blood clotting. Therefore the work we propose is critically important to help doctors and the pharmaceutical industry to develop new strategies in preventing a major cause of death in the UK and worldwide.

What outputs do you think you will see at the end of this project?

Our key endeavours are academic excellence, unravelling the molecular mechanisms that drive platelet hyperactivity, which could be used to improve the lives of patients at risk of thrombotic diseases. For example, in the lifetime of our previous licence we published two high profile papers describing novel mechanisms of platelet activity and how in principle they could be targeted therapeutically for clinical benefit. Our primary outputs will in the form of academic publications describing these mechanisms. We hope that these publications act as platforms for further studies by our group, and others, to translate our findings to patients at risk of thrombotic disease.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Pathological thrombosis is a major component of the pathology that underlies cardiovascular diseases (CVD) and other chronic diseases. In the UK, CVD accounts for 28% of annual deaths is the greatest cause of mortality, killing approximately 161 000 people in 2012 (www.heartstats.org - British Heart Foundation). Furthermore, these numbers do not take into account the thrombosis related deaths associated with diseases such as cancer and diabetes. Thus, thrombotic disease inflicts a significant health and financial burden on the UK.

The beneficiaries from these output will be varied and include the academic, clinical and pharma sectors. The outcomes we generate from our programme of work will provide new knowledge of platelet driven disease processes providing further opportunities to drive academic excellence. A second element of this will be the generation of new animal models, for example, the generation of platelet specific genetically modified mice that may be applicable to other areas of research including diabetes, cancer and immunity/infection. As is standard with good academic practice all models developed in our laboratory would be shared with the wider scientific community, both directly within our institute and wider afield. Should our work lead to refinements in laboratory practice for example as improved surgical, imaging or experimental procedures these would be made available for other researchers to utilise. Our work programme is focused on a key unmet clinical need. Further exploration of the mechanisms of platelet hyperactivity would allow clinical colleagues insight into the potential causes and management of disease. There are also potential advantages for the pharma industry, who remain highly interested in developing agents to control unwanted platelet activation.

Therefore, the project will continue to help us identify the specific roles of the proteins that regulate or inhibit platelet function and allow us to evaluate their potential as targets for the development of new antiplatelet drugs that could reduce/prevent heart attacks and strokes. While we have no guarantee that the proteins studied will in the future become useful therapeutic targets, it will add to the overall of knowledge of this area of research and help other researchers, both in the UK and internationally, who are focussed on solving problems associated with thrombosis.

How will you maximise the outputs of your work?

We will publicise our findings to the wider scientific community, industry and the public through annual conference presentations, publications and through other media.

Our work is presented on a regular basis within our institute, through research seminars, and often disseminated through academic conferences. These are used to discuss the work in progress and provides a forum with which we can discuss experimental issues (including animal welfare and phenotypes) informally with other experts in order to refine techniques and to help develop best practice. The publication of our work is another major form of dissemination, where we report the findings in a more formal manner. In our recent work we used a similar approach to that outlined in this application to identify a new mechanism of thrombosis.

We aim to publish at least two high impact publications, which build on our previous work. Upon publishing our research results in scientific journals, we will prepare press releases in collaboration with the press offices of the REDACTED. This transparency of approach to sharing of data will maximise our outputs, ensure that our research activities are complementary rather than competitive and that the field moves forward as quickly as possible.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The mice in this part of the project will undergo an altered feeding regimes for up to 16 weeks and then blood harvested under anaesthesia. The procedure will be performed once per animal followed by termination under an approved schedule 1 method.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

There are three areas where adverse effects maybe anticipated.

1. Dietary manipulation - on rare occasions some mice find high calorie diets unpalatable and begin to lose weight. Mice will be monitored daily for their general well-being and weighted on a weekly basis. Should an animal show signs of distress they will be removed from the study returned to a normal diet. If the distress continues the animal will be culled by a schedule 1 procedure.

2. Administration of metabolites/drugs - There could also be potential impacts of administration of substances designed to influence the recruitment of circulating platelets and/or thrombosis. Substances will only be administered where dosing and potential toxicity data are available in the mouse or similar species. Such substances, such as established drugs or metabolites, are therefore not expected to produce adverse side effects at the concentrations administered. It is anticipated that the drugs used in the proposed experiment will be given intravenously on three occasions prior to harvesting of blood. If adverse effects are suspected the animals will be withdrawn from the study. If the adverse reactions persist the animals will be killed by a Schedule 1 or other method stated in the protocol immediately. As data is collected we will review the protocol to ensure that the severity limits are appropriate.

3. Recovery during anaesthesia - The severity of this procedure will be controlled through use and careful monitoring of general anaesthesia throughout. There a possibility the animal recovers prematurely from anaesthesia, although this would be a relatively rare occurrence. To prevent premature recovery from anaesthesia there will be continuous monitoring of the depth of anaesthesia by testing the limb flexion/withdrawal reflex and/or the corneal reflex, which will be supported continual monitoring of heart rate and body temperature. Should there be suspicion that the animal is recovering prematurely additional anaesthetic will be administered by inhalation. However, it is noteworthy that this

has not occurred during the procedures performed in the last five years and therefore we do not anticipate this to be a common occurrence.

In our experience all of the possibilities highlighted above are rare.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The severity level for this protocol for all mice is mild and performed under terminal anaesthesia.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The study of blood platelets is dictated by three limiting factors.

1. There is no reliable in vitro tissue culture models for the generation of platelets from primary megakaryocytes or cell lines hence the only source of platelets is from an animal model.
2. Platelets are not amenable to genetic manipulation since they lack a nucleus. Therefore, transfection studies used by many other researchers as an alternative to animal experiments that work with nucleate cell systems are not possible.

Therefore researchers commonly use genetically altered mice to identify and delineate the pathways involved in platelet activation. This laboratory is committed to perform work with animals only when the potential biomedical advances warrant this. We are interested in developing new approaches that would reduce the use or generation of genetically altered mice to study platelet function, and we are monitoring closely studies in other laboratories that have begun to examine ways to produce genetically modified platelets (using siRNA technology) in vitro from bone marrow culture. Should this technology become available will look to adapting it for our own studies.

What was your strategy for searching for non-animal alternatives?

None

Why were they not suitable?

They lack recognisable platelets.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In the types of studies, we perform the anticipated response is usually “all or nothing’, that is the genetically modified mice fail to respond to stimuli when compared to the wild type. Therefore the numbers for *in vitro* studies of our programme are calculated based on the numbers of samples we can prepare per mouse. For example, the blood from each animal provides approximately 1 ml of washed platelets which is sufficient to prepare for four samples. With this knowledge we can extrapolate to the appropriate number of mice required by determining how many samples are required for each series of experiments within our project. Under these controlled conditions we aim to use approximately 6 mice per strain per assay (and 6 control animals), since platelet responses are generally very reproducible. In general we use between 10 and 15 assays during our functional evaulation.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Our experimental design is driven by studies performed in human platelets, which act as a guide to the potential importance of key proteins in the function of platelets. Careful analysis of the data emerging from these experiments will determine the need for experiments in animals. It is noteworthy that the experiments performed under this licence are *discovery science* and so very little information is available to guide our calculation of numbers. However, given the "all or nothing responses" expected, allows us to ascertain with relatively low numbers of mice whether extensive experiments using multiple in depth assays are required.

What other measures apart from good experimental design will you use to minimise numbers?

We have a number of strategies for optimising animal numbers.

1. The key step is the generation of pilot data from *in vitro* functional assays, lack of phenotype in these assays (usually between 10 and 15 assays) prevents mice being used in experiments that require dietary manipulation and reduces the breeding of mice.

2. All tissues from mice sacrificed under any of the protocols are available for other researchers within our institute.

3. All genotyping is performed by a commercial supplier to allow for industry standardised protocols. Correct genotyping is critical to implementing a targeted breeding strategy that allows for good colony management.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Currently the mouse haemostatic system is considered a strong model for that found in humans and has the advantage of genetic manipulation. Therefore the project will use mice for the proposed studies.

The project uses two key steps to determine how specific proteins affect platelet function, all of which have been designed to avoid suffering and distress in the mice

1. Dietary interventions are mild and therefore do not induce an extreme metabolic phenotype.

2. Harvesting of blood is performed under anaesthesia and without continued use, which again minimise suffering to the animals

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Non-sentient animals cannot be used for our studies since they lack recognisable platelets.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

The major refinement to our protocols is in the area of blood harvesting from mice. We have now moved away from the use of cardiac puncture and take blood from the inferior vena cava. The success rate of harvesting blood using this method is significantly higher and more reproducible, thereby reducing the numbers of mice required for experiments. Furthermore since this procedure is performed under terminal anaesthesia it minimises suffering in the mice.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Major guidance through the project is taken from the NC3Rs, whose website (hubs and microsites) provides a vast array of resources on the general principles underlying the experiments highlighted in this project; this includes anaesthesia, breeding strategy and numbers, and experimental design.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The applicant's laboratory is conversant with the 3Rs and in continually examining ways that the principles are implemented. To ensure this

1. Group members are encouraged to check the NC3Rs resources page

2. We are kept updated by the NIO on a regular basis regarding changes in best practice, courses and additional training.

3. We are aware of the scientific literature in the haemostasis field, where refinements to these types of procedures are reported.

Where changes/advances in practice have been reported we aim to up-skill either through training courses or visiting laboratories to receive guidance.

Explain the choice ofspecies and the related life stages

Mice are the smallest mammal with a haemostatic system similar to that of humans and therefore is an excellent model for evaluating thrombosis and haemostasis in vivo. The murine model has the added advantage of being amenable to genetic manipulation allowing the functional characterisation of specific proteins.

Home Office

NON-TECHNICAL SUMMARY

214. The long-term effects of developmental hypoxia on cardiac function

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Heart disease, Prenatal hypoxia, Antioxidants

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of the project is to investigate the long-term effects of insufficient oxygen supply to an unborn baby. Our specific aims are;

1. To understand the long-term effects of insufficient oxygen on the structure and function of the unborn heart

2. To study the suitability of a class of drugs called "antioxidants" to protect the unborn heart from a lack of oxygen and prevent the development of cardiovascular disease later in life.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The main benefit of the study is the advancement of current understanding of the underlying mechanisms that lead to heart disease in babies that received an insufficient oxygen supply in the womb. We hope to identify novel targets for drug intervention to protect people from developing cardiovascular diseases later in life. All of the findings will be published in peer-reviewed leading scientific and clinical journals as appropriate to ensure wide dissemination of the research findings. The information is of direct benefit to physiologists and clinical cardiologists and will provide key information enabling better management of cardiovascular disease.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Approximately 1110 Wildtype rats, and 30000 zebrafish over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Up to 70 pregnant rats will be placed in a chamber for up to 16 days where oxygen levels will be set between 9-21%. This level of oxygen will cause tissue hypoxia in the pregnant rats (known as prenatal hypoxia) and unborn offspring (known as fetal hypoxia). Most of the pregnant rats subjected to prenatal hypoxia will experience procedures which fall under the mild severity banding, including; 1) transient discomfort from blood sampling needles, 2) transient throat irritation (from intubation) and 3) a transient reduction in water intake. A lesser proportion of pregnant rats will experience symptoms which fall under the category of moderate severity banding, including; 1) a transient reduced activity, 2) a transient

reduction in food intake and body weight, and 3) a transient feeling of being unwell from maternal pre-eclampsia-like symptoms. In addition to maternal adverse effects, most of the pups (up to 550 rats) will experience procedures which fall under the category of moderate severity banding, including; 1) a transient or permanent intrauterine growth restriction (IUGR) which causes a reduction in body weight, and 2) a permanent increase in disease susceptibility. In very rare cases, pups will experience permanent physiological and morphological birth defects. All of the zebrafish in this study (30,000 fish) will experience a transient or permanent reduction in body weight caused by hypoxia. At the end of experimentation, all of the pregnant rats, some of the rat offspring (950 rats) and all of the zebrafish will be humanely killed. The rest of the rat offspring (150 rats) will be delivered to a collaborating establishment for a separate, parallel set of experiments; at the end of these experiments, rats will be humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

We need to use animals because our study is assessing the long-term effects of prenatal hypoxia (up to a year) which cannot be studied in cell lines, nor can they be suitably modelled using computer simulations. It is not possible to use human volunteers because human tissue is of limited availability. Lastly, we cannot use non-protected animal alternatives because we wish our findings to be clinically relevant to human diseases of the heart, and the use of other less sentient species, such as reptiles, fish and amphibians, is usually not appropriate for the main study animal as their hearts differ significantly from mammalian hearts. Nevertheless, we have utilised the zebrafish which are naturally tolerant to hypoxia to understand adaptive responses.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Experimental design has been discussed with, and approved by, our statistical advisor. In order to minimise the number of animals required, sample size has been estimated for each investigation based on existing published data and the use of power analysis. These estimates will be updated and recalculated throughout the project as we generate new data.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Experiments concerning rats:

We have chosen the rat as our main experimental species for several important reasons:

1. Rats reach reproductive maturity quickly and they have a short lifespan (2 years) which allows the long-term effects of prenatal hypoxia to be studied within a reasonable timeframe

2. The rat model of prenatal hypoxia is well-established; there is a wealth of information to base our investigations on.

3. My collaborator has already determined that antioxidant therapy reverses the negative effects of prenatal hypoxia which gives us an opportunity to develop drug treatments to protect the heart.

Steps to minimise welfare costs to animals:

1. It is not possible to house pregnant rats in groups because we need to monitor food and water intake during the study; but once pups have been weaned, rats will be housed in stable, compatible groups.

2. The following parameters will be measured during the protocol to ensure animals remain within the outlined severity limits: Body weight, body condition scoring (BCS), food and water intake and cardiovascular status.

3. Control animals not subjected to any procedures will be used as a benchmark for normal changes in these parameters.

4. For moderate levels of prenatal hypoxia (below 13% oxygen), rats will first be put into the chamber at normal oxygen levels (21%) for 24 hours, and then oxygen will be reduced slowly (over another 24-hour period) to avoid shock.

5. The following rules will be applied to rats transported to collaborator establishments;

- Prior to transport, all rats will undergo a health check by local NVS and at least 2 of the rats will be screened for viruses and pathogens.

- Rats will be transported according to the NC3R's best practice for animal transport, and in line with UK legislation according to the The Welfare of Animals (Transport) (England) Order 2006. We will use a reputable courier who is regularly used by the establishment.

- Upon arrival at the collaborator's establishment, another health check will be made by the collaborators NVS

Experiments concerning fish:

Similar to rats, fish have a short lifespan which make the suitable for longitudinal studies, but they also routinely experience developmental hypoxia in the wild, and they are known to mount adaptive responses to hypoxia. Studying these species will allow us to identify adaptive mechanisms which could be manipulated in mammalian hearts to provide protection against hypoxia.

Steps to minimise welfare costs to animals:

Zebrafish are extremely hypoxia tolerant, so we do not expect any adverse effects from hypoxia exposure. Nevertheless, we will regularly monitor the animals for signs of illness or disease.

Home Office

NON-TECHNICAL SUMMARY

215. The mechanics and energetics of locomotion in birds

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Galliformes (e.g. chicken, guineafowl)	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The overall aim of the project is to determine how muscles are used during locomotion and how this determines the overall amount of energy used (or effort) during exercise. These measurements will underpin efforts to develop methodologies for estimating energy expenditure in freely living birds.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Improving understanding of the energy used during locomotor is of broad scientific relevance and will have impact on a range of disciplines, from ecology to engineering.
Recent advances in engineering means that it is becoming possible to build legged-terrestrial robots and flapping air vehicles that operate on a similar scale to birds. However, their manoeuvrability, control and energy use are still far below that achieved in nature. Understanding bird locomotory systems will provide inspiration towards the development of bio-inspired robotics and more generally the design and control of micromechanical systems.

Such knowledge will also help in the development and refinement of computer models of animal movement. Ultimately, the research will contribute to the replacement, reduction and refinement of animals in testing since the development accurate computational models will allow some animal experiments to be replaced and in other cases reduce the numbers of animals required, as model simulations may allow research involving animals to be better designed.

There increasing interest in the changes in the distribution of organisms in response to climate change. Energy expenditure during movement is an important factor that could influence their migratory paths, distribution and ultimately their survival of birds. An improved ability to study energetics in the field will provide a useful tool to help explain current changes in population and species distribution and in predicting which species are likely to be adversely or favourably affected by future changes in climate.

What outputs do you think you will see at the end of this project?

Research publications targetted at the leading journals in the field.

Conference presentations at leading national and international conferences in a variety of fields to maximize impact.

Practical tools that will allow researchers to better estimate organismal energetics in the field.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Academic beneficiaries (Years 1-5): the research will be of interest to a range of biological fields, including physiology, biomechanics, ecology, robotics, computational biology. For example, ecologists studying the links between animal morphology and ecology and those interested in using practical tools for making informed assessments of bird energy use in the field.

General public (Years 1-5): animal locomotion is a topic that consistently arouses public interest. The research will inspire young audiences to take an interest in science and will have a positive impact by informing the general public about technological advances in animal science and the applications of biological research.

3Rs (Year 5): Developing accurate computational models of locomotion may allow some animal experiments to be replaced and in other cases refined or reduced as model simulations may allow research efforts involving animal research to be better designed.

Conservation NGOs (Year 5): An improved ability to study energetics of locomotion in the field will provide a useful tool, alongside ecological and developmental factors, to help explain current changes in population and species distribution and in predicting which species are likely to be adversely or favourably affected by future changes in climate. The rapid increase in the number of migratory species being studied has revealed the importance of higher resolution data at the individual and population level and the need to understand the ecological and energetic drivers that underpin lifetime reproductive success.

How will you maximise the outputs of your work?

Communication and Engagement
: presentation of the research at leading national and international conferences in a variety of fields to maximize impact.

Public Engagement
: Present our findings to audiences primarily made up of school children/young people [e.g. presentations/ activities associated with animal locomotion at National Science and Engineering Week events).

Internet Resources: A website detailing the objectives of the research will be set up for access by anyone with interest, including school children and teachers. The website will contain details about the project, links to our publications, public engagement activities, conference talks, and associated media exposure. Examples of high-speed video recordings illustrating the science will be included to engage public interest and inform them of the research and its applications.

Symposium/Workshop: organized to disseminate the information acquired during the project. Leading academics will be invited from biomechanical, physiological, and ecological fields, together with representatives from research departments at NGOs such as Royal Society for the Protection of Birds and British Trust for Ornithology.

Species and numbers of animals expected to be used

- Other birds: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Most birds will be trained to exercise until they can sustain locomotion for several minutes, including with the addition of external recording equipment. This may take several months.

Once the birds are trained, the birds will undergo exercise tests under a range of conditions while physiological recordings are made. Some of these recordings will be made while the bird exercises with external recording equipment attached. Other recordings will require the prior surgical implantation of devices internally, which will last approximately 2-4 hours, followed by recordings from the implanted devices once the birds has recovered from surgery, several days later. Once the recordings have been made during locomotion, some birds will be used to measure muscle contractile properties under non-recovery anaesthesia. Birds will be killed at the end of the protocol (7-10 days after surgery).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Some discomfort may be experienced from the presence of the internal devices and from the surgery for up to 24 hours. It is possible that some birds could lose blood during surgery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Unclassified - 29%

Mild - 21%

Moderate - 50%

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The overall aims of our research are to improve our understanding of how muscles function during locomotion. This work can only be done on live, freely moving animals and could not be replaced by a non-animal method. Furthermore to develop and validate computer models of locomotion requires data on the mechanics and energetics of movement. These data do not currently exist for birds, or indeed any other experimental animal. Therefore a systematic physiological and biomechanical investigation of bird locomotion is required in which all the primary determinants and measures of movement and energy expenditure are measured.

What was your strategy for searching for non-animal alternatives?

Computational models could potentially be used to investigate the control of locomotion and the influence of the energetics of locomotion on animal behaviour.

Why were they not suitable?

A comprehensive validation of a computer model requires that a high proportion of the model inputs are measured directly so that the model represents the behaviour of a real animal to the highest possible degree, and
that a high proportion of biomechanical outputs are measured directly so that the accuracy of the model outputs can be measured directly against real data.
These data do not exist for the locomotory system of birds, or indeed any other experimental animal. Although locomotion in animals has been extensively studied, no single study has measured both mechanical and energetics variables in the same species.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Power calculations were performed for each principal outcome measure to determine the minimum number of animals required. Past experience in performing each technique was used to assess the likelihood of success for each measurement, and incorporated into the calculation of animal numbers.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Online sample size calculators were used to calculate the appropriate number of animals for each part of the study together with means and standard deviations from the literature for each of the variables to be measured.

http://www.3rs-reduction.co.uk/html/6__power_and_sample_size.html

http://www.biomath.info

What other measures apart from good experimental design will you use to minimise numbers?

To minimise animal numbers, where feasible, multiple measurements will be made on each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Muscle performance during locomotion will be investigated using a variety of physiological techniques that have been selected as the most suitable approaches currently available for acquiring the data required. Since the purpose of the research is to investigate normal locomotion, it is important to select techniques that will not adversely affect locomotion.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The research must be carried out on animals capable of performing normal locomotion, and can only be done on live, freely moving animals, fully developed, adult animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Surgeries will be carried out by experienced (or closely supervised) individuals. Analgesics will be used post-surgery for pain relief. Post-surgery we will observe the animals for appearance and potential behaviour indicators of pain. In event of observing indicators of pain, analgesia will be used. Any

animal exhibiting excessive swelling at the surgical sites will be killed humanely using a schedule 1 method.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Including, but not limited to,

On anaesthesia and surgery: Degernes, L. (2008). Anesthesia for companion birds. Compend Contin Educ Vet. 30:E2

On husbandry: Hawkins, P. et al. (2001). Laboratory birds: re□finements in husbandry and procedures. Laboratory Animals 35 (Suppl. 1).

Guiding pricicples for preparing for and undertaking aseptic surgery. Laboratory Animal Science Laboratory (2017). http://www.lasa.co.uk/wp-content/uploads/2017/04/Aseptic-surgery-final.pdf

How will you ensure you continue to use the most refined methods during the lifetime of this project?

All project partners are already involved with 3Rs and will participate in reginal NC3R events and liaise with the NC3Rs regional programme manager. In pursuing the programme of research we will implement any advances into our research programme.

Explain the choice of species and the related life stages

Birds have been selected that will sustain either exercise in the laboratory. Species choice is based on experience in previous work. The size of animals that will be used will be determined by that which is suitable for the techniques that we will use. Relatively large species are most suitable because any added recording equipment will have negligible effect on their locomotion.

NON-TECHNICAL SUMMARY

216. The molecular regulation of the immune response

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand how the immune and inflammatory response is regulated with a view to generating novel insights into immune and inflammatory diseases hopefully leading to new therapies.

A retrospective assessment of these aims will be due by 22 November 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The molecules that we study, which are called chemokines, are central to the ability of white blood cells to move to sites of inflammation. Normally this is a healthy process but when this is dysregulated, these white blood cells can cause extensive damage leading to major diseases such as cancer, rheumatoid arthritis and asthma. Our aim is to try to understand how these molecules function with a view to helping to identify novel methods for therapeutically targeting them in inflammatory diseases.

What outputs do you think you will see at the end of this project?

We are interested in trying to understand how inflammation is regulated. Unfortunately this is currently poorly understood and we believe that the proposed programme of work, using existing and novel mouse modelling techniques, will provide unprecedented insights into the inflammatory response. Specifically we will define how molecules called chemokines are involved in orchestrating the inflammatory response. The data to be generated will shed light on the roles for chemokines and their receptors in basic inflammation as well as in inflammation-dependent cancer models and models of viral and bacterial infection. Our data will also have implications for our understanding of chemokine and chemokine receptor involvement in a wide range of human pathologies with the ultimate hope that this will lead to the development of novel therapeutics. We therefore propose that our studies will be of societal benefit in terms of enhancing understanding of inflammatory disease and improving options for therapy.

In addition we are interested in molecules called atypical chemokine receptors which sit in the placenta and are crucial for stopping chemokines moving from the mother to the embryo. When this mechanism fails, chemokines enter the embryonic circulation and can disrupt aspects of embryonic development. We therefore propose to study this mechanism in detail with a view to understanding the implications of disruption of atypical chemokine receptor function on embryonic health and development. We propose that these analyses will be important in helping to understand the molecular basis for a number of

known illnesses and developmental abnormalities that result from the effects of maternal infection and inflammation on the embryo.

At all points we will publish our data in peer-reviewed journals and make it freely available to the scientific community through open access publications.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The beneficiaries from our research fall into 2 broad categories:

1) as chemokines are essential for the establishment of inflammation in many inflammatory diseases, as well as in cancers, an enhanced understanding of their role in these pathologies will highlight novel opportunities for therapeutic intervention. We believe, therefore, that a major benefit of our research will be the development of novel therapies for currently untreatable inflammatory diseases and cancers.

2) the characterisation of the importance of atypical chemokine receptors for blocking chemokine movement from the mother to the embryo will help identify potentially novel mechanisms underpinning developmental abnormalities in children. Specifically we will be interested in looking at whether our molecules are the basis for what is called maternal immune activation in which offspring, born to mothers experiencing inflammation, display neuropsychiatric disorders and altered immune health.

How will you maximise the outputs of your work?

We are very well integrated in the international chemokine and immunology communities and take every effort to present our research to colleagues throughout the world. In addition we publish our research in high profile international journals making them available, through open access publishing, to any interested parties. Furthermore we put a lot of effort into public engagement and present talks to schools and lay groups about our research.

Species and numbers of animals expected to be used

- Mice: 25,000 over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically, animals will be treated with an inducer of inflammation and their response to that inflammatory agent assessed. Inflammatory responses to viral and bacterial pathogens will also be measured as will the involvement of chemokines and their receptors in tumour-associated inflammatory responses. In addition they may be injected with molecules capable of regulating immune response to see what effect this has. In a small number of cases we will surgically implant capsules capable of releasing immune and inflammatory mediators over time. This has the advantage of avoiding repeated injections into the mouse.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Depending on the protocol, animals may experience mild pain, weight loss (not to exceed 20%) and tumour development (tumours not to exceed 1.2 cm in maximum diameter). We also suspect that some of the offspring of mothers treated with inflammatory and immune regulators may display abnormal behaviour although we do not predict that this will be associated with pain. Animals will never be allowed to experience pain or display abnormal behaviour longer than is necessary for the analysis. Weight loss and tumour development have strictly regulated endpoints beyond which animals will not be allowed to remain on the protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The majority of protocols are associated with moderate severity and even for these, moderate severity will only be experienced by a minority of mice. We have 3 protocols which are associated with a severe rating and these relate to infection of mice with Influenza and/or bacteria, or virulent encephalitic viruses. Again not all mice will experience severe adverse effects and mice will be monitored throughout and removed from the study immediately upon appearance of such severe effects.

What will happen to the animals at the end of the study?

- Killed

A retrospective assessment of these predicted harms will be due by 22 November 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune and inflammatory response is complex and involves the interplay of numerous cell types. It is not currently possible to adequately recapitulate this response using cells in vitro. Only in the intact animal will the correct combination of cells and circumstances be present to faithfully reflect the biology of the immune and inflammatory response. In addition, there are a wide range of reagents and molecular approaches available to manipulate the immune and inflammatory response in animals to allow us to detail mechanisms. Again such analyses are currently not possible using non-sentient in vitro alternatives.

What was your strategy for searching for non-animal alternatives?

Wherever possible we use in vitro approaches. In terms of Objective 2, we will use in vitro trophoblast cell lines to analyse some mechanisms. In addition when looking at simple responses of immune and inflammatory cells we do, wherever possible, use cell lines or in vitro derived immune cells.

Why were they not suitable?

These cell lines are not suitable for the majority of analyses because they exist in isolation in vitro in contrast to the in vivo situation in which they are required to interact with a wide array of different cell types to mediate the overall immune and inflammatory response.

A retrospective assessment of replacement will be due by 22 November 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is based on previous HO animal returns and are breeding records. In general we use between 4000 and 5000 mice per year.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We routinely perform power calculations for experiments in which we have limited experience. For most experiments we have many years experience of optimising group numbers. Where power calculations are required we also seek expert advice from colleagues at REDACTED

What other measures apart from good experimental design will you use to minimise numbers?

In all experiments, mouse numbers will be determined to produce statistically robust data and we will not use any mice beyond the numbers required to this end. In addition, for all experiments, as well as harvesting key tissue for analysis, we will store other tissues to allow us to re-analyse them if relevant to addressing secondary questions. This will prevent the need to rerun the experiments for such analyses. We will also share data and tissues with any other interested and appropriately experienced parties.

A retrospective assessment of reduction will be due by 22 November 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

As there is extensive understanding of the immune/inflammatory system the mouse, and as many genetically manipulated mouse strains available, the mouse is the species of choice for our studies. Many of the methods to be employed have been developed and refined over decades of immunology research and are therefore ideal for our intended purposes. Details of minimising animal suffering are given with each protocol.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The majority of our studies are carried out on adult mice as only in these animals will a fully developed immune and inflammatory response be mounted. There is extensive evidence that anaesthetics can alter inflammatory responses and thus our protocols cannot be carried out on terminally anaesthetised animals.The sentient response to the immune inflammatory response is also a key readout of animal well-being and thus the use of less sentiment animals is not appropriate for our studies. In addition, these animals will generally have an immune and inflammatory system that is less well developed than mammals and will therefore not be appropriate for the majority of analysis proposed.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Throughout, we will ensure that we apply the least invasive methods of dosing and sampling including the use of anaesthesia for humane restraint will carry out surgical procedures aseptically and with analgesia to control post-operative pain. To avoid multiple subcutaneous injections we will use osmotic mini pumps to minimise suffering whenever appropriate.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow practice guidance as outlined in the NC3Rs website.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I sit on National grants panels and we have regular updates and discussions on 3Rs developments. We will also stay informed about further advances through the NC3Rs website. In addition there are numerous initiatives run by our REDACTED including local '3Rs' days which my group will attend to ensure that they are kept informed about the most up-to-date advances. We will also regularly access the REDACTED 3Rs website for additional up-to-date information.

Explain the choice of species and the related life stages

Over many decades, mice have been developed as the optimal species for studies of the immune and inflammatory response. Our ability to manipulate the genome of mice and the availability of a wide array of reagents capable of altering and manipulating immune and inflammatory response in mice further make them ideal for our study. In the main we will be using adult mice however we will occasionally study embryonic mice as we believe that some of the molecules that we study may be involved in helping protect the mouse during development.

A retrospective assessment of refinement will be due by 22 November 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

217. The murine hypothalamic-pituitary axis: development and tumorigenesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult, embryo, pregnant, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to understand the mechanisms that control the development of endocrine organs: the hypothalamus and pituitary gland (HP-axis), their effect on peripheral organs and how abnormal development leads to disease such as tumour formation and endocrine deficiencies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The hypothalamus is a part of the central nervous system that controls the secretion of hormones from the pituitary gland. The pituitary gland is at the base of the scull and secretes hormones (natural signalling molecules) that control body growth, reproduction, lactation and metabolism. Together the hypothalamus and pituitary form the hypothalamo-pituitary (HP)-axis which is considered a master regulator of many physiological functions vital for life. Among others functions, it controls reproduction, metabolism, stress response and growth. Moreover, the HP-axis regulates the secretion of hormones into the peripheral blood that control body circadian rhythms, appetite, body temperature and behaviour. Abnormal development of HP-axis, leads to multiple clinical phenotypes and severe endocrine disease affecting multiple organs. These conditions range in severity depending on which hormones are lacking; from severe short stature (due to lack of growth hormone) to multiple hormone deficiencies (with dwarfism, delayed puberty and infertility), gigantism (excess of growth hormone) due to a pituitary growth hormone secreting tumour. Importantly, the genetics underlying these conditions are poorly understood with only 5% of patients having a genetic diagnosis, whilst 95% of the patients have an unknown genetic aetiology that if known could allow for faster treatment and personalised clinical management. Understanding how the HP-axis develops in the mouse as an animal model is key to the identification of novel genes and the pathways that control their function. Moreover, the diseases at the centre of this project are very poorly understood and generating animal models of these conditions allow us to understand the pathology of these diseases, their progression and to identify possible therapeutic agents.

What outputs do you think you will see at the end of this project?

1. Understand the normal functioning and development of the hypothalamo-pituitary axis, but to also to identify causative role of novel genes which can be use to better diagnose these conditions, genetic counselling and personalized treatment based on the genetic abnormality. Publications and dissemination at scientific conferences. Sharing of protocols and reagents.

2. Most of the genetic causes conditions are not known, and these hampers the identification of treatments. Hence, knowing the genetic cause underlying these conditions we can identify molecular

targets (such as Wnt antogonist) that could have therapeutic potential for HP-axis disease. Possible therapeutic treatments of pituitary tumours. Publications and dissemination of results to design medical trials.

3. Increase diagnosis capacity by gene discovery in the NHS.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Patients with hypothalamo-pituitary axis endocrine disease: such as growth hormone deficiency, combined hormone deficiencies, excess of hormones (growth hormone, ACTH, PRL) due to pituitary tumours, infertility, metabolic disorders will all benefit from our research. The prevalence of hypothalamo-pituitary disease in the general population is 1:1000. However the genetic underlying these conditions is poorly undertsood. As stated obove, our research has identified genes important in the causation of hormone deficiencies (Foxa2, Tcf3) which now form part of genetic diagnostic panels. Within the life of this PPL (5 years) we will identify the function of several genes important in HP-axis development that could provide with new genetic diagnosis for congenital (present at birth) HP-axis disease.

Moreover, part of the research described in this PPL aims to identify treatments of pituitary tumours and hence results could have and impact on the mangement of HP-axis tumour disease.

Other researchers within related fields could benefit from the research from this PPL as protocols and reagents will be shared with the scientific community.

How will you maximise the outputs of your work?

All the results obtained from our research will be made available through scientific publications, presentation at international meetings, and local conferences.

All data will be published, even negative results on treatment, lack of specific phenotype in gene ablation experiments. This will ensure that duplication of the results is not produced unnecessary.

Protocols will be shared and mouse resources will be made available to the broader scientific community.

Species and numbers of animals expected to be used

Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

We will use mice that have genes (DNA) modified in the same fashion that human disease to understand how faulty genes results in pituitary disease. Most procedures will use early stage development. When these genes are modified in some instances produce benign tumours that are poorly understood. We will use these models to understand early stages of tumor formations. We will also use these models to assess the therapeutic effect of already established compounds on the tumor growth. As part of understanding the plasticity of the HP-axis upon physiological endocrine challanges, we will use surgical methods to activate the HP-axis by removal of HP-axis target organs such as the gonads (orchidectomy and ovariectomy) and adrenal glands (adrenalectomy). To further understand how HP-axis tumour cells grow and to identify possible tumour growth reducing agents, we will use tumour growth assays by subcutaneous injections and subcutaneous tumour growth in mice. These approach will avoid stereotaxic injections of tumour cells in the brain area (hypothalamus and pituitary gland) whilst providing with good experimental model on tumour growth and assay target thereapeutic agents. This will include injections and/or administration of substances and or imagine techniques. Since the pituitary gland regulates key physiological functions such as puberty, fertility, growth, metabolism, body temperature, partuition, several studies to understand the impact of HP-axis abnormal development and tumour formation on these organs will take place.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Most of the effects on this PPL project are mild, with some protocols being moderate. Protocols: 1. Recipient embryo transfer; 2. Super-ovulation 3. Breeding and maintenance genetically altered animals and 5. Effect of HP axis in puberty; are mild severity protocols with very few adverse effects. Only two protocols: 4. Surgical challenge of HP-axis and 6. HP-axis tumour bearing and growth assays are moderate. Each specific adverse effect is explained under protocol details section of each protocol and under Animal Experience section of each individual protocol of this PPL.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Most of the animals will have mild severity and 15% will have moderate. Although there are some experimental animals that will develop tumours, these tumours are not aggressive in nature and will be only be left to grow for short period of times and not to the point that these result in unnecessary pain.

What will happen to the animals at the end of the study?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The goal of this project is to understand the molecular mechanism controlling the development of the hypothalamo-pituitary (HP)-axis and how aberrant development of this structure affects the endocrine system and can lead to tomour formation. The study of these complex interactions between developmental tissues, signalling molecules and their effect on body homeostasis cannot be studied in humans and requires animal modelling. The interaction between tissues such as the central nervous system regulating secretion of the pituitary hormones which in turn affect peripheral endocrine organs such as reproductive organs, the adrenal glands, pancreas, growth plate, breast, muscles and the thyroid.

Wherever possible we will incorporate *in vitro* models, however it is well recognise that primary pituitary cultures do not recapitulate the physiological pulsatile secretion patterns and are very difficult to maintain for long periods of time. Moreover, pituitary tumours need tumour micro-environment which is important for tumour growth and the tumour micro-environment form of fibroblast, immunocells, fat, endothelial cells is highly complex and difficult to recapitulate in culture.

Additionally, the development of the HP-axis in mouse completely recapitulates the human development, with most of the genetic pathways and signalling molecules having the same pattern of expression and paralleling the development of human HP-axis.

What was your strategy for searching for non-animal alternatives?

We have considered in vitro culture, and whenever possible for tumour growth in vitro cultures will be used derived from human tumour cells lines. However, these in vitro cultures do not recapitulate the physiology of the HP-axis system. Moreover, although certain aspects of the project can be done in vitro (i.e expression of mutant proteins) others are just not feasable as the HP-axis is required for functions such as fertility and these requires a whole-animal system. In silico studies of physiological pulsatile hormonal secretion are not possible and no one has been able to recrate full pubertal or growht in silico as these requires multiorgans positive and negative feedback loops with the hypothalamus.

Why were they not suitable?

In vitro cultures do not recapitulate the physiology of the HP-axis system as this system is complex and involves crosstalk between several organs i.e hypothalamic hormones that impact on the pituitary that in turn via blood target peripheral organs such as the gonads. This multi organ-communication hormonal system has not been able to be created in a dish

Moreover, although certain aspects of the project can be done in vitro (i.e expression of mutant proteins) others are just not feasable as the HP-axis is required for functions such as fertility and these requires a whole-animal system. In silico studies of physiological pulsatile hormonal secretion are notpossible

and no one has been able to recrate full pubertal or growht in silico as these requires multiorgans positive and negative feedback loops with the hypothalamus.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used are and estimation of to maintain complex genetic crosses as breeding nucleus. For instance, the project uses mice that have several mutations (modifications) in different genes and hence need complex breeding schemes. To obtained the final experimental animal, 3 breeding nucleus need be maintained. The final genotype is then crossed with the Cre reporter line which gives 25% of embryos or pups with the desired genotype. Hence, a large percentage of animals is used to generate triple and quadruple transgenic to arrive to the desired experimental phenotype. We work with several genes that mainly form part of the Wnt/b-catenin pathways.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

To reduce the number of mice in this project, we will implement carefully optimised colony management and experimental design. All the genetically altered animals used in this project already exist and are in advance breeding stages in our animal facility.

To avoid surplus of animals, transgenic crosses are maintained in double homologous whenever possible to minimised the number of unwanted genotypes. We will keep stocks of frozen sperm and embryos to avoid unnecessary breeding if a line is not required for several months. Genotypes of mice carrying fluorescent trasngene can be genotype immediately after birth, preventing unnecessary weaning of unwanted genotypes.

For the disease models we aim to use the same parental mice for the first and second repeat experiment which reduces the amount of breading pairs.

For some of the quantitative experiments sample size and power test calculation have been performed based on either pilot study data or already published results. We have use several software methods including the Experimental Design Assistant (EDA) from the NC3Rs (https://www.nc3rs.org.uk/experimental-design-assistant-eda) to ensure that we use the minimum number of mice per group. Here we aim to achieve a minimum power of 0.8, assuming statistical significance of $p<0.05$ (https://www.stat.ubc.ca/~rollin/stats/ssize/n2.html).

In accordance with ARRIVE guidelines, randomisation and blinding will be implemented where appropriate to minimise experimental biases and all experiments will be documented and reported transparently (this is explain in each protocol under power test and sample size).

What other measures apart from good experimental design will you use to minimise numbers?

1. Efficient breeding and maintinance of the colony. Breeders will be kept up to 6 months old for females and maximum one year for males. Breeding cages will be check regularly for their litter frequency and size. Small litters or low litter frequency will be replaced with new breeders.

2. Whenever possible breeding nucleus will be maintained in double homozygotes to avoid genotyping and surplus of wild type genotypes

3. In addition we will share tissue samples with lab members and other users interested in our transgenic lines. This importantly, allows other scientist to gather preliminary results without having to generate their own mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice have been selected because they are a well-validated experimental model for endocrine disease of the HP-axis. They are the lowest form of mammals that mimics key aspect of HP-axis pathology. Moreover, mice are the only mammals where their genomes can be modified and transgene technology works reliably. We will use the Cre Loxp system tissue conditional approach by breeding flox alleles with fluorescent reporters and then we will use these to be crossed with hypothalamic-pituitary specific Cre lines.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Because in lower vertebrates like in xenopus or zebra-fish the HP-axis and its function is completely different not only anatomically but functionally to mouse and humans . Anatomically in lower-vertebrates the hypothalamus develops in a very different way and hence genetic studies do not provide accurate picture.

However, since the best HP-axis models to understand human physiology are mice, inducible models will be used whenever possible, providing with more experimental flexibility, reducing the time window when mice display a phentype.

All surgical procedures will be done aseptically and peroperative analgesia will be given and maintained after surgery for as long as necessary to alleviate pain. Mouse behavior and appearance will be carefully monitored for post-operative pain or discomfort.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinements:

All animals are checked daily by members of our research team.

Tracking breeding performance, age of breeding nucleus, litter frequency, prompt genotyping of unwanted animals.

Use of analgesia in all surgical experiments.

Early induction of oncogenes in tissue specific manner rather than at the genomic level to ensure narrow window of tumour growth.

Early events of tumour formation without allowing for clinical sings.

We will increase the post-operative care in surgical procedures with the help of local veterinary.

In specific protocols such as Imaging techniques, we will use in central facilities.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

1. I regularly follow all the news on the (https://www.nc3rs.org.uk/the-3rs as a member)

2. Best practices on breeding (https://www.jax.org/jax-mice-and-services/customer-support/

manuals-posters-and-guides)

3. I regularly follow news/protocols from the https://ec.europa.eu/environment/chemicals/lab_animals/index_en.htm

4. https://norecopa.no/prepare

How will you ensure you continue to use the most refined methods during the lifetime of this project?

I keep informed about all news related to 3R through the web pages https://www.nc3rs.org.uk/the-3rs.

I regularly attend the NC3Rs meetings organised locally, NC3Rs new letters sent regularly to my email account.

Communication with local veterinary and all members of the REDACTED facility.

Explain the choice ofspecies and the related life stages

Mice will be used in this project. The endocrine organs in mice, especially the pituitary gland develops in a similar fashion to human, therefore they make the perfect animal model to understand endocrine disease in humans. Strains carrying specific gene modification will be studied for their effect on endocrine effects during embryonic development, postnatally for puberty both males and females, and pituitary tumour formation such adenomas and craniopharyngiomas. Pituitary tumours are benign slow growing tumours that have physiological effects as they lead to low production or over-production of one or several hormones. Hence murine models will be studies embryonically (to assess impact of mutated genes in early development) and postnatally both juvenile and adult animals.

NON-TECHNICAL SUMMARY

218. The role of a newly identified calcium channel in cardiac function

Project duration 5 years 0 months Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Heart Failure, Arrhythmia, Ion Channel, Electrophysiology, Excitation Contraction Coupling

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The programme of work has three main objectives.

1. To define mechanistically how the newly identified calcium release channel regulates beating of the heart

2. To identify how the newly identified calcium release channel contributes to irregular calcium leak in the failing heart

3. To determine if this newly identified calcium release channel could be a new target for drug design in the fight against heart failure and fatal arrhythmias

Potential benefits likely to /derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The primary potential benefit of this project relates to new knowledge about the role of the newly identified calcium release channel in controlling the beat-to-beat of the heart and advancing our knowledge of how irregular activity of this channel can contribute to the generation of fatal arrhythmias and heart failure. The aim is to publish the findings in academic journals where the information is likely to be of interest to pre-clinical scientists interested cardiovascular science and ion channel physiology.

There is also a secondary potential benefit which relates to the value of the results to clinicians, in particular cardiologists, and to the possibility that new molecular targets may be identified, for which new pharmaceutical products could be developed

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use 980 GM mice during the course of this project (5 year period). We can breed from a pair of genet-ically altered mice lacking our protein of interest, meaning that all offspring will be genetically identical to their parents. Breeding appears to be normal for genetically altered mice with an average litter size of 4-6. Mice will be used at 16-20 weeks old.

By knowing the standard deviation (SD) from the mean from previous published (both from our group and others) and/or pilot experiments, the expected size of the response and the number of cells/experiments from an isolation that I can typically record data from, power calculation approaches can be adapted to give an indication of minimum required number of animals. The estimated number of animals required for each experiment is based on is the results of 2-tailed power calculations for each type of experiment. For all power calculations power value= 0.9.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Our experiments will involve the use heart tissue obtained from mice following the killing of animals via humane methods. The severity of the procedures conducted are expected to be subthreshold.

The genetically modified mice are already established in our collaborators laboratory and show no obvious sign of any adverse effects. Severity is therefore graded in the sub-threshold or mild range .This is a new line of investigation however and so during the lifetime of the study should any animals exhibit signs of pain, distress or significant ill health they will be killed humanely. All animals will be humanely killed at the end of the experiments by trained staff.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Most of the studies on the properties of this new calcium permeable channel have been initially carried out in-vitro both at the single molecule level and using a cell culture models. We have recently begun to utilise human stem-cell derived cell culture models to investigate these basic principles. Human stem cells however are electrically different from mature heart cells. Full testing of the role of this calcium channel in regulating heart beat can therefore only be validated using a genetically altered mouse model whereby the protein is lacking. There are no other mouse models available to investigate this protein. There also remain too many unknowns for computer simulations to replace the use of animal tissue.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Our use of the in-vitro methods already discussed (single molecule electrophysiology, cell culture material and human tissue cultures) will reduce the numbers of animals required for the in-vivo investigation stage. One of the key principles of our experimental design is that the maximum amount of data should be obtained from each animal killed thus reducing animal numbers. This is facilitated through the use of isolated heart cells which last up to 4 hours. The design of individual experiments will generally involve factorial designs, which maximise the information obtained from the minimum resource. The proposed experimental designs and methods of analysis of the results have been discussed with the Statistical Services Unit.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The advantage of using a transgenic mouse model (where the protein of interest is lacking) is that it may give a more accurate result than using standard molecular methods which only reduce the amount of protein expressed. Such standard (knock-down) molecular methods have a low efficiency rate and the level of protein expression can be variable. The use of transgenic mice will therefore reduce variability and produce better scientific results. This will minimise the number of animals required over the lifetime of the project.

NON-TECHNICAL SUMMARY

219. The role of DNA Damage response and replication factors in genome stability and cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

During the course of the most recent licence, we generated several new DNA Damage Response (DDR) gene knockouts in mice, some of which presented with accelerated tumourigenesis, immunodeficiency, neurological problems and/or infertility. Hence, the overall aim of this project is to better define the role of DDR genes in tumorigenesis and the impact on other diseases/phenotypes including immunodeficiencies, neurological problems and/or infertility. We would like to determine which DDR genes are involved in tumorigenesis particularly and which strategies could be used to counteract the development of these tumours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The DDR is composed of multiple pathways and involves processes necessary to repair DNA lesions such as double-strand break, damaged bases, impaired replication and other genomic insults. The DDR is critical to healthy cells in order to preserve genomic stability and prevent tumor formation and other pathologies. In humans, hereditary mutations in DDR genes are associated with a wide range of cancer susceptibility, neurodegenerative, immunodeficiency and infertility disorders. Furthermore, the DDR is often somatically deregulated in many cancers, which renders the cells more susceptible to DNA damage and makes them more reliant on other pathways for survival. Targeting DDR is one of the most exciting therapeutic strategies for treating cancer, which can be exploited to selectively induce cancer cell death. Studying the DDR in more detail may reveal unappreciated vulnerabilities that could be targeted in cancer therapy. Interrogating the DDR in animals will also improve our understanding of the roles of these processes in immunity, fertility and/or neurophysiology.

What outputs do you think you will see at the end of this project?

The focus of my lab is to understand how DDR pathways, including homologous recombination (HR), contribute to organismal homeostasis and disease. Since DDR processes are commonly inactivated in hereditary human diseases and are frequently inactivated at a somatic level in many cancers, we aim to understand how these pathways impact on human pathologies including cancer, immunodeficiency, accelerated aging and fertility. By exploiting the respective experimental strengths of C. elegans, frog extracts and mammalian cell culture my lab has discovered new DNA repair genes relevant to human disease. The purpose of this project is to determine how these disease relevant genes contribute to genome stability, immunodeficiency, aging and cancer using mouse models. Our work also has the potential to inform on novel opportunities for directed cancer therapy and other human syndromes affecting fertility, immunity, development which we will also explore in mice.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may

accrue after the project is finished)?

Our studies aim to provide fundamental new insights into mechanisms by which cells and whole organisms repair DNA damage to maintain genomic integrity and how unrepaired DNA can affect cancer development and other pathologies (immunodeficiency, infertility, accelerated aging).

The questions addressed in our studies are clinically relevant as unrepaired/mis-repaired DNA damage has been shown to be an important first step in the process of carcinogenesis and also impact on the development of germ cells and the immune system. The data generated by this project will not only improve our understanding of DNA repair mechanisms and how this affects organismal homeostasis but will also inform on the development of targeted therapeutics. Only by inducing dysregulation of DNA damage repair pathways in vivo will we be able to uncover their roles in carcinogenesis and/or organismal physiology.

How will you maximise the outputs of your work?

Findings will be made available to the broader scientific community through publication in peer-reviewed journals and presentations in scientific conferences. Data will also be deposited onto publicly accessible databases. Newly created transgenic animals will be distributed widely to the scientific community as these lines generated under the authority of this Project Licence will be very valuable to the research community.

Species and numbers of animals expected to be used

- Mice: 15200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice used will be generated to create conditional knockout, knockin, conditional over-expressing and/or BAC transgenic mice for genes we have previously implicated in the maintenance of genome stability (Protocol 1 and 2) or will be provided by other projects with authority to breed, maintain and/or supply transgenic mice.

We will investigate the relationship and genetic interactions between the resulting mice and other mutant mice that exhibit genome instability phenotypes and/or meiotic defects (Protocol 3, 4, 8, 9).

We will also characterise the tumour predisposition, neurological, immunological and/or meiotic phenotype of these mice (Protocol 3, 4, 5, 6, 7, 8, 9).

The principle aim of objectives 1-3 will be the detailed examination of tumour incidence, meiotic, immune-deficiency or neurodegenerative phenotypes in mice mutated in novel genome maintenance genes. The significance of tumour predisposition, meiotic, immune-deficiency or neurological phenotypes conferred by a particular genetic background will be judged by comparison to established mice (Protocol 3), which should show clear statistically significant difference from controls (ANOVA). Tumour predisposition will also be assessed by treating mutant mice with gene inducers or modifiers, DNA damaging agents, carcinogens, tumour promotor (Protocol 3) or by injection of cells mutated for DNA damage response genes (as for example ALC1, Rad51, WRNIP) into nude mice (Protocol 4, 5, 6, 7). These objectives can only be addressed using whole animal models, as modelling tumour development to this level of detail is not possible in vitro. The minimum number of animals will be used and all suffering kept to the lowest possible level by ensuring that animals bearing tumours are sacrificed before the tumours reach a size that is likely to cause distress.

In general, determining tumour predisposition in mice bearing a mutation in DNA Damage response genes will be fulfilled by 2 complementary ways: first, we will monitor mice in aging cohorts by performing a daily health check (clinical examination, abdominal palpation and imaging if necessary) (Protocol 3). Second, we will use a small cohort of animals, which will be treated with chemicals and notably tumour inducers/promoters and/or carcinogens (Protocol 7, 8). These 2 complementary ways should allow us to demonstrate if a particular DNA damage response gene has a role in tumour formation. Chemical carcinogenesis is one of the best-established in vivo models for the study of tumour development and for evaluating tumour initiation, promotion and progression (Protocol 8). Well-established methods also require use of a procarcinogen such as diethylnitrosamine in combination with a high fat diet to allow tumour development (Protocol 7). The high fat diet will also induce obesity, which will be used as a tumour promotor. The quantities and frequencies of the chemical used should result in no more than transient discomfort and no lasting harm. Carcinogenesis protocols (chemical or UV) have been developed for the study of tumours in mice (i.e., tumour incidence, latency, multiplicity and progression). In complete carcinogenesis protocols, tumour development occurs either after the administration of a single high dose (or repeated applications of a lower dose) of a carcinogen or by repeated low dose exposure to ultraviolet (UV) light. UV/X-irradiation will also be used as a potential in vivo inducer of DNA damage that will in a time dependent manner induce tumour formation. Mutant animals as well as controls will be subjected to single or multiple doses of either UV or X-irradiation to allow us to determine the role of specific DNA damage response genes in DNA repair (Protocol 3, 4, 5, 6, 7, 8, 9).

Non-invasive imaging will be employed in Protocol 3, 4, 5, 6, 7, 8 to ensure that we can detect tumour(s) arising in mice as soon as possible and minimize animal suffering. We will use different types

of imaging such as bioluminescence or fluorescence imaging to monitor tumour formation and growth (when for example using B16F10 cells expressing a fluorescent or bioluminescent transgene: B16-F10-Luc or B16-F10-RFP). In some cases, we may want to follow tumour progression by non invasive MRI or microCT. All imaging will be performed by experienced people working at the REDACTED imaging facility.

Clinical examination, abdominal palpations and imaging will be used to assess and confirm tumour presence in our animals. It will allow us to limit tumour burden to a minimum.

We will also assess neurological problems by employing SHIRPA behavioural tests in protocol 3.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

An important aspect of our research is to monitor animals that have genetic modifications throughout the term of their natural lifespan (up to 24 months) in order to study and assess their phenotype (Protocol 3). Humane endpoints for mice used in such longevity studies have rarely been addressed, despite the expectation that health problems will become more common as the mice age. Natural and spontaneous death can occur without being linked to any genotype. In rare cases, aged animals can die without having shown any prior signs of illness or deterioration in health. We will monitor animals at risk with greater than usual frequency and any changes in their health status will be accurately recorded in a form specifically designed for animals at risk of death and archived. If animals are found dead without having shown prior clinical signs, post-mortem investigation will aid determination of cause of death and this data will then be analysed as soon as possible so that early euthanasia can be performed on other animals to promote their wellbeing as well as facilitating collection of valuable samples and measurements.

Mice on protocol 4, 5, 6, 7, and 8 will develop tumours as adverse effects. For mice used under protocol 4, 5, 6, tumours development will generally be monitored twice a week by either calliper measurement and/or imaging if possible. Animals developing tumours larger than 1.2cm or 1.5cm will be humanely sacrificed. These experiments should be short term experiment that may be no longer than 3 months. Mice under protocol 7 and 8 should also develop either external (protocol 7) or internal (protocol 8) tumours that will be monitored frequently. These protocols may last up to a year to follow induced tumours development in a genetically altered animal.

In this project, substance administration should not cause adverse effects that are longer than temporary and transitory as we will for most of them use doses that have already been described by the scientific community.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Only mice will be used in this project.

A high proportion of mice (75%) should develop phenotypes of moderate severity as a result of tumours development, immunodeficiency and/or neurological problems. A subset of these mice will also be used for tissue harvest and/or cells production.

25% will have a mild severity and the remaining would be subthreshold.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our studies and those in the published literature on the DNA damage repair pathways and other DDR genes are suggestive of roles in maintenance of genome stability and tumour avoidance; Brca1, Rif1, Rtel1 and ALC1 have been observed to be either amplified or inactivated in tumours depending on context. What remains unclear is if these changes are a cause or a consequence of tumorigenesis. Animal experiments remain the only definitive test of whether inactivation/over-expression of these genes is relevant for tumour formation. These issues can only be addressed using whole animal models, as modelling tumour development to this level of detail is not possible in vitro. The use of mice offers an unparalleled level of genetic tractability in an organism that develops cancers, immune-deficiency or neurological logical problems that are comparable to those occurring in humans.

3D model such as cultured organoids are good model to answer a specific question but the relevance at the human level is very limited as it does not include the specific environment in which a tumour is growing. Only a genetically altered mouse model will be reproducing the same environment than the one observed in a human body. Moreover, genetic drift in organoids culture may happen quicker and won’t be as well controlled as it is in a mouse model.

What was your strategy for searching for non-animal alternatives?

All of our proposed studies aim to build on extensive groundwork in model organisms, mammalian cell culture and during the last 5 years in mouse models. The objectives outlined in this application represent the next and most pertinent step forward in our mouse studies, which is likely to provide novel insights into the impact of these factors on organismal biology and disease. We are currently using a multi system approach to answer questions addressed in our studies. For example, we use the

C.elegans worm model as it is a very easy organism to genetically manipulate. It makes the study of synthetic lethality very accessible due to its quick reproduction and also is a very good model for studying meiosis as all steps of it are represented in the germline. We also use the frog model X.laevis to study replication-coupled DNA repair. One of our main tools is the use of mammalian cell culture, which was recently revolutionised by the discovery of CRISPR. Generation of genetically altered mouse or human cell lines is proving to be easier and quicker with CRISPR techniques and these cell lines can be used to do targeted proteomic screens that will give us more insight on molecular mechanisms that we will be able to study more in depth at the level of a whole organism. Only by inducing dysregulation of DNA damage repair pathways in vivo will we be able to uncover their roles in carcinogenesis and/or organismal physiology.

Why were they not suitable?

The proposed experiments simply cannot be addressed in frogs, worms or other model organisms, as they do not develop tumours, immune-deficiency or neurological problems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For obtaining statistically significant and reproducible results, we will include a positive and a negative control group which will give validity to the ongoing experiment. Wherever possible, power calculation with a power of 80-90% and a type I error rate of 5% will be used to more accurately estimate the number of animals needed to ensure a statistically significant outcome and avoid unnecessary experiment duplication.

In all in vivo experiment, the number of mice required for a specific experiment is based on 3 criteria:

1. The number of animals for each set of experiments
2. The number of experiments (needs to be perform 2 independent times)
3. Pilot studies and previous experience performing a similar experiment

Where necessary we will also consult the bioinformatics and biostatistics group at the REDACTED during the experimental design stage to ensure that the appropriate numbers of mice are used per experiment.

All experiments/procedures notably tumour development measurement will be performed limiting the animals' number to the minimum required for a valid scientific outcome.

A specific subset/cohort of animals will be used under each protocol. We will also use animals to harvest tissue and/or produce cells (MEFs, ES cells). Some experiments could require up to five genetic modifications to be bred into one animal, which would require extensive breeding programmes.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Mouse breeding experiments will be planned in consultation with the REDACTED BRF and the basic principles of mouse breeding will be adhered to and gestation times, weaning age and litter sizes used to calculate the numbers of mice required to optimise the size of the colony. REDACTED will be routinely maintained by keeping 2 breeding pairs. For crosses under analysis for specific phenotypes it is likely that 5-6 breeding pairs will be maintained for the duration of the experiment. However, every effort will be made to reduce the number of animals required for experiments, always keeping in mind that enough animals are used not to prejudice the generation of statistically relevant results. For exploratory (pilot) experiments the least number of animals will be used (usually 4-6 per genotype/experimental group) to provide a reasonable estimate of the numbers of animals needed to produce statistically relevant information in subsequent quantitative experiments. Where possible we will use data from published experiments to provide an estimate of the sample size.

Where necessary we will also consult the bioinformatics and biostatistics group at the REDACTED during the experimental design stage to ensure that the appropriate numbers of mice are used per experiment. We will also use the Experimental Design Assistant from NC3R to help us design our experiments (ensure the use of minimum number of animals consistent with our scientific objectives).

For multiple genetic modification, we will investigate alternative methodologies to enable reduced numbers of animals to be used. This will be to use viral delivery of the expression modifying genes CRE and tetracycline activator via different routes (intratracheal, intraperitoneal, topical application). This would require two less genetic modifications to be present in the mice, so would greatly reduce the size of the breeding programme.

We will also reduce numbers of mice by cryopreserving sperm or embryos with the help of the Genetic Modification Services of the REDACTED.

What other measures apart from good experimental design will you use to minimise numbers?

We are always looking for ways to reduce the number of animals that we produce. Breeding efficiency is key and for strains that are known to have low breeding efficiency, we feed females with baby milk mash. This allow us to use less mice for breeding and also increases the chance to have a higher number of embryos/pups in some of our C57BL6 mice. Moreover, most of our xenograft studies start with pilot experiment using small animal cohorts that lead to a refinement in term of cell number

injected, and/or doses used for specific compounds and give us insight into experiment duration; and where possible we will use a single group of animals as a control for several treatment groups.

Other ways in which we will aim to reduce mouse numbers will include freezing down transgenic lines; deriving cell lines from mice for specific cell culture experiments; providing tissues from our mice to other labs.

The breeding of genetically altered mice will be reduced through collaborative access to strains.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Mice will be our model of choice during this project. The use of mice offers an unparalleled level of genetic tractability in an organism that develops cancers, immune-deficiency or neurological problems that are comparable to those occurring in humans. This is particularly relevant to our objective where we are attempting to provide evidence that DNA damage response factors are involved in specific diseases. We will first attempt to test our hypothesis in tissue culture with cells derived from these animals, but ultimately, it is experiments within the animal that will have the biggest impact on human disease. We will minimise the numbers of animal used and minimise the suffering of animals during experimental procedures.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice and Human are biologically and genetically very similar. By using mice, we ensure that we can study the effect of a single specific genetic alteration (for example found in human breast cancer or any other disease that have a deregulated DNA Damage repair pathway) in a very controlled organism. Moreover, spontaneous tumourigenesis resembling human tumorigenesis cannot be reproduced in other organisms (flies, worm, frog, cell culture) than a mouse model, as they do not develop tumours, immune-deficiency or neurological problems. Where possible experiments on animals will be replaced with experiments on cultured cells, C.elegans and X.laevis as outlined above. We will first attempt to test our hypothesis in tissue culture with cells derived from these animals, but ultimately, it is experiments within the animal that will have the biggest impact on human disease and new therapy findings. We will minimise the numbers of animal used and minimise the suffering of animals during experimental procedures.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will monitor animals at risk with greater than usual frequency and any changes in their health status will be accurately recorded in a form specifically designed for animals at risk of death and archived. If animals are found dead without having shown prior clinical signs, post-mortem investigation will aid determination of cause of death and this data will then be analysed as soon as possible so that early euthanasia can be performed on other animals to promote their wellbeing as well as facilitating collection of valuable samples and measurements. We will use palpation and imaging in order to limit adverse effects due to tumour development.

The weight of the animals going through a procedure will be monitored closely to ensure weight is stably increasing and is not affected by any procedure that a mouse went through.

Most of the protocols that we are using in this project are well established protocols that have been widely used by the scientific community. We will follow them closely by administering the recommended concentration of substances (such as chemical carcinogen, tumours initiator and promotor, IR/UV doses, antigen concentration).

To improve our breeding efficiency with difficult to breed mice, animals will be fed with mashed food supplemented with milk powder.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

FELASA “Working Group on Pain and distress” and NCRI guidelines will be employed to aid in the assessment of pain and distress and used to determine the earliest endpoint possible to allow a valid scientific outcome.

When assessing tumour burden, the NCRI Guidelines for the Welfare and Use of Animals in Cancer Research will be followed.

In addition, we will follow the PREPARE guidelines when designing experiments and ARRIVE guidelines when publishing to allow better reproducibility and avoid work duplications.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We are currently subscribing to the NC3R monthly newsletter which gives us information on any techniques’ improvement and 3R advances. We are also in relation with the regional programme manager for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) who can give us advice and support on the 3Rs for our project.

Explain the choice ofspecies and the related life stages

The use of mice offers an unparalleled level of genetic tractability in an organism that develops cancers, immune-deficiency or neurological problems (such as ataxia, impaired balance, coordination and/or behaviour) that are comparable to those occurring in humans. This is particularly relevant to our objective where we are attempting to provide evidence that DNA damage response factors are involved in specific diseases (any types of cancer, Riddle syndrome, Hoyeraal-Hreidarsson syndrome, FILS). We will first attempt to test our hypothesis in tissue culture with cells derived from these animals, but ultimately, it is experiments within the animal that will have the biggest impact on how human diseases such as cancer develop. The proposed experiments simply cannot be addressed in flies, worms or other model organisms, as they do not develop tumours, immune-deficiency or neurological problems. Where possible experiments on animals will be replaced with experiments on cultured cells as outlined above. However, in cases where this is not applicable, we will adhere to the three Rs (Replacement, Reduction and Refinement) to minimise the numbers of animal used and minimise the suffering of animals during experimental procedures.

Home Office

NON-TECHNICAL SUMMARY

220. The role of muscle stem cells in health and disease

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Skeletal Muscle, Muscle stem cell, Muscle Cancer, Muscular Dystrophy, Facioscapulohumeral muscular dystrophy

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Skeletal muscle is able to repair and regenerate because of resident stem cell. However, as people get older, this repair becomes less efficient, leading to muscle weakness and wasting. Repair also fails in some diseases, again leading to weakness and wasting. Muscle stem cells can also become deregulated, which can lead them to forming cancerous tumours. We investigate the regulation of muscle stem cells to understand how they are controlled in healthy muscle, and what goes wrong in disease. This research will inform the development of therapies to treat such muscle disease and possibly ameliorate some of the effects of aging on muscle function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Understanding how muscle stem cells are regulated in healthy muscle, and what goes wrong in disease and cancer, will lead to potential therapies to ameliorate this deterioration in muscle stem cell function.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We use mouse, and estimate that we will use approximately 2600 over the five year duration of this licence.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

To understand how muscle repairs itself after injury, we need to damage specific muscles while the mouse is anaesthetised and then examine the repair process. Since we only injury one muscle, the vast majority of the limb musculature is unaffected, and so gross limb function remains overtly normal. After the experiments, the mice will be humanely killed and their tissues removed for analysis.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Obtaining muscle cells directly from patients for every experimental procedure is impractical. We will use human cell lines derived from healthy and patients, together with mouse cell lines where available.

The most effective model for routinely obtaining stem cells however, is mouse, and mice have been generated that model many human diseases. These cells form muscle fibres in tissue culture, but do not mature without nerves, blood vessels and connective tissue. This is why we have to examine muscle stem cells directly from the mouse.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Our extensive use of cell lines limits the numbers of animals required. Where possible we initiate regeneration in one leg and use the other as the control. Mice will be bred so that we get the maximum progeny with the correct genotype that we need. Pilot studies will be performed to determine the lowest effective dose with new reagents and estimate sample size. The aim is to use the minimum number of animals to obtain statistically significant results and thus be able to determine any difference between experimental and control group.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our standard non-human model is the mouse, a mammal with a short gestation period and the ability to be relatively easily genetically altered, thus there are many mouse models available. Mouse is also a good model to study regulation of muscle regeneration since there are many useful reagents available. Furthermore, human and mouse cells will fuse together to form mosaic human/mouse muscle fibres in culture, showing that many of the signalling molecules are able to interact. Importantly, many of the key genes involved are conserved in man. We would therefore expect findings on mouse satellite cell regulation, muscle regeneration, disease progression and therapeutic intervention to be broadly applicable to human.

Good animal husbandry practice is used, and advice sought where necessary. There is a regular use of pain-killers after surgery, and steps like providing moistened food on the floor on the cage used where needed. For transgenic and genetically altered mice, inducible constructs will be used whenever possible, so there should be no phenotype until candidate gene expression or deletion is induced. By targeting the induction to muscle for example, we should avoid any potentially damaging effects of systemic expression. We do not undertake any procedures that are classified as severe.

NON-TECHNICAL SUMMARY

221. The role of RAS and RHO-like GTPases and their regulators in lung cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To identify changes in signalling genes in lung cancer cells, and to relate these changes to the ability of lung cancer cells to multiply and spread. Ultimately, to use this knowledge to develop new treatments for patients with lung cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lung cancer accounts for nearly a quarter of UK cancer deaths. Its most common histological subtype is adenocarcinoma (50-55% of patients), of which the most common driver mutation is in the small GTPase KRAS (a cell signalling gene) (~30% internationally). Genetic data has altered the classification of non-small cell lung cancer (NSCLC) over the past 10 years, highlighting specific genetic alterations (in signalling genes), which have improved prognosis and are susceptible to targeted therapies. However, no targeted therapies exist for lung cancers caused by the KRAS mutant gene (KRASm). There are three main variations of the KRAS gene in NSCLC. Breakthroughs in targeting these mutant KRAS variants have the potential to offer similar, if not greater, clinical impact to current targeting therapies against other signalling genes. Studies increasingly support the hypothesis that distinct KRAS activating gene variations may promote lung cancer formation via different mechanisms and this may be exploited for variation-specific treatment interventions. We therefore aim to characterise the relative roles of KRASm gene variations in NSCLC tumourigenesis using cell as well as mouse studies. In doing this, our goal is to further refine classification of NSCLC providing evidence to support the subdivision of KRASm lung cancer resulting in more personalised medicine.

It is well established that the enzyme RAC is required for the formation and growth of many types of tumours including KRAS mutant NSCLC. Our recent cell derived data have also shown that RAC and certain of its activators are required for survival of small cell lung cancer cells (SCLC), a highly metastatic subtype of lung cancer accounting for around 15% of all lung cancers. RAC is a member of a family of related molecules called RHO GTPases. These molecules and their activators and regulators are important not only for the survival and growth of tumour cells, but also for the metastatic (cancer spread) process. Metastasis is a challenging clinical problem and is the cause of most cancer deaths. The involvement of RHO GTPase signalling in the survival, growth as well as metastasis of cancer cells, means that RHO GTPases and their many regulators are candidate therapeutic targets for cancer growth and spreading.

What outputs do you think you will see at the end of this project?

The primary output of this project is data / information that advances our mechanistic knowledge of how different mutant variations of RAS and RHO GTPases drive the development and progression of lung cancer. Our findings will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences and meetings.

The expected benefits of the work can be summarised as follows:

1) Knowledge of the pathways by which the different KRAS variants and associated biochemical pathways present in NSCLC control lung tumour formation and progression

2) Understanding the role and mechanism by which members of the RHO GTPase family of enzymes regulate NSCLC and SCLC

3) By integrating the knowledge gained from the above research, we aim to identify key therapeutic targets for future hypothesis driven therapeutic intervention

4) Test novel therapeutic agents currently investigated in clinical trials and their potential mechanism of loss of effectiveness due to drug resistance

5) Publication in high quality journals and presentation at conferences to share the work with the wider scientific community

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We anticipate that a large part of benefits stated above would be seen within the 5 year duration of the project. The main beneficiaries of these will be other scientists, health professionals as well as pharmaceutical companies working on lung cancer. We anticipate that patients won't be able to benefit from this work within the time frame of this project licence, but might benefit in the next 10 years. Patient benefit might be via better classifying lung cancer and understanding better which patients are likely to respond to current treatments as well as by developing new compounds.

How will you maximise the outputs of your work?

Our findings will be made available to other scientists through collaborations, publication in high quality journals and presentations at scientific conferences and meetings. Our Institute has a policy of ensuring that all publications from Institute scientists are available on free access to all.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Some mice (bred under other Project Licences) harbour genetic modifications that pre-dispose them to the development of lung cancers when exposed to an appropriate inducing agent. Furthermore, some genetic modifications allow us to track specific cells within the tumour (such as T cells). In other mice, which are bred specifically to tolerate human cells, tumours will be implanted under the skin of the mouse for ease of monitoring or into the lung so that cells are placed in their physiological environment. Mouse cancer cell lines can be transplanted into mice sharing the same genetic background (so called syngeneic mice) without rejection. Tumour growth is not associated with pain during the period in which we conduct our observations. Tumour growth will be monitored regularly by either use of callipers for superficial tumours, or by imaging methods for internal tumours. Mice with tumours will be monitored daily. For some procedures that involve surgery under general anaesthesia, such as implanting human tumour fragments or removing a primary tumour in order for a secondary tumour to grow, we will administer pain killers and monitor the mice closely during recovery from anaesthesia.

Some mice may have either potential novel therapeutic agents, existing clinical agents or dummy-drug administered by a variety of routes, but usually either by mouth, or by injection either under the skin or into the abdomen to study the effects on tumour growth and / or tumour composition. Mice may be studied for up to 200 days after a period of therapeutic agent treatment for tumour growth. The mice will also have blood samples taken either from the tail vein or by sampling from a heart chamber under anaesthesia (in which case the animal does not regain consciousness before humane termination). Occasionally mice may be administered organ preservative whilst under non-recovery anaesthesia to allow us to undertake investigations on slices of selected organs observed under a microscope.

Mice will be group housed in ventilated cages which have their environment enhanced with items such as tunnels, houses, nesting material and gnawing blocks.

At the end of any protocol mice will be humanely killed.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The impact of tumourigenic mutations are not expected to cause any adverse effects per se as these in most cases only manifest following inhalation of inducing agents. Following inhalation of inducing agents mice carrying tumourigenic mutations are expected to have lung tumours. It is possible that the tumour growth might affect normal physiological functions (such as eating, locomotion or breathing). However, mice will be observed daily and any side effect that cannot be managed satisfactorily will result in humane culling of the animal.

Injections would only cause very transient pain.

After surgical procedures we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of mice are only expected to experience the mildest clinical symptoms due to tumour growth before they are humanely sacrificed. Additionally, some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery with a specialist tube. We will aim to utilise the least stressful route of administration wherever possible.

A minority of mice will undergo surgery and these will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing this is not painful.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While valuable studies of human cancer are performed using tumour material and cell lines derived from both mice and human samples, the mechanistic understanding of cancer development and spread requires use of living animals. In particular, cancer development and spread involves a plethora of interactions between cancer cells and their surrounding host and their behaviour is governed by multiple signals originating from both their immediate neighbours and from distant tissues.

Genetically altered mouse models have been engineered to develop cancers, which accurately mimic their human counterparts. These models can be used to test the effectiveness of novel cancer therapeutics that have been developed for humans as there is a big similarity between human and mouse proteins. Mice cannot be replaced by different animal models such as zebrafish or insects which remain far less complex than their murine counterparts and for the purpose of our work do not have lungs.

What was your strategy for searching for non-animal alternatives?

We will use a variety of cell-based approaches to investigate how manipulation of RAS and signalling pathways of interest alter cell behaviour in cultured lung cancer cells prior to undertaking in vivo studies. We also make use of human lung cancer specimens and sequencing data to generate further evidence in support of our hypotheses and to check that findings are relevant to clinical samples.

Why were they not suitable?

The study of cells in culture (in vitro) provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume or tumour incidence following manipulation of a gene of interest or treatment with a drug can be determined using a minimal number of animals.

Data available from the literature or from pilot studies are used to determine an appropriate sample size for the definitive experiment. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.

Based on past experience, group sizes of between 10 and 30 animals (dependent on the readout; fewer for transplanted tumours compared to spontaneous tumours in genetically modified mice) per experimental group suffice. However, for an experiment to be well controlled and meaningful, we may include more than one experimental group. For instance, in implantation experiments where we deplete a gene in cells, we will use two independent reagents targeting the gene as well as a control. Moreover, we would typically examine more than one model cell line. Likewise, we may use several doses of a drug, or several different drugs or drug combinations to test a theory. Considering power, the number of experimental groups, and the number of genes and drug targets we are interested in, we have then estimated the total number of mice to be used over the licence lifetime.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

For genetic mouse models, efficient breeding strategy will minimise the number of mice used to obtain the desired genotype.

Experiments will be appropriately controlled and mice of the same age, genetic background and source will be used to reduce the variability of results and to produce highly consistent data. Wherever possible and appropriate, a single group of animals will serve as a control for more than one experimental groups.

We will be conducting and recording our experiments to be able to publish our results following the ARRIVE guidelines [https://www.nc3rs.org.uk/arrive-guidelines] and will use randomisation, blinding etc. where appropriate so as to minimise biases. Furthermore, additional resources may be used to aid experimental design such as the NC3Rs experimental design assistant tool

(https://www.nc3rs.org.uk/experimental-design-assistant-eda).

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be performed if applicable and, after analysis of the results, group sizes for subsequent experiments will be determined based upon these data. As far as possible, multiple parameters will be evaluated in a single mouse. Live imaging of the same animal at multiple time points also greatly reduces the numbers required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The mouse is the lowest vertebrate that offers an in vivo situation (anatomy, physiology, metabolism) relevant to human cancer and that can be manipulated in a manner that will generate data relevant for the treatment of human cancer. As such, the mouse is the most appropriate animal model to achieve the stated objectives. Moreover, techniques required for the proposed types of analyses are established for studies using mice making predictions of possible adverse effects more reliable.

We will use mice that have been altered genetically to either allow specific tracking of cells or which are predisposed to lung cancer conditionally upon treatment with inducing agents. Tissue specific and inducible gene alteration will reduce the potential burden of genetic loss in the whole organism. The vast experience of animal technologists within our animal facility will be harnessed to minimize potential suffering by regular monitoring of tumour size and potential impact on the general health status of the mice. By responsibly considering the adverse effects associated with the regulated procedures, mechanisms are in place to minimise these (e.g. appropriate analgesic regimes for pain relief).

To reduce any suffering of tumour bearing mice, they will be killed humanely as soon as tumour formation is sufficient to yield satisfactory data and always before they become moribund, manifest severe pain or lose significant weight (all of which are closely monitored).

For any new procedure, we will seek expert advice and follow the most refined techniques available, experimenting at first with a limited number of mice.

For any inoculation/transplantation procedure we will follow the route that causes the minimal burden on the animal's well-being.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Less sentient animals do not have lungs. Mouse is far more similar to humans than other animals having lungs e.g. birds or reptiles and this is critical both for using reagents like drugs developed for human targets and for translating findings to the clinic. Furthermore, cancers develop over many weeks to months, so use of terminally anaesthetised animals or immature animals is not practicable. Also immature mice lack a functional immune system which is desirable in cancer research.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Assessment of the size of superficial tumours would usually be by callipers (usually of two diameters at right angles). The total tumour burden should not normally exceed 1500 mm3 as calculated by the formula: tumour volume = ½(length x width x 2). Sub-cutaneous tumours will be measured at appropriate intervals (usually once a week using callipers). If a tumour reaches approximately 2/3 of the maximum permissible volume, it will be measured more frequently.

Additionally, superficial tumours will be monitored for signs of local inflammation, irritation, or pinpoint scabbing to an ulcerated state. Animals with ulcerated tumours will be cared for according to the best practice at our Institute. Wherever relevant, animals will be provided with analgesia as detailed in the relevant Protocol to control adverse symptoms associated with the treatment.

For non-superficial lung tumours imaging will be used to monitor the disease burden alongside measures of the health status of the animals (e.g, respiratory rate, lethargy).

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).

We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)] administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.

Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23]

How will you ensure you continue to use the most refined methods during the lifetime of this project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our NACWO, NVS and HO inspector.

Explain the choice of species and the related life stages

Mice are more comparable to humans than other animal model systems (fish, invertebrates) in pathophysiology and show higher similarity of genetic and protein sequences. This is important as we intend to use reagents such as small molecule inhibitors and antibodies that have been developed to target human proteins.

Moreover, non-protected species and less sentient species (fish and invertebrates) do not have lungs so we would be unable to use them for animal models of lung cancer. Embryonic stages would not provide us with a sufficient window to follow tumour development and besides it is not feasible to perform the desired interventions in embryos (such as inhalation of activating agents). Therefore adult mice are to be used.

Home Office

NON-TECHNICAL SUMMARY

222. The use of novel patient derived and mouse models to develop better treatments for advanced resistant cancer

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

Prostate Cancer, Metastasis, Resistance, New Treatments

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Prostate cancer is the most commonly diagnosed cancer in men and a common cause of male cancer-related death. Treatment of prostate cancer has improved over the last decade, but while the disease often responds to treatment initially it is common for it to become resistant and reoccur. The re-occurring disease is always more aggressive then the initial tumour and is accompanied by painful metastasis often to the bone and the cancer has been proven to be find various ways to escape the selective pressure of medicalisation given to the patient. In order to develop therapies that prevent or cure the advanced state, it is extremely important to understand how prostate cancers become drug resistant and what type of strategy might help. For this we need cells to be grown in petri dishes to select the best candidates for new treatments and in mice to prove or disprove that the selected drugs are suitable for treating cancer in a living organism. Current prostate cancer culture models used to study the disease and to develop novel treatment strategies for lethal prostate cancer have been generated more than two decades ago and do no longer adequately resemble the human disease. Better models to develop new advanced therapeutic approaches are therefore urgently needed. Scientist all around the world including ours have been trying to develop new models with some success, but not enough to cover the full spectrum of different resistance tumour types we are currently facing in the clinic. Our group has recently developed a very successful strategy to make small tumour pieces from patient biopsies grow in mice first, in order to get enough tumours to then develop cell lines growing in petri dishes and mice. So far, we have developed 4 new models and that cover some but by far not all types of resistant prostate cancer. These have been used in various tests and have greatly contributed to the field already. We now would like to apply this successful strategy to cover a broader range of resistance mechanism for the benefit of patients suffering from other types of advanced prostate cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

We plan to develop better in vitro and in vitro models of prostate cancer grown from small tumour pieces called ‘biopsies’ taken from patients suffering from treatment-resistant prostate cancer. We will use these models to better understand how these cancers become resistant and to develop strategies to reverse resistance and cure patients suffering from the at the moment un-curable disease stage. We will furthermore develop mice that do not express or overexpress genes that have been identified as new drug targets and cross them with mice that have been engineered to develop prostate cancer. This will help us to better understand the importance of these genes for prostate cancer growth and survival and will validate them as potential drug targets in order to then develop new drugs and therapeutic strategies to better treat the disease.

Both types of models will help us to better understand the biology of these tumour types and how to best address them therapeutically. This will greatly add to the gain of knowledge in the field as we will publish our results in peer reviewed journals to make our findings accessible to other scientists around the world and will be extremely useful for testing new therapeutic approaches for multi-resistant prostate cancers in culture as well as in living animals.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We will use no more than 13,000 mice over the whole five-year period.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

All of our experiments will ultimately lead to mice that will suffer from prostate cancer. We will therefore take extra care for them and our trained personal will monitor them closely under the supervision of a veterinarian trained in the field of cancer related animal studies. Mice will be checked at least four times per week for signs of tumour growth and distress, and will be weighted once per week. Tumours will be grown up to a size limit in order to ensure they do not interfere with normal activities and behaviour, and mice will be killed using a humane method as soon as their tumour reaches the size limit or their behaviour is affected.

The mice used to implant the tumours need to be special immune deficient mice, some of them need to be irradiated in order to suppress immune response or to treat the cancer after implantation. To prevent infections, the mice will be kept under strict aseptic conditions with sterilised bedding, water, and food and supplied in cages with filters to remove pathogens from the breathing air. Immune deficient mice will be monitored daily and mice and environment will be regularly tested for potential pathogens that could endanger wellbeing of the colony.

Implantation of biopsy requires surgery that will be under aseptic conditions, general anaesthesia and post-operative analgesia. After the procedure, mice will be observed carefully and painkillers or antibiotics will be given if necessary. In order to minimise distress, we will use non-invasive methods to monitor tumour growth such as callipers, ultrasound, NMR or PET, some of which need general anaesthesia. Treatment will be applied by injection (under the skin, or into the abdomen) or given directly into the stomach using a needle or tube inserted into the mouth which will cause some distress but is not likely to cause long lasting discomfort. Some of the treatments given will cause side effects such as weight loss. Radiation can potentially cause skin burn, or weakness. We will closely monitor the mice and humanely kill them if we can’t treat adverse effects with the measures described above and are concerned about the severity of distress they are experiencing, or otherwise at the end of the experiment.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Our group and others have greatly improved methods to culture of tumours pieces in culture (known as tumour organoids) for use in drug testing. We plan to use these methods to test novel therapeutic approaches in culture first, which will markedly reduce the number of mice needed for experiments. Although it is possible to use the biopsy directly in culture, this approach is limited as patient tumour biopsy is small so we can only use it for a small number of experiments. We therefor plan to increase the number of possible tests in order to compare and optimise treatments by growing the small biopsy into little larger tumours by implanting it under the skin of a small number of mice at a side and up to a size which will have the lowest impact possible on the wellbeing of the mouse. These tests will greatly decrease the number of animals needed to understand the tumour biology and to identify the best strategy to treat tumours that are resistant to established treatments, however, to ultimately test if such a treatment is working in a living tumour and before it can responsibly used in patients, an animal experiment is inevitable.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use inbred mouse strains with very low degrees of genetic variation to maximise those that will be useful for experiments. Genotypes that are not currently needed will be frozen down to reduce the number of animals bred for future needs. We will discuss proposed experimental designs with statisticians to ensure we can minimise the number of animals used while still ensuring that our data is robust. Wherever possible, we will replace mouse experiments with in vitro experiments and only use mice for validation of in vitro validated results. All experimental results will be published in peer-reviewed journals to avoid duplication.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

A mouse’s genes are around 98% similar to those of a human. It is possible to grow human tumours in immune-deficient mice to study how they behave in a whole organism, and to test out new treatments. The models developed in this study will reflect the disease with greater accuracy and will reduce the number of experiments to come to a meaningful conclusion. We will choose non-invasive methods to monitor tumour growth, which will also allow us to observe potential adverse effects earlier and end the study before the mice are showing clinical signs. Wherever possible, we will carry out monitoring and treatments at the same time to reduce stress and the number of separate interventions. When assessing a treatment in mice for the first time, we will perform a small pilot study within a range that should not cause harm, to explore its possible side effects. We will carefully choose drug doses that are effective but avoid side effects. We will plan husbandry and procedures to minimise pain and distress, observe

animals daily using trained staff. We will use anaesthetic and analgesic regimes and appropriate humane methods of culling.

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of the project is to evaluate the safety of various types of chemical materials when given to test animals. The work is designed to meet the requirements of government regulators in Europe and elsewhere, who must agree to the sale and use of chemical materials in society.

A retrospective assessment of these aims will be due by 11 December 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work is required to help protect the safety of people who are involved with the manufacture and transport of various types of materials, as well as those who may be exposed to them during deliberate use or accidental exposure. Without these studies, it is currently not legally possible to manufacture and sell these materials in the UK, in Europe, or into other markets in the world. Development and use of safer and better materials requires conduct of these studies.

What outputs do you think you will see at the end of this project?

Data collected will be information on the safety of various chemical materials, for those who would be involved in the manufacture, transport or use of such materials. This will include efforts to identify systems within the body or particular organs of the body that may be affected by short term exposure to, or accumulation of the chemicals. For example, blood testing and post mortem examination of tissues can demonstrate change in function or structure of body organs. Some studies will be to check if there is any effect on ability of animals to breed. This work then helps to predict effects that might be seen in people through exposure at work or everyday use.

The data will be collected to the standards required by government regulators in the UK, Europe and elsewhere, who will make decisions on whether these materials can be safely marketed and used in society.

Improved methods of conduct of specific data collection processes may be developed during the course of the project.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our clients, typically commercial chemical companies, will benefit from the provision of high quality data. This will to help them in their work to produce safer and more effective materials which can be safely made and used without increasing health risks for those who make, use or transport them.

Enabling development of successful chemical materials will benefit society, for example by enabling improved crop yields.

The wider scientific community may benefit from publication of refined approaches to animal use.

How will you maximise the outputs of your work?

Our organisation has colleagues with extensive experience of such work in different parts of the world. Collaborations and information exchange with others within the organisation helps to identify and spread information on successful and unsuccessful approaches.

Collaboration with clients (knowledge gained on products).

On-going collaborations with NC3Rs on various aspects of regulatory safety studies, over many years.

Presenting outputs at scientific conferences and contributing to publications in the scientific literature where relevant.

Species and numbers of animals expected to be used

- Rabbits: 2600
- Mice: 9000
- Rats: 50000
- Beagles: 350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals will be given a chemical material by the same method that people would be exposed to them - normally by mouth, or by inhalation. Inhalation of materials generally requires that animals are accustomed to close restraint in a purpose-made device while breathing the material. The materials will normally be given at a range of different dose levels, samples such as blood samples are commonly taken to assess any effect and/or to assess how much of the material is absorbed. Behavioural tests may be conducted to check for effects. Some studies are to assess if the material has an effect on the unborn, or on the development of young animals. A small number of studies involve giving the material to rodents for an estimate of their lifetime, to check if the materials might cause cancer.

Animals will usually be used once only, and then will be humanely killed to check for effects in the body, including by examining the tissues microscopically.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The process of dosing animals or taking samples can cause a degree of discomfort during conduct. Behaviour and health may be affected by the materials being given, and reduced health can be measured, eg by reduction in food consumption, weight loss, changes in blood results. Some studies may have effects on the ability to breed or on development of the young. In lifetime studies, adverse effects are usually those seen in ageing animals, such as reducing function of the body's organs, resulting in reducing quality of life over time.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The vast majority of harms described above are expected to fall within the mild category, some have no significant identified harm. Most animals of all species will have harms considered as mild or sub-threshold (not observed). An estimate of up to 15% of animals may experience harms categorised as moderate. Severe outcomes are not anticipated; if seen in individual animals, these would be reported to Home Office.

What will happen to the animals at the end of the study?

- Killed
- Rehomed
- Kept alive

A retrospective assessment of these predicted harms will be due by 11 December 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are used in some aspects of the programme of safety assessment of new materials, they are currently not able to predict effects on whole body systems or to provide information on how much of a material is absorbed. It is not currently possible to acquire all of the information on how the body systems such as the heart, liver and kidneys may be affected by new materials, without using animals. This information is essential, to protect people involved in the manufacture, transport or use of chemical materials. The protocols described in this project are conducted according to internationally-agreed guidelines, and are expected to be performed before government authorities will authorise the marketing of new chemical materials.

What was your strategy for searching for non-animal alternatives?

The organisation conducts non-animal tests as part of the programme of safety assessment of new chemical materials, but as noted, above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes.

Why were they not suitable?

There currently remains general scientific agreement that to protect people involved in the manufacture, transport or use of chemical materials, non-animal alternatives do not, as yet, provide enough information to replace all animal studies.

A retrospective assessment of replacement will be due by 11 December 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

The animal numbers for studies required by government regulators typically follow those identified in internationally-accepted guidelines, as expected to provide sufficiently significant outcomes. Longer term studies use larger groups as these are designed to enable identification of effects which might only be seen in only a small percentage of animals over a lifetime. Screening studies and dose ranging studies generally use minimal numbers, commonly between 1 and 3 animals per group, to generate initial data.

What other measures apart from good experimental design will you use to minimise numbers?

Pilot studies will be used to investigate the potential of new designs or processes to improve outcomes, before being used in larger numbers of animals. Initial screening studies, using small numbers of animals, are designed to identify and eliminate materials with undesirable results, and so reduce the numbers of animal which are then used in the studies required by government regulators.

A retrospective assessment of reduction will be due by 11 December 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

Dosing of materials is by the same way in which people would be exposed during manufacture, transport or use of the materials, most commonly by mouth; occasionally by inhaling the material, or by applying to the skin. These are all very well established and common methods for the species to be used. Volumes of drugs to be given are in line with published guidance on minimising discomfort, and/or are known to cause minimal discomfort based on extensive experience at the site.

Blood sampling follows published guidance on suitable volumes which can be taken while minimising harms to animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The species used are selected based on known standards of outcome which will answer the scientific questions. They are species proposed as appropriate for the work by internationally-agreed guidelines, and are studies expected to be performed before government authorities will authorise the marketing of new chemical materials.

Response to tests is assessed over a time period which makes continued anaesthesia impractical, and would interfere with the outcome in most circumstances.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Refinement of on-going procedures occurs as and when any concerns are identified; for example additional assessments may be included based on initial outcomes. Habituation of animals to restraint is a routine process, and the schedule can be amended in response to outcomes for individual animals.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of Diehl et al: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

Welfare end-points are developed in general line with publications on the topic, including the NC3Rs document from 2010 on dose level selection for regulatory toxicology studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Both our clients and our colleagues working in the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which propose refined approaches to conduct of work.

Explain the choice ofspecies and the related life stages

The animals (and age/life stage) used in the project have been shown to provide important information for assessing safety of chemical materials, and this is reflected by the inclusion of animal studies in European Directives and Regulations, and in internationally-agreed guidelines for how to best produce the safety information required.

A retrospective assessment of refinement will be due by 11 December 2025

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

224. Treatment strategies for familial breast cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of this project is to identify and test new treatment strategies for familial breast cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Breast cancer is the most common cancer in the UK, accounting for 15% of all new cancer cases (2016). Most breast cancer patients are treated successfully with endocrine, radiotherapy and chemotherapy. However around 20% recur. Familial breast and ovarian cancers are sensitive to certain treatments aimed at damaging DNA, these cancers also become resistant over time.

We aim to identify new treatments to kill cancers and to kill those that become resistant to current treatments.

What outputs do you think you will see at the end of this project?

Breast cancer patients are currently being treated with anti-cancer drugs that leave patients with a high risk of cancer recurrence and resistance.

We hope to provide data that will support efforts to treat these patients with agents that either prevent recurrence or that can successfully treat a tumour resistant to current modalities. Outputs of this information will be through sharing our findings at national and international conferences, through collaborations with other researchers, and by publishing in peer-reviewed journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The work will add to the knowledge of agents that are, and are not, effective in treating BRCA-mediated cancers (output). In the short term the outputs will accelerate scientific progress towards a greater understanding of these types of cancers (output expected during or slightly after the project).

The impact of this may be felt in the Pharmaceutical sector (those that make the new agents we test and show are successful, or make agents that also impact the targets we are inhibiting (output expected some 1-5 years after the project). Our evidence may thus accelerate trials and/or identify the patient group that the agents may be effective in (output of the current project expected to be released some 5-20 years after the project depending on the agents used (new or already developed).

How will you maximise the outputs of your work?

To maximise the outputs we are collaborating with different groups internal and external to this establishment that will lend their expertise and knowledge to our work. We will publish our work in peer-reviewed journals and present at conferences to disseminate new knowledge including reporting of unsuccessful approaches. We will also share best practice of new techniques and protocols we have developed and validated to collaborators.

Species and numbers of animals expected to be used

- Mice: 2700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Animals are injected or pieces implanted with tumour cells just under the skin on the back of the mouse or near the mammary glands. The tumours can take between two weeks up to 12 weeks to form. The tumour growth is monitored by several methods:1) measurement of a visible tumour with calipers (that provides precise measurements in millimetres); 2)feeling the abdominal area for the presence of hard lumps. With some cells, we can monitor the tumour growth using a machine that will take live images of tumour cells that are tagged with fluorescent colour. Animals may be given anti-cancer drugs or placebo ("fake drug") by injection or by giving it orally through a long thin tube. Treatments will not exceed 8 weeks. Mice will be humanely killed at the end of the experiment. We will analyse their tumours and organs and blood to see how the drug has worked.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Mice will experience tumour growth which will not cause any pain but may cause animals to lose weight, have a less plump appearance, may sit in a hunched position, or may not act as lively as normal. Potentially, this could include weight loss (maximum of 18%), a reduction in Body condition (we use a score to monitor this), reduced activity, failure to respond to gentle stimulation, lethargic, abdominal distension, jaundice, piloerection, intermittent hunched posture, diarrhoea, or intermittent laboured respiration.
These symptoms usually appear at the later stages of the tumour development. Animals will be killed according to monitoring for adverse effects set out in the protocols.

It is possible that delivery of chemotherapeutic drugs will cause adverse effects. As the drugs we will use as well reported in the literature, we will be able to pay close attention to the development of any signs of distress. For example, anaemia and leukopenia are common side effects of chemotherapy, and we will be able to monitor the extent of this by tail vein blood analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

About 90% of animals are expected to get tumours and may also receive anti-cancer treatments and have implantation of hormone pellets/mini-pump is a surgical procedure and will be classed as moderate.

The other 10% of animals, will not get tumours or will receive low doses of agents and will have a mild severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use non-animal methods to validate our treatment approaches but these conditions are artificial. They do not give an accurate picture of the effects that targeted treatment will have on the growth of tumours especially at the doses you could give to patients.

Very few, if any, in vitro cell culture based models are able to recapitulate the complex interplay between cancer cells and the tumour microenvironment. Indeed, studies using murine models of cancer that enable the modelling of disease within a complex multicellular living organism have been fundamental in enabling a better understanding of the processes that lead to malignancy that could not have been achieved otherwise. As a direct consequence of this, new drug targets and insights into the molecular mechanism of disease have come to light.

We need to use breast cancer tissue and cells in a live organism to evaluate the effectiveness of targeting a specific molecular targets on cancer development of real patient tumours.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

What was your strategy for searching for non-animal alternatives?

In vitro data obtained from cell culture approaches has guided the proposed in vivo studies. We always conduct cell culture based experiments to justify the need to use animals. These system include culturing cells in monolayer as a homogeneous population on plastic, and the more sophisticated 3D culturing of either cells lines grown in matrigel (as acinar) or mouse/human derived tissue as organoids.

Why were they not suitable?

There are significant limitations of basic culture conditions using cells gown in isolation as a monolayer on a piece of plastic as this is not an accurate representation of what occurs within a patient. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment. Technologies are being developed to address this gap, including the development of 3D cultures (acinar cell line cultures and organoid mouse/human derived tissue). However, none of these model systems are yet able to phenocopy the integration and interplay between the numerous cell types that constitute the tumour and its microenvironment, or the fact that tumourigenesis occur in and is influenced by biological systems (such as the immune system). Moreover, genetic manipulation of organoid cultures is still technically challenging. Modelling cancer in mice is thus still required to fully model disease progression and identify novel therapeutic avenues.

Bioprinting and organ/human/mouse-on-a-chip are technologies that we have explored but these require significant investment in time and money to validate as they are not yet accepted as replacements for animal experiments.

The development of 3-D tissue culture of tumour cells bearing the specific genetic changes we require risks losing the precious patient material, as many of the tumour and non-tumour microenvironment cells do not survive. Nevertheless this is an avenue we are eager to continue to investigate. The advantage of in vivo propagation is it may allow us to increase the tumour material to test alternative means of 3D culture and organoid development (with REDACTED).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

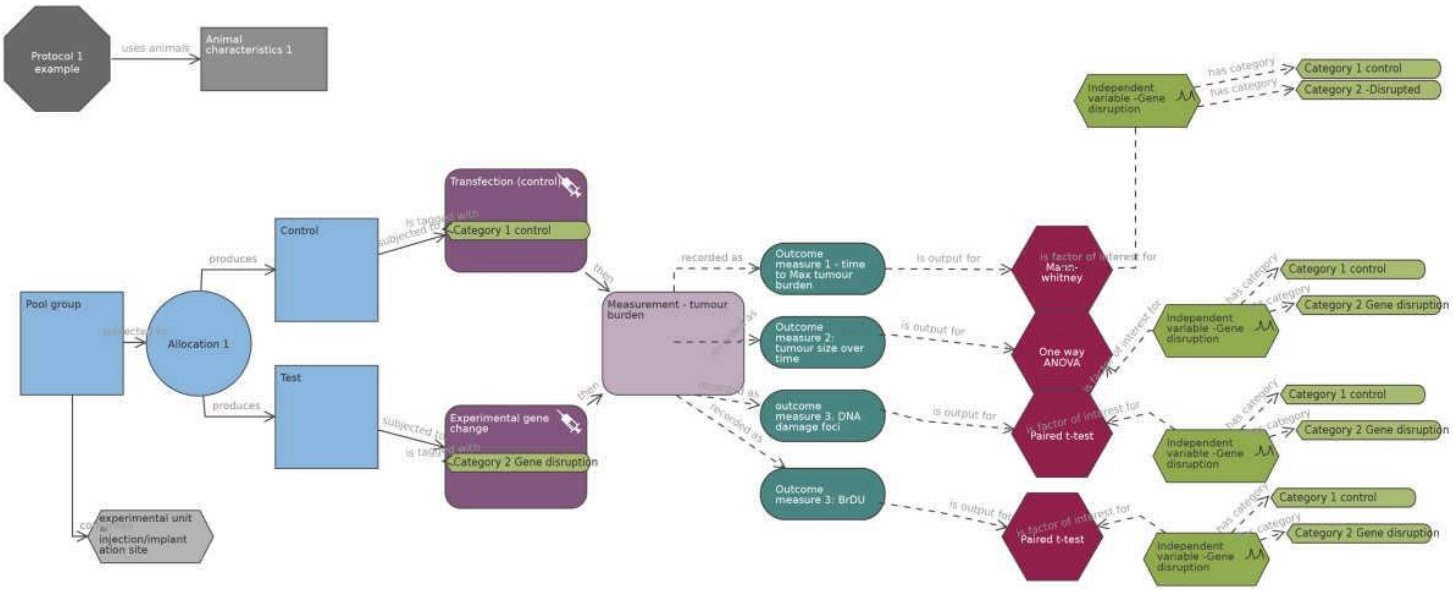
When possible we will always use power calculations to determine estimate number of animal that should be used. For most quantitative experiments, animal cohort size will be calculated via power analysis. Expected effect size will be determined through consultation of the literature, cell culture based in vitro analysis or through small pilot experiments when possible.

We have used statistical methods to calculate how many animals we need to get meaningful data, how many patient samples and how many drug combinations we will look at.

We aim to characterise about 8 patient samples each year. We aim to do about 4 treatment experiments per year. Estimating that we will test around 4 anti-cancer drugs each year.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have used the NC3Rs' Experimental Design Assistant to design experiments (example of an experiment in protocol 1 below) and taken advice from researchers who have performed similar research projects in the past.



We aim to reduce animal numbers, methods to reduce subjective bias, and appropriate statistical analysis without compromising the scientific objectives. When possible, experiments will involve a factorial design that will maximise the information obtained from a minimal number of animals. For example, non-invasive imaging and quantification techniques of transplantations will enable multiple measurements on the same animal over a period of time. In such cases, ANOVA will be utilised for statistical analysis.

When conducting xenograft experiments, where experimental design will allow, we routinely inject two contralateral flanks of the mouse, thereby reducing the number of animals being used by a half.

Where possible, we will use live imaging to track tumour development longitudinally. Not only does this mean fewer animals are needed overall as there is no need to cull at each time point, but it also reduces variation and so improves quality of the data produced.

What other measures apart from good experimental design will you use to minimise numbers?

We will use pilot studies to estimate variability and perform power calculations to calculate sample sizes.

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.

We always strive to generate the most effective breeding strategies to ensure that we obtain mice of the desired genotype with minimal animal wastage. If we are unable to estimate an effect size from our in vitro data, the literature, or our collaborators, we will conduct small pilot experiments.

All tissue surplus to requirement may be deposited into SEARCHBreast (https://searchbreast.org), a resource to facilitate sharing of archived material derived from in vivo breast cancer models

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mouse models to engraft human breast cancer tissue and cells. Mice with internal tumours have been refined through pilot studies where we are confident of window of treatment and experimental time point where most mice do not show any adverse effects.

We use immune compromised mice in order to achieve engraftment.
These models are characterised in pilot studies to identify any unexpected adverse effects.

For human xenografts models we will use immune compromised mice, hence heterologous cells will be more easily engrafted. Imaging of engrafts will be conducted where possible through the use of non-invasive techniques that will enable us to monitor tumour progression in living animals throughout the experiment, and will therefore reduce animal numbers. Here, the tumour volume as determined by non-invasive calliper measurements or bioluminescence imaging will be plotted against time. This design offers the advantage of determining significant differences between tumourigenic growth potential of cell lines before the limited tumour volume is reached.

In addition the pilot studies will help us to develop score sheets and robust humane endpoints so that harms can be contained within our need for a certain level of harm to answer the scientific questions.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Mice are the least sentient species that will allow us to achieve our objectives.

We need to study tumour development in adult mice as this is what most closely resemble what occurs in humans. We have chosen to use mice over other less sentient species such as Danio Rerio (zebra fish) and drosophila melanogaster (the fruitfly) as mice and humans share 97.5% of their coding DNA sequences. Moreover we are able to grow human tumour samples in these animals and assess therapeutic responses.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Through advice of colleagues performing similar work we are aware of refined treatment doses and route of administration of four of our most commonly used anti-cancer drugs so that we know the maximum tolerated dose, the minimum effective dose, and sub-optimal doses. This minimises the possibility of adverse effects from chemotherapy.

Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.

We are fortunate to have excellent colleagues both in Academic groups and within the BMSU with extensive, relevant animal procedure experience, including PDX models, from whom we can learn refined techniques from. Our team will undergo extensive training on dead animals and require to be authorised by BMSU before being allowed to perform a procedure on live mice.

Examples: Repeated injections (therapeutics) will be done on opposite sides or at different areas from previous injection so as to not aggravate any visible bruising. Gavage rather than injections for drug delivery, and vacuum blood collection rather than sequential blood sampling from tail vein. Use of refined handling where possible, depending on size and location of the tumours; cupping maybe preferable to avoid knocking the tumour (s). Humane endpoints use body condition charts.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the Workman et al, 2010 (reference below) for experimental design, best practice, and humane endpoints for cancer research in animals, and we will publish in journals that adhere to the ARRIVE guidelines published by the NC3R's, we consult Simon Bate's book, The design and statistical analysis of animal experiments, for experimental design, statistical analysis, and sample size calculations.

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.

We will publish in journals that support the ARRIVE guidelines and conduct our experiments with advice from the PREPARE publication (PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Literature searches, attendance at vendor's information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.

We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.

My Lab group twitter follows the NC3Rs - helping us keep up with advances in the 3Rs which will be discussed an implemented through our lab meetings.

Explain the choice ofspecies and the related life stages

We are using mice because they are able to grow human tumour material as xenografts enabling drug testing and in vitro genetic manipulation before implantation. This enables us to mechanistically interrogate tumour growth, and hence identify new way in which to treat breast cancers.

A number of our approaches require the growth of human cancer cell lines or tumour pieces, and this has to be conducted in mice that have a disabled immune system to prevent human cell rejection. We choose to use adult mice of a specific age range (6-9 weeks of age) to minimise variability.

Home Office

NON-TECHNICAL SUMMARY

225. REDACTED pathogenesis & treatment in REDACTED and medaka

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult
Medaka	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Our aim is to advance our understanding of how mycobacteria produce tuberculous disease and how the host responds to infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our research is centered on understanding REDACTED, a contagious infectious disease, caused by the bacterium Mycobacterium REDACTED. This REDACTED bacterium has very ancient origins and has been infecting humans at least for 30,000 years. Over the millennia, this highly specialized pathogen has evolved mechanisms to counteract, evade, and even benefit from host processes, particularly immune responses to cause disease. The REDACTED (TB) bacterium has a complex life cycle in the host that involves distinct processes at each stage. As a result, from new infection to active disease, REDACTED is delineated by complex steps, which remain largely unknown.

According to the most recent World Health Organization (WHO) report, TB caused disease in ~ 10 million individuals and killed 1.5 million individuals worldwide in 2018 (https://www.who.int/news-room/fact-sheets/detail/REDACTED). Additionally, REDACTED has had important social implications for sufferers of this disease over the course of human history. TB sufferers are often not able to work or take care of themselves, and to make matters worse are stigmatized leading to social rejection and isolation even from family members.

The reason that TB continues to be an enormous problem reflects the failure of public health measures that have been implemented more affluent parts of the world - these include ventilation, improved air quality and nutrition. In the face of the inability of most of the world to implement such public measure, it is important to note that the currently available vaccine BCG and the currently available drug regimen to control the global burden have not been adequate to control the disease burden. This scenario is worsened with the emergence of multi drug resistant REDACTED that is difficult to treat. The work described in this application aims to find completely new ways to treat and prevent TB through a better understanding of how it interacts with the host to produce disease.

What outputs do you think you will see at the end of this project?

This project is expected to yield new understanding of the bacterial and host determinants that promote REDACTED infection and antibiotic resistance. In the next five years, we intend to continue to dissect and identify the genetic determinants responsible for the 47 susceptibility mutants identified during the previous license period. We also expect to find 50 additional mutants based on the number we identified in the last period. We will try to find drugs that can treat (counter) these susceptibilities, and expect to find hundreds of drugs based on our previous experience where the investigation of the mechanism of susceptibility of a single mutant has identified 15 drugs. We are currently also exploring

the virulence mechanism of 5 bacterial determinants, and this will continue over the next five years. These studies will also lead to the identification of new drugs. Based on past experience, we anticipate identifying 5 new drugs from the study of these bacterial virulence mutants.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

We expect that several of our findings will lead to human clinical studies and trials. During the last year, we have identified a new pathological pathway which led to the identification of two groups of cheap, readily-available oral drugs that can be re-purposed to treat REDACTED. We anticipate additional findings going to human clinical studies in this next phase of the project license.

Therefore, TB patients will ultimately benefit from these outputs. Since human studies and clinical trials take several years, this may not happen during the period of the project license. However, we expect that some human studies and clinical trials based on our findings will have started during the tenure of this license.

How will you maximise the outputs of your work?

We will disseminate our findings through publications and presentations at conferences and in various institutions. This will include the publication of unsuccessful strategies. We will continue to collaborate with human geneticists, with clinical REDACTED researchers who can take the findings to human clinical studies, and with other REDACTED and mouse researchers, as warranted by the work.

Species and numbers of animals expected to be used

- Zebra fish: 2,019,000 from egg to neonate; 1,011,000 from egg to adults
- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

<u>For genetically altered animal generation, maintenance, gamete recovery and breeding protocols:</u>

Eggs might be injected with proteins, DNA or RNA to generate new genetically altered animal lines. In many cases, we attach fluorescent reporters that are light sensing substances to the DNA introduced into the animals. This allows us to monitor the introduced DNA under a microscope and allows the determination of the exact steps by which disease occurs. Because these experiments are completed

before the fish are five days old, these are not regulated procedures. In case of new mutant lines, juveniles or adults will be genotyped by fin tissue removal under anesthesia at 2-3 months of age. Fish regenerate their fins, so these small amounts of tissue removed grow back within two weeks. Founder fish may have additional mutations, so they will be outcrossed with wild type animals to remove these mutations and establish the line that bears only the mutation of interest. Founders will be killed when the next generation has been genotyped. Animals from these new lines will be used to generate eggs by natural spawning. These eggs will be used in other protocols in the Project License . Some of the animals from these new lines may be used to recover gametes to cryopreserve the line (males) or to recover a line that has been cryopreserved (females). Gamete recovery will be performed in a given animal up to 5 times maximum and these animals will be used for natural breeding after this procedure. Animals used for breeding will be kept up to 2.5 years of age. Animals showing clinical signs of disease or damaged during maintenance and breeding procedures will be immediately killed.

For phenotyping of genetically altered animals with mutations causing harmful phenotypes:

Animals undergoing this protocol will be obtained from our genetically altered animal stocks by natural spawning. These animals might be screened by microscopy before five days of age and genotyped by fin tissue removal under anesthesia at 2-5 months of age when phenotyping experiments are performed blinded and the genotype is known only at the end of the experiment. All mutant animals will be killed immediately after showing clinical signs of disease.

For infection protocols:

For any given adult fish, bacteria will be administered by up to two of the described routes and if a subsequent drug/substance is administered, it may be by the same route or a different one with use of a maximum of 3 routes. Generally, for injected substances, we would expect to inject substances only once but there will be instances where a drug such as an antibiotic (e.g. streptomycin) has to be administered daily by intramuscular injection, as is done for human treatment. We will minimize the number of injections per animal. Bacteria will be administered to most adults only once with no further treatments. Survival experiments in adults will normally last for up to 2 months.
All animals will be killed at the end of the protocol.

For any given larval fish, we will perform a maximum of three administrations of the infectious agent. We anticipate administering the compound at most once a day whether by soaking, injection or gavage. For compound administration, we will typically use only the immersion method unless the compound is not absorbed through immersion or we require its localization to a specific area. In rare cases, we may need to use up to 2 additional routes of administration. Bacteria will be administered to most REDACTED larvae only once. In many cases, these infected animals will be treated with substances by soaking which is not invasive. In some cases, other substances will be administered before or after infection by injection.
Infection experiments in larval fish will be terminated when or before animals reach 14 days of age.
All animals will be killed at the end of the protocol.

For fish younger than 30 days used for pilot experiments:

Animals undergoing this protocol will be obtained from our genetically altered animal stocks by natural spawning. These animals might be screened by microscopy up to five days of age. Substances will be administered to find the dosage used in further infection experiments. Pilot experiments in larval fish

will be terminated when or before animals reach 14 days of age.
All animals will be killed at the end of the protocol.

Use of non-Schedule 1 killing methods:

These methods will be used to kill the animals in experiments where biological samples or the whole animal must be preserved for future analysis. At any stage of the experiment and independent of the age of the animal, fish will be killed by anesthetic overdose (medaka and REDACTED) followed by either
1) Chemical dissociation of tissues (e.g. Phenol, Hot Shot buffer, detergent-based lysis buffers) to preserve genetic or protein material, 2) Chemical Fixation (e.g. Paraformaldehyde, Glutaraldehyde, (dithiobis [succinimidylpropionate]) or Dithio-bismaleimidoethane) to preserve structure of tissues and organs.

Only in exceptional cases where the anesthetic can interfere with instruments used for analysis, only REDACTED will be killed by use of ice slush (where the animal is physically separated from the ice) followed by snap freezing of fish in liquid nitrogen to preserve all components of the animals.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The infected adult fish will eventually suffer from the consequences of a REDACTED-like disease manifesting lethargy and very small surface hemorrhages that are less than 1 mm. These clinical signs would increase in adult fish until they eventually become moribund and die from the infection, within weeks to months depending on the inoculum. Infected adult fish will be monitored twice daily and will be killed immediately when they show clinical signs of disease and before they become moribund, to decrease suffering.

For larvae, we cannot evaluate the severity of disease as they do not show any clinical signs of disease. However, to decrease suffering, infected larvae will be killed as soon as they become unresponsive to tactile stimuli (i.e. do not swim away when touched with a plastic pipette).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Protocol 1: 100% Mild

Protocol 2: 100% Mild

Protocol 3: 100% Mild

Protocol 4: 100% Mild

Protocol 5: 80% Mild and 20% Moderate

Protocol 6: 100% Mild

Protocol 7: 100% Mild

What will happen to the animals at the end of the study?

- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

REDACTED is a complex disease involving interactions between bacteria and many different types of host cells. Disease pathogenesis involves multiple cellular processes, including the movement of various types of host immune cells, engulfment of bacteria by these cells and the death of infected host cells and nearby cells. Moreover, multiple interactions between different host cells influence disease. This is exemplified in the tubercle, the hallmark structure of REDACTED in which multiple host cells, both infected and uninfected, come together and form an organized structure in which the bacteria reside. The tubercle houses the REDACTED bacteria and is the product of the interaction of multiple cell types. Adding to the complexity, REDACTED can occur in multiple host organs and tissues. This multicellular structure isvirtually impossible to replicate outside the host.

What was your strategy for searching for non-animal alternatives?

In vitro infections using the various cells that become infected by the REDACTED bacterium. We use these non-animal alternatives to ask very specific questions that are dependent only on direct interactions between the bacterium and its infected cell on its own, rather than in the context of the complex multicellular structure, the tubercle.

Why were they not suitable?

Human cells in culture do not always behave as they do within the tissues in the host.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Adults included in Protocol 6 are included in these numbers as they are the same animals (200,000 adult REDACTED and 10,000 adult medaka). We have estimated these numbers by the number of animals used under the previous Project License.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We use the NC3Rs experimental design assistant in combination with strategies to reduce the number of animals required for each experiment as described below.

We use pilot studies to look for differences caused by genetic mutations in the bacterium or the host, or by drugs that change bacterial or host determinants. This allows us to determine sample size for subsequent studies. For instance, a strong effect will allow us to reduce the number of animals used in subsequent studies.

Control animals are always required including for the pilot studies. When possible, we use siblings to minimize variability and thereby reduce sample size. Similarly, we use randomizations in all experiments: sibling animals from a single clutch are randomized into the various experimental groups. In the case of studies with mutant fish, we design our crosses so as to generate wildtype and mutants that are siblings. We perform genotyping only at the end of the experiment, so that we look for differences in infection without knowing which group the animal belongs to. This avoids any bias based on how our preconceived notion on how a mutation should affect infection.

What other measures apart from good experimental design will you use to minimise numbers?

We will use PREPARE and ARRIVE guidelines at experiment planning stages and when preparing manuscripts for publication, respectively.

For all experiments, we use the minimum number of animals required based on prior experience. For new experiments, we run small pilot studies to assess the impact of a condition and how much it varies among the animals. This then allows to use statistical calculations to determine the minimum number of animals that we can use.

For experiments where the whole animal or tissues from the animal are preserved for further studies such us gene expression of tissue microscopical analysis, these are shared between researchers so the same experiment is not repeated while enough tissue sample remains.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use larvae, juveniles and adults of REDACTED and medaka. We use larvae rather than adult fish to the extent possible and limit the studies to a few days where possible. We are always seeking to refine our techniques to identify differences in the responses to infection to keep the infected animals for shorter time periods. This means that we can evaluate differences in the response to infection before the animals show any clinical signs of disease. We use adults for key confirmatory experiments only. All procedures in adults and larvae are performed on anaesthetized fish and animals are euthanized immediately once the experiment is completed.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The bulk of our experiments involve fish larvae rather than adults. We do not use species such as fruit flies (Drosophila) and worms (*C. elegans*) that are used for certain types of research because these species do not have the same types of immune cells that humans do and that are important to fight against REDACTED. Fish do have these cells and we have shown them to be similarly important in fish REDACTED as they are in human REDACTED.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To minimize impacts in animal welfare during pairing to produce eggs, the spawning tanks are placed on shelves covered with a black background. This mimics the natural habitat where the light is entering the water from above and the bottom is dark. We have found this improves the number and quality of eggs that are produced. The tanks used to house the fish are transparent to allow the light enter the tank and the bottom is darker due to the shelving.

Genotyping trays are used to ensure fresh water and food is provided when the animals need to be individually housed. Fish are fed live diets using newly hatched brine shrimp (*Artemia salina*), which stimulates the animals as they chase the prey. Fish are housed in groups where possible, and are feed a suitable diet and follow a regime which has increased survival, development and breeding of the fish. When housing of three or two animals is required, artificial plant material is supplied to provide hiding places in order to decrease aggression.
We use black shelving under each tank so as avoid stress from light surfaces and reflection.

Use of small molecule inhibitors or other chemicals (i.e. drugs) as a treatment for experimental groups: if the chemical has been used in the REDACTED or medaka before, we use that dose as a reference for the experiments under this Project License. In the case of new chemicals, pilot experiments will be used to test chemical toxicity. This will be done with small number of animals (5-10). The minimum nontoxic dose of chemical that has an effect in the outcome of the experiment will be used for further experiments.

All experiments will be ended early if it is determined that significant differences between treatments can be observed before the expected endpoint of the study. During all infection studies, any moribund animals (larvae or adults) are killed using a Schedule 1 method. For studies utilizing chemical or other synthetic compounds (e.g. drugs), we use the lowest effective dose that minimizes adverse effects. Furthermore, in the context of severe severity work, all infected animals will be inspected twice daily as

this will be enough to spot changes in behavior or clinical signs of infection before animals become moribund .

With respect to severity protocols, we do not feed the larvae for the 14 days post fertilization during which we conduct our experiments. We determined that this was advantageous to the health of the larvae under the conditions of the experiment where the fish water cannot be treated or replaced. The larvae derive all necessary nutrients from the ample high-density lipoproteins stored in their yolk. Restricting food from larvae from hatching to 14 days post-fertilization has been shown by our lab to reduce super infection of the larvae by food-borne commensal infection susceptibility.

Survival studies are a critical component of our goal to understand human REDACTED. For example, host mortality can result from inappropriate immune responses rather than bacterial growth. In such cases, an analysis of bacterial burden may not provide understanding of a disease process. In these cases, survival studies can provide important insight into central disease processes. When survival studies are necessary, experimental animal numbers are minimized via statistical Power Analysis and up to 20% of animals undergoing this protocol may develop moderate clinical signs of disease. To minimize suffering during these experiments, we kill any animal with clinical signs of disease or moribund immediately using a Schedule 1 method. All infected animals are meticulously inspected twice daily to ensure that moribund animals or animals showing clinical signs of disease are quickly detected in order to further minimize suffering. These checks are conducted by experienced technicians and researchers who have had rigorous training and assessment before conducting checks alone. During these inspections, any action taken is recorded to be available for the researcher in charge of the experiment, the rest of the technicians doing the checks and the NACWO. Any fish found dead (<10%) or culled because of signs are recorded within the room and also a database. This allows all relevant parties to know the health status of the stocks under experiment and monitor numbers closely to ensure we work within the license allowances. In instances when unexpected number of animals show signs of disease, different from predicted by fish line and bacterial strain and inoculum used, the researcher in charge of the experiment, as well as the NACWO, is notified immediately.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

Humane methods of euthanasia have been evaluated outside of the current and future acts of UK law relating to the use of animals in scientific procedures and have been cited as having a potential to improve the welfare of animals such as REDACTED RSPCA's 'Guidance on the Housing and Care of REDACTED', May 2011. The method entails the immersion or exposure of REDACTED to temperatures of 4^{o}C or less for periods greater than 2 hours as a means to halt metabolism. Only 39% of chilled fish showed signs of distress, compared to 100% of fish exposed to the anesthetic agent MS-222 (tricaine). After this step, the REDACTED will be subjected to Snap Freezing. The advantage of Rapid Cooling/Snap Freezing is to humanely euthanize REDACTED without causing them distress (Rapid Cooling/Snap Freezing as a means of euthanasia of ectothermic REDACTED for larvae up to 14 days of age. For euthanasia of adult REDACTED this method will require the REDACTED to be held within 2-4^{o}C ice slush until loss of operculum (the support structure on the side of a fish's head which forms a protective cover for the gills) movement followed by introduction to liquid nitrogen to confirm death and preserve tissues (snap freezing). We have received training to perform this procedure from the REDACTED International

Resource Centre and have since presented the method at meetings within the UK. Following this, other facilities have also adapted their protocols to incorporate this method due to its welfare improvement.

We will also use PREPARE and ARRIVE guidelines at experiment planning stages.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will be closely in contact with the NACWO, NIO and NVS to be informed of any new publications or reports regarding 3Rs. The NACWO will attend relevant continued professional development training as well as REDACTED husbandry meetings as with the previous license.

Explain the choice ofspecies and the related life stages

We have developed the REDACTED and medaka as models to study REDACTED by infecting it with the pathogen *Mycobacterium marinum*, a close relative of the human REDACTED bacterium. *M. marinum* naturally infects REDACTED and medaka, causing a REDACTED-like disease. This allows us to study REDACTED pathogenesis in these organisms as the mechanisms of disease are conserved between these species of fish and humans. The REDACTED has proven to be an ideal model for the study of REDACTED and has enabled us to address questions that have been elusive in the more traditional models of REDACTED - mice, guinea pigs, rabbit and more recently nonhuman primates. The medaka has provided information into human resistance to REDACTED. The model has several advantages over existing REDACTED animal models which use the human REDACTED bacterium in mice, guinea pigs, rabbits and nonhuman primates. First, because these fish naturally get REDACTED with *M. marinum*, the disease is more similar to human REDACTED than when the human REDACTED bacterium is used in non-natural hosts. Second, the transparency of the fish larva allows for the direct visualization of the steps that lead to REDACTED in live animals; third, the genetic tractability of the fish allows for the effective dissection of the host immunity to REDACTED - genetic fish mutants that show variation in disease susceptibility can be identified and studied in detail. Fourth, the effective use of pharmacological interventions enables both identification of pathways in conjunction with the genetic studies above; it also helps identify new host- and bacterial-targeting drugs against REDACTED. These unique benefits have together proved tremendously powerful and have allowed us to make surprising discoveries about REDACTED pathogenesis that have immediate clinical implications.

We take advantage of the transparency of the the larval stage of the fish. The REDACTED and medaka are transparent during the first stages of their life, and this allows us to perform experiments that last only for a few days when possible. In the larva, we can visualize different stages of infection as they happen in real time in live animals.

For some experiments we use adult animals with a fully developed immune system to ensure that our results obtained in the larvae are reproduced in adults.

Home Office

NON-TECHNICAL SUMMARY

226. Tumour Growth Regulation

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

cancer, sarcoma, therapy, REDACTED

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The work aims to understand how cancers grow, so that we can develop ways of blocking cancer growth in man. This understanding will direct our potential to develop new drugs for treatment of childhood and adult cancers. Based on a thorough understanding of molecular mechanisms, this work will not only inform what drug therapy, but also how to best apply that therapy so that it is administered

to the right patients at the right time. The specific objectives include determining the activity of one such drug therapy, that acts to block cancer growth. The effects of REDACTED treatment on cancer growth will therefore be assessed. In addition, we will determine what genes promote growth in rare cancers called sarcomas, so that we can develop new treatments. Sarcomas are cancers with unmetneed. They affect children and young adults, and despite treatment with mutilating surgery, high dose chemotherapy and radiotherapy, and still associated with poor survival.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The benefits are directed ultimately towards developing new treatments for cancer. Initially, the benefits will be to generate new knowledge, to identify new cancer targets and to validate these, to then develop evidence of new agents that modifiy these targets as the basis for new treatments. For the clinical trials that then follow, the benefits are for humans that might have cancers appropriate for treatment with the new drugs, and for society following commercialisation of new drugs that show benefit for cancer patients.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Species: Mouse
Number: 1050
Time: 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

In the protocols, adverse effects relate to the induction of growth of tumours placed under the skin, and following injection of agents and tracers. Both may impact on the animals, but the likely level of severity being moderate.
Continuous monitoring of symptoms and signs will be performed so as to minimise impact of procedures and to avoid rare adverse effects (<5%), including limiting the size to which tumour will be allowed to grow. The growth of tumours will therefore be monitored with ultrasound imaging, but in addition, animals will be treated with therapeutic substances to try and prevent tumour growth. Animals will undergo anaesthesia prior to procedures in order to minimise adverse effects such as pain. All animals will be humanely killed at the end of all the protocols.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

There are currently no alternatives to animal models when the objective is to study the genetic and functional effects of a growing tumour arising in a whole animal context that aims to mimic the situation in human cancer. We have replaced stages of some experiments, for example, in the early stages of designing an experiment, we now routinely use new CRISPR/Cas9 genome editing technology in cells in culture, as this optimises genetic controls in cancer models that are more informative and that can replace the use of genetic modification in animals. Alternatives to animals are also being developed in several laboratories, and are based on growth of cells in small chambers (cancers on a chip), and may be also utilised as an alternative by us in the future.

Reduction

Explain how you will assure the use of minimum numbers of animals.

To reduce animal numbers, we have adopted a number of approaches. Firstly, we will use optimal genetic controls to compare against the test substance. This approach reduces the numbers of animals needed, as controls are specifically designed. These controls can be tested in cell culture screens, and as a result, optimises the relevant combinations of treatments requiring testing, and so significantly reduces the number of animals required. Secondly, we will image tumour growth in experimental and control groups using accurate non-invasive ultrasound, so reducing experimental variation due to measurement error, requiring less animals to meet the need for statistical power. We will also use standard experimental design that incorporates blinding, randomisation and gender differences.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We will utilise humane endpoints and imaging throughout the protocols to quantify early stages of tumour growth minimising the risk of mice developing potential symptoms from tumours that reach the limit of size. By objective and regular evaluation with ultrasound monitoring, we will be able to intervene earlier. We also routinely ensure that all animals receive anaesthesia to avoid pain, we will utilise LASA guidelines, and if animals exceed a predetermined humane endpoint before suffering or harm, to then be killed humanely.

Home Office

NON-TECHNICAL SUMMARY

227. Type 2 immunity in infection and maintenance of tissue health

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo
Gerbils	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We want to understand how the immune system functions to protect the host from parasitic worms, which cause damage as the migrate through the body. By extension, we aim to learn how these immune pathways help heal wounds or cause disease by overzealous tissue repair.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Helminths (parasitic worms) infect over a quarter of the human population, and an even greater proportion of animals. Although not generally fatal, they cause substantial suffering, particularly in low income regions. Disease can be caused by competition for nutrients, physical injury due to migration through the body, and/or an excessive immune response to the parasite. The type 2 arm of the immune system is a highly complex network of cells and molecules, which is very distinct from the pathways that control infection with bacteria and other microbes. Type 2 immunity is necessary both to control helminth numbers and to repair the physical damage they do. However, overzealous type 2 responses can lead to allergic diseases, asthma and chronic tissue scarring (fibrosis). Wound repair and scarring features of type 2 immunity are common even in regions with no helminth infections. Thus, fundamental research into the mechanisms and consequences of the type 2 immune response will lead not only to improved understanding and control of helminth infection, but greater understanding of the many allergic and fibrotic diseases that are major killers worldwide.

What outputs do you think you will see at the end of this project?

This project aims to disseminate new knowledge by publication in peer reviewed journals and presentations at conferences, seminars and workshops. We hope that in the longer-term our work will contribute to new immunology-based therapies. In the 5 years, we aim to continue our high standard of publication, averaging more than 5 research papers per year in highly-respected peer-reviewed journals.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

This project aims to answer fundamental scientific questions. The new knowledge generated, and the unravelling of important immune mechanisms, will be relevant to a broad range of human and animal conditions.

Parasitic worms (helminths) afflict over 1/4 of the human population and the vast majority of wild mammals. They also represent an enormous economic burden in terms of livestock productivity. In the

next five years we expect to make significant strides in understanding the mechanisms by which these parasites are killed, which will be relevant in the longer-term to prevention or treatment strategies. In addition, helminth infection can increase susceptibility to other infectious agents, such as viruses and bacteria. Our analysis of how cells function during helminth infection should help us understand how to manage these common co-infections.

Our work is directly relevant to fibrosis (tissue scarring) and asthma. Fibrosis in people is estimated to contribute to 45% of all deaths in developed countries. In the UK, around 5.4 million people are currently receiving treatment for asthma, which equals 1 in every 12 adults and 1 in every 11 children. We expect our work over the next 5 years to define the key molecules involved in how the tissue becomes restructured and remodelled to cause more severe disease, and potentially whether the process can be reversed once it has started. This is particularly relevant as new biological drugs that target type 2 immune pathways are now used in the clinic for skin disorders, and our studies would highlight their potential role in other diseases.

Because several of our models involve the investigation of the body cavities, they may provide important insight into a major clinical problem: the adhesions (inner body scars) that follow abdominal surgery. The underlying cause of these very painful adhesions are poorly understood, but have been linked to the immune cells we study. Our unique expertise in the cavity around the lung (the pleural cavity) will also provide insight into build-up of fluid in the cavity resulting from heart failure, pneumonia and cancer. In particular, we are interested in the possibility that idiopathic pulmonary fibrosis, a fatal lung disease of unknown origin, may start in the pleural cavity. Our work with a parasite that lives in the pleural cavity, has the potential to reveal whether scar tissue initiated in the pleural cavity can move into the lung.

One of the most specific outcomes we hope to achieve is an understanding of the function of chitinase-like proteins. Increased levels of these proteins in the blood are markers of poor outcome in a wide variety of diseases from asthma to cancer but their function is unknown. We hope to reveal why chitinase-like proteins are associated with disease and whether drugs designed to block them could be beneficial. This work could lead to new therapeutics in the next 10 to 15 years.

How will you maximise the outputs of your work?

Communication of our findings will be primarily through publication in widely-read peer-reviewed journals, but also presentation at local, national and international congresses and institute seminars. To ensure maximum dissemination, only journals that allow open access without payment by the reader will be considered. Furthermore, we will place the first drafts of our published data on an open access repository such as www.biorxiv.org. To prevent unnecessary repetition of experiments by others, we will seek to publish all data generated under this project including negative results.

To enable rapid translation of our findings to the clinic we will exploit new and existing collaborations with local clinicians as part of the translational environment within our institution. We have highly effective systems in place for technology transfer. Additionally, pharmaceutical and biotech companies could be engaged through presentation at national and international forums at which representatives are often present.

Species and numbers of animals expected to be used

- Gerbils: 500
- Mice: 40000
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Typically a mouse will be either 1) infected with a parasitic worm by injection under the skin, 2) injected with a molecule that induces a scarring response, or 3) given a mixture of allergy inducing molecules through the nose. Experiments might look at the immediate immune response in the first few days but can last as long as 3 months to allow full development of the parasite, or full development of diseased tissue (e.g. asthmatic lung).

Many animals will also receive an injection of a molecule or cells to modify the immune system. For example, an animal might receive an antibody that will get rid of a particular immune cell. In addition, small volumes of blood may be taken from a vein, for example to screen for parasites or blood cell changes. Experiments will often end with animals being killed under terminal anaesthesia.

Hence, the cumulative experience of mice will typically be exposure to 2 or 3 procedures that may each cause short but usually separated periods of typically mild or potentially moderate degrees of suffering.

Separate from the above experiments, some genetically altered animals will be used only to breed and maintain animal lines.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The vast majority of animals will experience no adverse effects or only mild adverse effects. The parasite infections are generally well tolerated and will rarely reach moderate severity. In the hookworm model a heavy infection can cause weight loss and laboured breathing but we use low doses to avoid this. The fibrosis and allergy models are designed to assess the structural changes to the tissues without major overt clinical symptoms. However, some manipulations can make animals more susceptible to infection, injury or allergy, which may increase the severity from mild to moderate. All animals will be humanely killed before they exceed moderate severity limits.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Based on our previous experience, we expect approximately 85% of mice to experience mild severity and less than 4% to experience moderate severity. The gerbils and rats all experience only mild severity.

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune system relies upon a complex series of interactions, which occur between immune cells, structural cells and the extracellular matrix. The nematode models involve migration of parasites through living tissue. To understand such complexity, it is essential to undertake research in vivo, since this cannot yet be modelled meaningfully in vitro.

What was your strategy for searching for non-animal alternatives?

1) Analysis of human biopsies.

2) Use of cell lines

3) Use of organoids - artificially grown cells that resemble an organ.

Why were they not suitable?

The types of experiments required to track cell function in vivo are not possible with human tissue biopsies, nor can we experimentally infect humans.

Many location-specific features of cells are lost once they are removed from the tissue, which makes the use of cell lines impractical.

Organoids cannot test the impact of nematode migration through the body or replicate the changes in the extracellular matrix and cell migration that occur during injury, tissue remodelling or scarring.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For Rats and Gerbils, the calculation is based on our current requirements for maintenance of parasites. The number of mice has been estimated based on experience gained under my previous Home Office licenses. This experience-based estimation has reduced the predicted animal use by over 30% compared with my previous license.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Maintenance of parasites: On the previous license we estimated 8000 animals for lifecycle maintenance - our procedures have improved dramatically such that we have reduced our estimate for this license to 5050. For mite feeding, we have reduced both the number of mice and the number of infected gerbils needed.

Experimental mice: For all of our experiments in-bred mice are used to reduce experimental variation, which makes it possible to use fewer numbers of animals to achieve statistical significance. For the majority of our studies, mice from the same litters are used for control and experimental mice, reducing variation that can occur due to differences in the microbiota. Overall, our experiments are designed to reduce the number of variables (for example age) to as few as possible and thereby reduce the number of control groups required.

We work with the NC3Rs Regional Programme Manger to ensure all lab are introduced to NC3Rs experimental design assistant and encouraged to use it. Everyone in the lab is trained in statistical methods and these are regularly discussed at lab meeting, to ensure all agree the best methods are being used. Tissue-sharing is a major tool we use to reduce animal usage.

Breeding: A significant proportion of our animal use is related to breeding programmes for GA lines. We follow the advice of our BSF staff to optimise breeding and regularly discuss numbers at lab meeting to ensure we do not overbreed. Our breeding number estimates have been considerably reduced from my previous license. Where possible and appropriate, we use antibody blockade instead of gene knockout mice.

What other measures apart from good experimental design will you use to minimise numbers?

My group routinely perform pilot experiments to determine the optimal number of mice to achieve statistical power. Experiments are then performed on a minimum of two separate occasions to ensure reproducibility, following which data pooled from experiments are statistically analysed to reveal less pronounced effects without increasing overall animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use mouse models of nematode infection, fibrosis and tissue remodelling. Mice represent the most appropriate species for in vivo study of these conditions, because of the extensive knowledge of their physiology as it relates to humans, the genetic and biological tools available and the ability to be easily bred and handled.

The nematode infection models do not cause significant pathology and we use them to understand the immune response to the infection process. The infectious doses are carefully managed such that the animals will experience minimal suffering.

Our model of fibrosis will result in scar tissue and has been chosen to mimic what happens to people who undergo peritoneal dialysis. The model is terminated at a point where the causes of scarring can be assessed but before the animals experience evident suffering. Our model of severe asthma has been designed to generate remodelling of the lung airways and study the causes of airway stiffening that lead to asthma. The models are designed to allow us to quantitatively assess substantial remodelling of the lung airways, in order to mimic human disease. However, the experiments are terminated before the animals exhibit serious breathing problems.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We are studying long complex processes and trying to understand how the adult immune system handles these conditions and how different tissues communicate to orchestrate an appropriate response. Only adult animals would give meaningful results. The long duration of the processes to be studied prevent using mice under terminal anaesthetic.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

In line with the establishment's policy, we will adopt the latest techniques in animal handling (eg cupping) to significantly reduce the stress associated with procedures. Furthermore, where possible, the least invasive methods for dosing and sampling will be applied.

Anaesthesia and analgesia will be provided where suitable (eg for humane restraint, during and recovery from surgery). The best aseptic technique will be used during surgery.

Infection experiments will use the lowest doses possible and early endpoints will be used that prevent animals experiencing more severe harms.

We are continually refining our procedures with regard to the Litomosoides/mite lifecycle and over the years have made dramatic improvements for which we have won 3Rs awards. We are acutely aware that the gerbils are social animals and work to avoid isolation where possible. We recently moved to refine blood taking from the gerbils by switching from tail vein bleeding to saphenous vein bleeding, a procedure that is less stressful for the animal and easier to quickly get sufficient blood. Another refinement is that the gerbils are given treats after being handled and now exhibit minimal anxiety on being handled. Best practice is discussed regularly at lab meetings. In addition, the lab manager has been sent to collaborators labs to discuss and observe their practices and see if our practices can be refined. This has resulted in continual improvements to our life cycle processes.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The lab consults the recommended https://www.nc3rs.org.uk/3rs-resources on a regular basis including watching videos of best practice techniques. For specific models, we read papers from other groups doing similar experiments, as well as consulting directly with other researchers to discuss the most refined procedures.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The animal facilities includes a team of dedicated veterinarians that are continually seeking to improve animal welfare and refine animal use. My group consult closely with them and take full advantage of the extensive resources provided to ensure we are following current best practices. We are also in the process of adopting the improved rodent handling methods that reduce animal stress (detailed by Hurst et al. Nat Methods 2010) and now provide environment enrichment as standard. We will regularly consult with the NC3Rs representative and their resources page to ensure we are aware of new 3Rs developments.

Explain the choice of species and the related life stages

We study adult mice because the immune system, tissue organisation and development of all mammals are similar allowing mice to be a model for humans and other animals. We also use mice because scientists have created many genetically altered REDACTED that allow us to dissect in fine detail what happens during immune responses. Genetically altered mice and many of the tools designed to work with mice allow us to define in precise detail how particular cells and particular molecules work together to repair tissue or fight infection. By manipulating these cells and molecules, we can understand how these processes go wrong during diseases such as asthma.

We also use gerbils and rats to maintain our parasite lifecycles, and neonatal mice to maintain the mite vector that transmit parasites. In each case, the animal is the most susceptible to infection, allowing us to use the least numbers of animals to maintain the parasites or mites in sufficient numbers for experiments.

Home Office

NON-TECHNICAL SUMMARY

228. Understanding colorectal cancer risk factors and progression of disease

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

No answer provided

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

This project aims to identify and characterise CRC risk factors and understand how different parameters (genetics, age, sex, environmental, diet, tumour promoting/preventing factors) impact on pathways involved, to enable appropriate and personalised intervention and treatment.

The objectives are:

(1) To understand how CRC risk factors contribute to normal cellular function, tumour initiation, development and progression in order to be able to intervene.

(2) To understand what and how environmental and genetic parameters (eg. genes/pathways) contribute to tumour initiation, development and progression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

CRC has a high death rate, however, if detected early, this rate decreases dramatically. Understanding the risk factors associated with CRC can help tailor screening programmes to those most at risk and we can better understand pathways to target therapeutically and indeed intervene with pre-clinical trials of potential anti-cancer therapies/preventions.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Up to 10,000 mice will be used over 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The programme of work will be -

(a) To alter CRC risk genes to understand their contribution to tumour development and progression as well as their normal function.

(b) To create combinations of mutated genes in order to determine which gene mutations contribute to tumour development and what parameters and factors affect this and how.

(c) To use or create exposure to potentially tumour causing and tumour preventing agents to understand how environment may contribute to or modulate tumour development.

Due to the nature of the experiments to understand tumour formation, progression and prevention, adverse effects are expected as a result of aging; tumour development via genetic background, tumour promoting agents and inflammation; dietary manipulation; injections; multiple anaesthetics; surgery; imaging; single-housing. The animals will be housed in a modern animal care facility and monitored daily for signs of illness (using a number of Veterinary agreed monitoring and scoring systems including weight loss, distress and clinical factors) due to tumour formation and for other well being factors. The expected adverse effects due to tumours will be kept to a minimum (mild/moderate level of severity). At the end of the studies, mice will be humanely culled and dissected to analyse various tissues for tumour formation/progression.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Cancer formation is complex and study in mouse models will allow us to fully understand pathways and different factors linked with tumour formation.

We will utilise mice to investigate CRC risk factors, as they are similar to humans in terms of numerous features (anatomical, genetic, pathological and physiological). We have shown by analysing human intestinal tissue, that CRC risk factors have a larger effect in the tissue of disease origin and therefore we can use genetically altered mice to analyse particular tissues and investigate stages of tumour development, including any interactions between genes, cells, tissues, the surrounding microenvironment, with and without the impact of other factors.

Functional studies involving ex vivo samples (growing intestinal crypts, tumours, human cancers) and in vitro (cancer cell lines) will be performed before and during the studies, however understanding the complexity of tumour formation in its surrounding tissue structure is critical and these mouse studies will recapitulate the human disease.

Throughout the project we will seek, review and incorporate alternatives as appropriate.

Reduction

Explain how you will assure the use of minimum numbers of animals.

The experimental design has been optimized to ensure use of minimal animal numbers to produce meaningful results and is helped by our previous projects.

We plan to use efficient breeding practices/sourcing methodology and utilise imaging technologies to help to reduce animals where possible.

We plan to use ex vivo intestinal crypt culture studies and in vitro cell line pilot studies for functional analyses of gene effects.

We will harvest as many of the tissues possible, for archiving and storage, to minimise repetition of experiments.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Mice are chosen in this research due to their small size, relatively short lifespan, rapid reproductive cycles and similarity to humans in terms of many different features. Mice are prone to both spontaneous and induced tumour formation. As they are more defined genetically, they allow a much greater insight into the roles of specific genes, alterations and environmental effects. We will use existing mutant mice where possible and indeed utilise the intestinal crypt culture to both reduce and refine the research.

We will use anaesthesia and analgesia as appropriate, with guidance from NVS and utilise imaging technologies to help refine the procedures.

The animals will be housed in a modern animal care facility with barrier housing to minimise infection and harm. The staff are well trained and we will ensure they receive the highest standard of care with appropriate stimulation to allow social enrichment where possible. The animals will be assessed daily and we have developed a scoring system with guidance from the NVS, to ensure that animal suffering is kept to a minimum, with animals being culled when mild-moderate clinical signs are observed.

NON-TECHNICAL SUMMARY

229. Understanding haematopoietic dynamics in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We aim to understand how the cells responsible to sustain blood production (blood stem cells) are affected by stresses such as infections or leukaemia growth. Because it is not yet possible to maintain and grow blood stem cells in a test tube, we study them directly in the bone marrow, where they reside, with the aim to understand what other cell types interact with them, exchanging what molecular signals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite bone marrow transplantation having been practiced in the clinic for decades, and being the treatment of choice for an increasing number of conditions, availability of blood stem cells is a critical limiting factor for its applicability. Understanding what cells and molecular pathways support blood stem cells in the bone marrow is critical to learn how to grow them in test tube so that more patients can be treated successfully. Moreover, it is now clear that blood stem cells are damaged by stresses such as infections and leukaemia, therefore it is important that we learn how to preserve them or regenerate themselves following stress. This will enable healthy ageing.

What outputs do you think you will see at the end of this project?

By the end of this project we will have significantly increased the understanding of blood stem cells and leukaemia biology, and identified specific cells and molecular pathways that are promising for the development of novel, improved therapeutic approaches for leukaemia and cancer patients, and for survivors of severe infections. Our findings will be published in highly respected journals (always in open access format) and presented at prestigious conferences. All data generated will be accessible to the research community either directly through deposition in existing databases or upon request by collaborators.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Our data will be useful to drive future research led by us, other research groups and industry in collaboration with clinicians and to drive the development of improved therapeutic and preventative approaches for blood diseases. Patients will be the ultimate beneficiaries of our work.

Outputs from our work will immediately benefit the closer research community, and will reach the global research community once they are published. In the medium term (2-10 years) they will underpin future research projects led by me and others, including potentially clinical trials that test novel therapeutic approaches. In the longer term (5-20 years), our findings will impact human kind in terms of improved therapeutic and preventative approaches in the areas of leukaemia, cancer and infection, and will therefore contribute to develop strategies to enable healthy ageing.

How will you maximise the outputs of your work?

I strive to publish all our findings, positive and negative. This is becoming more feasible through the increasing availability of open access data repositories and pre-print publications (e.g. Wellcome Open Research, BiorXiv). Moreover, both myself and trainees in my group regularly present our findings at scientific meetings, and engage with the public and, most importantly, with the technology development, technology transfer and intellectual property departments of both the institutions and the funders who support us. This maximises the opportunities for our work to be evaluated and further developed to drive improved therapeutic and preventative approaches.

Species and numbers of animals expected to be used

- Mice: 16,250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

The length of our experiments, both in terms of actual time they take to be completed and of number of procedures performed on an animal, varies greatly depending on the questions asked and the most relevant models used. For example, our infection models develop within 5-7 days, but our leukaemia models develop within 3-12 weeks. Infections are mimicked by injecting specific substances intravenously or intraperitoneally, or by administering malaria parasites intravenously or via the bites of infected mosquitoes. Leukaemia grows following intravenous injection of malignant cells, with or without preparing the mouse with agents such as irradiation. In the vast majority of cases mice will develop either infection of leukaemia, and not both. Only in later stages of this project, once we have

learned the specific damages caused by infection, we will let the mice fully recover from infection and we will subsequently administer leukaemia cells to them, asking whether they are now more susceptible to develop leukaemia. Within these models, we treat mice with substances that activate genes or modify cells that regulate blood stem cell function. These could be hormones administered over 2-4 weeks, or chemotherapy leukaemia treatment administered for 5-10 days. To assess the functionality of blood stem cells, donor mice will be culled and blood stem cells harvested and transplanted into irradiated recipients, mimicking bone marrow/stem cell transplants performed in the clinic. Specific to our programme of work, we will use advanced microscopy to directly observe blood stem cells and support cells interacting within the bone marrow. This is done under anaesthesia, either as a terminal or recovery procedure. Less frequently, longitudinal studies will require multiple, short microscopy sessions to take place over the course of a few days.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Mice will experience either mild or moderate levels of severity. Moderate levels of severity are expected for all mice undergoing recovery surgery, and for those experiencing multiple mild procedures within a short period of time (for example daily blood sampling or daily injections).

We expect adverse effects to be very rare (<2% of animals). An exhaustive body of evidence demonstrates that stress affects HSC biology, and it is therefore paramount to us that stress, such as that generated by adverse effects, is minimised, or else we would not generate trustworthy data.

Peri-operative analgesia is provided and animals are expected to be fully recovered within 24 hours, most often within 2 hours from the end of surgery/anaesthesia. Very few animals will undergo more than one surgery (for example, two bone marrow aspirates, or one bone marrow aspirate and one imaging window implantation), and the second surgery will only be performed once full recovery from the first one has taken place and it is clear that that did not cause any adverse effects. We are not currently planning to perform any further surgery on splenectomised mice, and should this become necessary we will discuss it and plan it in tight collaboration with NVS and NACWO, and following the same principle of performing a surgery only if the animal has not shown any adverse effects at any point.

Irradiation is not expected to cause any adverse effects to our animals because either they will be culled before these arise or they will receive sufficient numbers of haematopoietic cells to guarantee their survival. In the latter case, mice will be cytopenic for 3-4 weeks, with the nadir at week 3 post-irradiation. While this is an adverse effect, this does not cause observable clinical signs to the mice. The worst-case scenario is failure of the injected cells to reconstitute the mouse, however this is never planned and therefore it is not an expected adverse effect for this project. If further procedures need to take place following irradiation and injection of cells, these take place either before or after the time window when mice could develop adverse effects, or are terminal procedures performed under anaesthesia (eg intravital microscopy).

Leukaemia cells can cause health deterioration which is only ameliorated by chemotherapy treatment. Animals are expected to respond quickly to treatment and clinical signs to resolve within 24 hours, otherwise humane killing is triggered.

Malaria can develop into cerebral complications, which are lethal. Our experiments are all performed before the onset of these complications, and the onset of signs such as reduced motility and hunched posture is carefully monitored (daily inspections) and triggers humane killing.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Expected moderate: about 30% of animals

Expected mild: about 70% of animals

What will happen to the animals at the end of the study?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is currently impossible in the laboratory to mimic the complex three-dimensional relationship between normal blood stem cells and other cells in the bone marrow, and therefore completely replace the use of animals.

Mice are the smallest, less-sentient animal model that can be used to perform the studies described here. They are the only species for which there is a wide availability of genetically altered animals, which makes it possible for us to test the role of specific genes within the blood production system and to visualise cells of interest directly within the bone marrow. Finally, the blood production system that we are studying is remarkably similar to the human system.

What was your strategy for searching for non-animal alternatives?

We continuously strive to replace animals as much as possible, and provide here some examples. We have implemented mathematical modelling to test theories about certain aspects of blood stem cell biology and simulate interventions. This work allows a partial replacement of the use of animals as it allows us to select parameters to be tested experimentally and therefore reduces the number of animals used. We have also been using our findings from animal studies to develop laboratory systems. For example, we reproduced the disease effects of leukaemia on the cells normally supporting blood stem cells by growing both types of cell in the same experimental dish, and we have been studying the interaction with other cells using similar approaches. In many cases these systems rely on cells taken from mice to set them up, but they do allow us to perform further studies without the need to use more animals although it is only made possible in conjunction with our research findings in mice.

Why were they not suitable?

Commercially obtained cells or those grown in the laboratory are not suitable replacements for cells freshly taken from mice because they are too different and any experimental results would not be relevant to our research.

Specialised techniques using cells are increasingly used in our type of research, but are not yet suitable for research involving blood stem cells, however our findings from animal studies will contribute to improving them.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use statistical modelling to estimate the ideal number of mice we need in order to achieve meaningful scientific results.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

When statistical modelling indicates that numbers needed are high (for example more than 15 or 20 mice), we use preliminary pilot studies with smaller numbers of mice. Depending on the results, we either abandon that experiment if it is shown not to work or adjust, and often reduce, the number of animals needed if the pilot results are promising.

What other measures apart from good experimental design will you use to minimise numbers?

We breed mice that can have more than one particular trait which minimises the number of animals that we need to use.

By using the same control (untreated) animals and by increasing the breadth of analyses conducted on cells and tissues from each animal, which gives us maximum data per animal, we have in the past been able to use smaller numbers of animals than initially expected. We expect this trend in reduction of numbers to continue in future.

Careful planning of microscopy allows us to follow events as they develop within the same mouse, avoiding issues due to mouse-to-mouse variation and therefore reducing the total number of animals that need to undergo the procedure. Moreover, careful refinement of mouse monitoring and surgery/anaesthesia reduces animal death and ultimately the number of mice required to complete data collection.

In addition, we maximise our breeding efficiency by minimising the number of pairs required through careful crosses and monitoring of all breeding animals.

Allowing malaria parasites through their whole life cycle including in both mice and mosquitoes maintains parasites stocks more consistently, reducing variability and the number of mice required to complete data collection.

The use of state-of-the-art hormone administration protocols increases the efficiency of embryo production, reducing the number of females needed to generate the embryos required.

Finally, as multiple personal licence holders work under this licence, experiments are coordinated so that tissues can be shared as much as possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The experimental models of leukaemia and infection used in this project have been selected to minimise pain, suffering and distress to the animals, while providing scientifically relevant data. No lasting harm is experienced by any of our animals.

Of note, the use of naturally occurring infectious agents is a refinement as it eliminates the question whether the observations made following administration of large amounts of specific molecules are relevant to real-life scenarios. Still regarding the infection models we use, and in particular malaria

infection, opting for infected blood inoculation rather than insect bites whenever compatible with the specific scientific question addressed reduces the suffering of animals as it does not require anaesthesia and it shortens the overall duration of the infection.

The use of sophisticated genetically altered animals where mutations are restricted to specific cells of interest instead of affecting the whole organism drastically reduces the emergence of adverse effects due to the genetic background of the animals. For this reason, our breeding protocol leads to only mild levels of severity experienced by the animals.

The use of sterile males whenever possible reduces the need for vasectomy and therefore avoids using surgery to achieve the same output.

Finally, throughout our experiments, mice are carefully monitored at a minimum through daily inspections, which increases to twice daily at times when adverse effects are expected (for example at late stages of leukaemia development, or the peak of malaria infection). Monitoring may be undertaken continuously in some situations, for example for the few hours following recovery surgery, to ensure recovery is smooth and prompt.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The mouse is the ideal model organism to study blood stem cell systems as it is most similar to the human. Less sentient animals such as zebrafish and the fruit fly can be used to ask very specific questions, but their blood stem cell system is too different from the human to address our research questions.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Our past experience has brought to our attention specific adverse effects that can be monitored and minimised. For example, we refined our breeding protocol (P1) to identify certain genetically altered animals by eye inspection using fluorescent goggles whenever possible. As a result, we have been able to eliminate tail clipping as a procedure.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

LASA guidelines for the administration of substances are followed at all times. Moreover, NACWOs and NVSs bring to our attention relevant publications describing practices that we can implement. For example, as a result of such interactions we have implemented the body conditioning score system to ease the identification of human end points in all our experiments.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

Because this is a follow-on project licence (PPL), the majority of the protocols have been revised and refined from the REDACTED I held.

All protocols undergo constant refinement as new and improved approaches are developed that minimise mouse discomfort and allow better welfare monitoring. Continuous collaboration with local Named Animal Care and Welfare Officers (NACWOs) and NVS ensures that our work is constantly refined and always up to date with any 3Rs advancements. In particular scheduled PIL re-trainings have been proving an excellent approach to ensure implementation of any 3Rs advances.

Explain the choice ofspecies and the related life stages

We work with mice because their blood production system is remarkably similar to the human one. Moreover, they are small, and can be genetically altered, allowing us to test several theories about the cells and molecules causing damage to blood stem cells during leukaemia and infection stress. We work with young to mature animals, typically between 4 weeks and 6 months of age at the beginning of our experiments. This is because we model human adult blood production, and in the mouse, it has been shown that by three weeks of age blood production has completely switched from the foetal/developmental type to the adult/steady-state one.

NON-TECHNICAL SUMMARY

230. Understanding immune modulatory processes to prevent and treat pathology and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The immune system fights off infections and ensures the well-being of the body, but is also the cause of a wide range of different diseases, such as allergies, cancers or chronic fibrotic diseases. It is the aim of this project to understand how the immune system is balanced so that it governs the well-being of the body. Based on this knowledge we want to develop novel therapeutic approaches to prevent the development of pathology and disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system co-evolved with mammals. It protects the body against infections and regulates a wide range of processes of the body. For instance, during infections, immune responses ensure that pathogens can efficiently be cleared. At the same time, the immune response also initiates a wound healing process so that tissue damage can be kept to a minimum. Failure to regulate these processes in the correct way are an underlying reason contributing to the development of inflammatory chronic diseases, such as auto-immune or chronic fibrotic diseases, as well as cancers. In order for us to be able to find new therapeutic approaches to treat and heal these diseases, it is important to understand how they develop and at which stage the immune response has become dysregulated. This project will address these different processes.

What outputs do you think you will see at the end of this project?

The experiments performed under this licence will give a deeper understanding of a physiological relevant mechanism which is mediating local immune modulation.

We expect that this knowledge will then help us to understand how these mechanisms shape immune responses so that they can efficiently clear pathogens but do not cause autoimmunity. In line with this understanding, we may also better appreciate how commonly used immune modulatory drugs, such as TNFα inhibitors, actually work. Such results may then allow us to develop alternative immune modulatory drugs that may complement or replace currently used drugs.

Furthermore, we expect that this knowledge will reveal how immune responses maintain tissue homeostasis under inflammatory conditions and thereby prevent the development of pathology, such as tissue fibrosis. In the context of this licence, it is the aim to further develop and test novel drugs to target the pathological processes, in order to prevent further disease progression and to revert pathology.

Finally, experiments performed under this licence will reveal whether tumours are using this immune modulatory mechanism to establish a tumour-intrinsic immune-suppressive microenvironment and whether we can use specific therapeutic approaches to disrupt this immune-suppressive microenvironment and to enable immune mediated rejection of tumours.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Each of these three different topics affected by experiments performed under this licence are areas of great research activity. Thus, any results from our experiments will be of great benefit for other researchers as well as for clinicians working in this field.

Several experiments will also address the underlying mechanisms of drugs already approved for clinical application. Thus, our experiments may suggest for a better educated application of these drugs or the application of these drugs for other/novel disease descriptions. Thus, a wide range of patients suffering from auto-immune or chronic inflammatory diseases or cancers could directly profit from our research.

Finally, all these different areas of research have the clear potential for the development of novel therapeutic drugs, that could complement or replace drugs already approved for clinical application. Following further development of these drugs for clinical application and clinical trials, these drugs could then potentially further enable the treatment of patient groups - potentially also of patients suffering of diseases, which currently cannot be treated.

How will you maximise the outputs of your work?

A critical aspect of maximising the effect of our research is to find recognition by key, influential people in the field. These could be other researchers or clinician or stakeholders in companies. To achieve this, we will aim of publishing our results in recognised journals and to "spread the word" in social media. Furthermore, it is important to attend influential conferences in the field and to present our work.

Furthermore, critical for the translation of our findings into clinical approved drugs is to find collaborations with pharmaceutical companies, with whom together we will develop our research findings into translation-able compounds.

Species and numbers of animals expected to be used

- Mice: 8000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Using well-established, standardised methods, animals will be immunised, given an infection or auto-immune diseases will be induced (Objective 1).

Wounding can actively be introduced or chronic inflammation induced. Similar to human asthma or atherosclerosis, also in mice such chronic inflammation will then lead to pathology (Objective 2).

Tumour development will be induced (Objective 3). This can be slowly on a predisposed genetic background, or this can be done by the transfer of tumour cells. Tumour growth will then be blocked using different immune mediated approaches.

To experimentally manipulate the immune responses in above mentioned model systems, mice may receive substances or cells via injections. Also their food and drink might be altered (high-fat food to induce atherosclerosis) and animals may inhale allergens.

The infection models are relatively short (about one week), the auto-immune models last longer (about 6 weeks), while the tumour and chronic tissue remodelling experiments tend to last over several months.

All animals are closely controlled during the experiments and euthanised at the end of experiments.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Almost all experiments have minimal impact on the well-being of the animals.

Similarly as to what is known for humans, also our animals may not yet experiencing any discomfort although, for instance, their atherosclerosis might have progressed substantially, or their asthmatic lungs might already have lost a substantial fraction of their lung capacity, or a tumours might have grown to a substantial size. These are all critical read-out measures for our experiments, but at this stage may not have caused any discomfort to animals, yet.

Nevertheless, some infection models may lead to transient weight loss (still moderate) and some auto-immune models may for instance lead to substantial, transient paralysis, as seen for the mice undergoing EAE, the mouse model of human MS.

All experience of significant pain (for instance during wounding) will be under anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Mild 80%, includes animals used for:

- Breeding colony for GA strain

- Short term immunisations or mild infections

- tumour experiments

- chronic tissue remodelling

Moderate 20%, includes animals used for:

- infections intended to introduce wounding or mice with induced auto-immunity. These mice may experience weight loss till about 20%

- in EAE (the mouse model of human MS) experiments animals may experience transient paralysis

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Pathological processes, that often underly diseases, progress over a very long period of time. During this time, a wide range of different cell types need to communicate with each other. The immune system is key player in these pathological processes. Nevertheless, the immune system itself is yet again a highly complicated network of different cell types that at different time points secrete distinct patterns of factors that all influence each other. In particular, key players of the immune system, so called T-cells, are activated at locations that are physically separated from the site of inflammation or infection. Pathogen derived products are actively transported to these sites, where T-cells are activated, and the these activated T-cells return to the site of inflammation / infection, where they perform their protective function. These functions can then lead to pathogen clearance but may also contribute to wound healing and the maintenance of tissue well-being. Thus, while in the last decades we have made tremendous progress in understanding the underlying processes of this system, we are far away from being able to replicate these processes *in vitro* or in computer simulations. Thus, only animal experiments will allow us to thoroughly address these issues.

What was your strategy for searching for non-animal alternatives?

A substantial part of our research will be performed using *in vitro* model systems. For instance, we perform T-cell cell differentiation in a dish to understand the underlying mechanism that contribute to their differentiation. Also, single cell sequencing of T-cells is performed, which allows us to determine the affinity of T-cell receptors in vitro. Furthermore, mutant cell lines are established that simulate

mutations induced in mice. These cell lines can then be tested for change in established cell biological mechanisms.

We use these model systems like these to establish and test specific hypotheses, that can then be tested in animal experiments for their validity.

Why were they not suitable?

These *in vitro* model systems are very valuable to define and test some hypotheses, in specific on a single cell level. Nevertheless, pathological processes are highly complicated and the interplay of several different cell types determines the disease outcome. Thus, in order to determine the physiological relevance of a novel immune modulatory process appropriate mouse experiments will have to be performed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Only a fraction of these mice will undergo an experimental procedure. Most animal will be used for breeding. Experience from the last 5 years suggest that this is about the number of mice we need to keep our mouse colonies going.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We normally plan exactly, when experiments can be performed. In this way, we very efficiently can use every single mouse born. Given a mouse cannot be used for *in vivo* experiments, then these mice are normally used for *in vitro* experiments.

In addition, for many tumour experiments, we moved to in vivo detection of tumours, using luciferase. This allows us to track tumour growth and responses to our experimental manipulations in one and the same mouse. So far, we always had to cull test groups at different time points of an experiment. In this way, we can safe several test groups. Furthermore, use to more precise measurements, this method may also allow us to reduce each experimental group as well.

What other measures apart from good experimental design will you use to minimise numbers?

We very carefully manage your breeding colonies in response to experimental plans to reduce wastage. Excess bred mice might be killed and cells and organs be used for in vitro experiment or may be used to carry out pilot experiments to optimise dosing/new protocols to maximise data output.

Any new developments in the field we will adapt to be able to diminish animal usage.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will follow and characterise immune responses induced in several different ways. All proposed procedures follow world-wide standardised methods, which have been refined extensively over the years.

In this way, the standardised read-out systems can reliably reveal and explain underlying mechanisms of a process, while causing minimal distress to the animals.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The immune system has developed in vertebrates, thus lower animals would not suit for our studies. Furthermore, the immune system in mammals is substantially more advance than the one in, for instance, fish. Thus, the lowest mammal species is required for our studies, with the mouse being an excellent and well studied model system for which a wide range of standardised read-out systems have been established.

With regard to sedation, immune responses are usually studied for between 5-15 days and pathology is normally studied in models of chronic exposure. No animal can be under sedation for such a long period of time.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Over the last 20 years, we consistently have been refining our work.

For example, the majority of animals will be euthanised before showing clinical disease symptoms; less virulent pathogen strains feature more frequently in our experiments; and we have improved the ways that we administer drugs and blood sample infected animals. Furthermore, we avoid single-housing mice so they can benefit from huddling and social interactions.

We are also continually refining our endpoints as we gain more experience with different experimental set ups. Furthermore, animals at critical time points of specific sets of experiments are monitored at

least daily and often around-the-clock during symptomatic periods, so that measures can be taken to facilitate their recovery.

If animals show signs of sickness they are given supportive nursing measures (e.g. mash, transgel).

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The REDACTED regularly issues guidelines for how to improve experimental procedures.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

REDACTED communicate advances and development opportunities regularly.

Furthermore, we are in close contact with researchers worldwide, who keep us informed on developments in this field.

In addition, we feel it is imperative to communicate closely with animal care technicians to inform the monitoring of animals and how to make interventions more effective. We will further invest into this line of communication.

Explain the choice ofspecies and the related life stages

Mice are an exceptionally good model system to understand the functioning of the immune system and the contribution of the immune system to pathology and disease. Major breakthroughs in cancer immunotherapy, which currently heal thousands of people suffering from cancers, have first been achieved in mouse experiments. This has been achieved thanks to the uniquely characterised biology (e.g. immunity and physiology) of lab mice. Murine immune responses are well defined and the technology is highly developed that
enables sophisticated manipulations of the immune system and of individual cell types that contribute to its functioning.

Home Office

NON-TECHNICAL SUMMARY

231. Understanding phenotypes resulting from imbalances in protein O-GlcNAcylation

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

We will study the molecular mechanisms underpinning the intellectual disabilities seen in people carrying mutations in genes that control the modification of certain proteins by the addition of carbohydrate components.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Intellectual disability affects ~1% of the world population and its causes are only beginning to be understood. This work will results in an increased understanding of a sub-type of this disease paving the way for future development of therapeutics.

What outputs do you think you will see at the end of this project?

The primary benefit from this project will be novel information of this particular class of protein-modifying enzymes and their substrates within biochemical pathways. Our insights in this area to date have had significant translational impact, through the development of a number of in vitro assays/inhibitors which are now in use by a number of drug companies in their pre-clinical programmes targeting these enzymes in neurodegenerative diseases.

In addition to the direct scientific benefits, we perform patient and public outreach. For example, we have presented our result at a forum attended by patients, to explain the science that we perform and how this adds to the knowledge of their disease. The close scientific links between our group and clinicians in Scotland and Europe will facilitate patients coming to REDACTED from nationwide to better understand their condition.

Although the generation of REDACTED is time-consuming and expensive, the clear-cut highly reproducible answers which stand the test of time that this approach delivers makes the effort worthwhile. Furthermore, mouse studies on these new potential targets will lead to new interactions and collaborations with other researchers, clinicians and pharmaceutical companies who will use our models in their own analysis to drive the research field forward. We will share our animals, reducing the need for others to generate lines and therefore reducing overall animal use.

The key aim of our mouse work is to use knock-in or knock-out mice in which the modification of proteins by carbohydrate components is disrupted and use these in in conjunction with other research to provide a robust framework of knowledge of how the signalling pathways are regulated and organised. We also wish to understand how these pathways intersect with others that appear to be involved in Parkinson’s and Alzheimer’s diseases.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The results from this work would indicate that patients bearing these mutations/suffer from these neurodegenerative diseases might benefit from a future drug that targeted OGA and this information would be useful for pharmaceutical companies developing OGA inhibitors.

How will you maximise the outputs of your work?

Primarily the new knowledge generated will be published in open access journals. REDACTED generated will be made available to others in the field to maximise output from them. Even where the original hypotheses are rejected we will publish these data in a peer reviewed scientific journal.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

Mice carrying patient mutations will be generated using genetic approaches. Tissues derived from these mice will be used for biochemical analyses. Mice will undergo behavioural assays aimed at testing memory/habituation functions in a non-stressful setting. Some animals may receive substances that are intended to affect the biochemical pathways under study.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We will use established mouse models of neurodegenerative disease and generate new models that carry the same mutations as patients suffering from specific inherited intellectual disabilities. We will study the molecular changes that occur in cells and tissues as a result and will correlate these findings with behavioural and cognitive testing in the mice. We may administer agents that are already known to affect how the enzymes of interest work in isolated cells. As neurodegenerative disease in humans is usually associated with ageing, we expect to have to keep some animals at least for one to two years, in order to be sure that we would significant significant changes in behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We do not expect any animal to become seriously unwell.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While we can introduce genetic changes of interest into previously “normal” cells, we cannot recapitulate the complexity of the human (or mouse) nervous system that might translate a change at the DNA level into a behavioural difference, without using an intact animal.

What was your strategy for searching for non-animal alternatives?

We already use cell lines and the fruit fly as models where possible.

Why were they not suitable?

There are no suitable “Alzheimer’s” or “Parkinson’s” cell lines in which to study whether the enzymes of interest are affected in these human diseases.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Breeding and maintaining the required number of lines, with the final numbers being dictated by the genotypes obtained.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Hypothesis-testing experiments will be designed to have sufficient statistical power to be robust, without using too many animals.

What other measures apart from good experimental design will you use to minimise numbers?

Breeding and maintenance will be carefully managed so as to prevent waste.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use genetically modified mice.

Why can't you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We have chosen to use mice as they are easily genetically standardised and modified. Their nervous systems are more similar to our own than, for example, the fruit fly system is.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We expect the great majority of animals to experience very near-normal welfare but will implement scoring systems to ensure that any adverse effects of neurological changes are recognised and kept to the minimum consistentwith the scientific objectives.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will follow the LASA guidelines on administration of substances.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will regularly consult the NC3Rs website and participate in local animal use discussion platforms.

Explain the choice ofspecies and the related life stages

Mice are genetically tractable, have a short generation time and a gross central nervous system similar to our own.

Home Office

NON-TECHNICAL SUMMARY

232. Understanding platelet function and regulation in a Zebrafish model

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.

Key words

Zebra fish, Platelet, thrombosis, haemostasis, development

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Platelets are small cells in the blood that play an important role in the prevention of bleeding. However, platelets can also stick together to form a clot, called a thrombus, which can result in a blocked blood vessel. This can reduce blood flow to the heart, leading to a heart attack, or to the brain, leading to a stroke. Platelets have also been shown to play an important role in the interaction with other types of cells. Currently treatments which influence the behaviour of platelets are not effective for all patients and some patients experience life threatening bleeding. This programme of work aims to understand how platelets work to identify new and safer targets for patients. The programme will also enable judgments to be made of potential side effects of drugs with influence the interaction of platelets with other cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project will advance our knowledge of platelet function and how this can be manipulated to develop new and safer ways to treat patients at risk of heart attack or stroke. By understanding platelet function, a better understanding of potential side effects from drugs which influence platelet function and the interaction of platelets with other cells can be achieved.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use 12500 adult Zebrafish over 5 years. Where possible the larval form, before the onset of independent feeding, will be used

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Most of these animals will be used for breeding only (mild severity) and it is expected that there will be little or no adverse effects from breeding. Some animals will experience minor procedures such as small blood samples. Most experiments will be conducted under anaesthetic from which the animals will never wake up from. Some animals may be exposed to substances in the water or occasionally by other routes, before being anaesthetised for the procedures. The animals will then be humanely killed. We do not expect the animals to experience more than minor distress from these procedures. Any animals which show more than minor discomfort will be humanely killed.
Some of these animals will be kept until they reach the end of their healthy lifespan (usually between 2 and 3 years). These animals may be exposed to substances in the water and be imaged non-invasively

under anaesthetic at intervals. Once these animals display signs of distress they will be humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

How platelets respond to injury and contribute to developmental processes cannot be understood without the use of animals. It is not currently possible to recreate the complexity of these processes with alternative approaches which do not need to use animals. The majority of experiments we will do in this project will be in Zebrafish larvae. The majority of protected animals will be used to breed fish with genetic modifications

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use the literature and discussions with others with relevant expertise to ensure we are using the minimum number of animals. Animals will be used for breeding only over their healthy lifespan. The literature and data from pilot studies will be used to predict the group sizes needed to generate statistically significant data.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Zebrafish are used to identify and understand genes which affect human development and diseases as many genes and cell biological processes are found in both humans and Zebrafish. Zebrafish have many of the genes important for platelet function and genes which mediate the interaction of platelets with other cell types. Where possible substances which influence platelet behaviour will be given in tank water removing the need for physical administration. Anaesthesia will be used to minimise any discomfort experience by the fish and fish will be continuously monitored while under a procedure.

Home Office

NON-TECHNICAL SUMMARY

233. Understanding the behaviour and welfare of ruminants

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
Sheep	neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

Farmed ruminants can experience poor welfare from many sources: painful management procedures, early mother-offspring separation, artificial rearing, inadequate environments, among others. The aim of this project is to develop a better understanding of the impact of these interventions on behaviour and welfare, and to develop management practices to improve or mitigate welfare challenges.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ensuring the welfare of all farmed livestock species is an important part of ethical and sustainable food production of animal origin. Historically, whereas there has been a lot of attention given to the welfare issues affecting very confined animals, especially pigs and poultry, rather less attention has been directed towards ruminant species, particularly as they may often be relatively less confined. However, there are a number of management practices that can have a very significant impact on ruminant welfare, where information on the impacts and best practices are still being be determined. Currently the separation of very young animals from their mothers, particularly in dairy animals (sheep, cattle and goats), are significant welfare challenges in ruminant production. The work outlined here will address these issues, and seek to develop novel or alternative practices that can improve ruminant welfare, by providing objective scientific evidence of the short and longer term impact of these management practices. These data will lend scientific rigour to discussions and debates around what can often be emotionally charged discussions on animal welfare.

What outputs do you think you will see at the end of this project?

We would publish all new information in peer reviewed journals, and make the data available to other researchers on request, and present our work at conferences. We would anticipate a minimum of 10 published papers as a result of this work. As the aim of these studies is to improve on farm management we will also present the work to stakeholders (farming community, farmer organisations, etc) and work with agricultural consultants to disseminate the work. We will make use of existing networks and platforms to share the information to farmers, veterinarians and advisers across Europe.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

The beneficiaries of this work will be:

Animal welfare and other scientists - who will gain further knowledge on the impact of the mother on the development of young animals. This will inform other research in other species (e.g. dairy cattle), and contribute to the body of work on early life impacts on development. The work will also develop standardised tests, which will have wider benefit for application in assessments of animal responses in other experimental settings. These benefits will be achieved throughout the lifetime of the project.

Farming community - who will gain information on optimal husbandry strategies for managing young animals, particularly for those using artificial rearing. These benefits are likely to be realised towards the end of the project when the complete data are available.

Farmed ruminants – the aim of this work is to improve the welfare and management of young farmed livestock, resulting in improved quality of life for ruminants in the future. The knowledge and understanding of the issues may also be relevant to other species, where early weaning and raising without the mother may also occur, such as rearing of surplus piglets.

Policy makers - the information developed will be of use to policy makers in the formation of animal welfare and food policy to develop ethical practices for the treatment of farmed animals. We will work with government and other agencies throughout the project to keep them appraised with the work, and benefits could be achieved throughout the project.

Retailers - ethical food production is increasingly on the agenda, and consumers have become more concerned about the way animals are treated on farm. The work will be of benefit to retailers seeking to respond to this concern by providing informed evidence on which to base decisions.

How will you maximise the outputs of your work?

We will continue our collaboration with scientists in REDACTED, who are working on brain imaging techniques which informs the behavioural responses we would expect to see, and develop new collaborations where appropriate. New knowledge will be disseminated through academic channels and news-worthy outcomes will be disseminated via press releases and articles to allow uptake by the general public. Animal behaviour, including of farmed animals, is often of interest to the public and we will aim to make the work widely available. We will use as many of our existing channels as possible to reach policy makers, farming organisations and retailers to ensure that they have access to good quality evidence on the impact of husbandry practices on animal responses. We will also share the behavioural testing paradigms used widely with others in the scientific community, including information on those aspects of the work that have not been successful.

Species and numbers of animals expected to be used

- Sheep: 240
  Goats: 24
  Cattle: 24

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the

likely duration of suffering.

Typically animals in the project will be separated from their mothers between 24 and 48 hours of age, mimicking what occurs in the dairy industry for different ruminant species. The impact of this early life event on subsequent emotional and neurological development will be assessed through the use of behavioural tests that ask how well the animal can learn different tasks, or how they respond to pleasant and unpleasant events. These tests are designed to be relevant to the species and would be similar to, or not exceed in unpleasantness, the normal practices of rearing these species on farm. To help us understand the full impact on the animal we will combine behavioural outcome measures with sampling of blood, saliva or faeces to build a complete picture of how early life events influence animal development.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

We anticipate that rearing without the presence of the mother will alter neurological development in young ruminants, and will be associated with distress on initial separation. This may not have long lasting impacts on the animal when maintained in benign and stable conditions, but could increase distress, anxiety and fear when animals are exposed to frightening or challenging stimuli, and may also limit the ability of the animal to experience pleasant responses. In addition, this may impair the learning ability of lambs, calves or goat kids, which could lead to feelings of frustration or anxiety. Rearing without the mother may also reduce immune function, which increases susceptibility to disease, and cause greater responsiveness to pain and stress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

We anticipate that the severity of the procedures to be used will be mild, and for nearly all the animals used in the project. Our aim is to mimic commercial on farm practice throughout, and as far as possible we will use behavioural tests that rely on animals learning through rewards and pleasant experiences rather than negative events.

What will happen to the animals at the end of the study?

Kept alive
Rehomed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal welfare is about the experience of an animal: its feelings and how it copes with the environment. We use animal behaviour as a key indicator of how the animal is experiencing its environment. It is not possible to replicate this in a non-animal model.

What was your strategy for searching for non-animal alternatives?

Computer-based modelling studies may allow us to make some predictions about how animals might cope with environmental changes.

Why were they not suitable?

These methods are useful to help refine and improve design, but to be able to access animal welfare measures there is no suitable substitute for the use of living animals.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers were estimated based on our previous experiments to derive data for power calculations, or from the literature.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have used advice from our local statistical consultants in designing the studies to minimise the numbers of animals required, and drawn on the expertise of our collaborators and our own experience of running similar experiments to optimise the numbers of animals required for the project.

What other measures apart from good experimental design will you use to minimise numbers?

Where the variance of some behavioural outcome measures is less well known, or the impact of early life experience on these measures is less well studied, we will monitor animal numbers and effect strengths to

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

We will use the newborn offspring of sheep, cows, or goats, from birth through to weaning and until they reach adulthood for some. These animals, and their mothers, are most commonly used on farm in normal commercial production, and we need to know how they respond to various challenges in order to ensure that we can improve their management to reduce suffering and improve on farm welfare.

The main methods we will use will be behavioural observation. This may be by observing and quantifying spontaneous behaviour (such as maternal care) or by imposing various behavioural tests on an animal - such as responses to novel objects, ability to solve spatial or other puzzles, discriminatory abilities, startle or judgement bias tasks. These may require minimal unpleasant experiences of the animals (e.g. exposure to novelty can provoke fear in some animals) but as far as possible these will be paired with neutral or pleasant experiences.

For some parts of the study we will replicate procedures typically conducted on commercial farms (such as early mother-offspring separation as used by the dairy industries). These may be associated with fear, or distress, but to ensure that we can understand the impact of these procedures on behaviour or other biological outcomes, and in order to be able to develop improved methods or advice, this is unavoidable. As far as possible we will ensure that we make use of appropriate protocols to minimise suffering, and will apply rigorous endpoints and interventions in our management.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

The work will assess the behavioural and cognitive impact of on farm procedures - this cannot be achieved by using other species or life stages, as farm management is specific to species, and the impact of these procedures may be less important or less long-lasting in other animals. Maternal care differs between species, and the impact is also dependent on the stage of development of the offspring at birth (for example some animals may be very immature at birth, whereas others are considered to be precocious). Although studying maternal care in other species can be useful for developing hypotheses, for the work to have application in improving animal welfare if must be conducted on the relevant farm species.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

We will monitor the impact of early mother-young separation on our outcome measures, and adjust these if the severity is greater than anticipated. Should we find that the impact on neonatal development leads to greater fear and distress in the testing process than we expect we will modify test design to reduce the fear-related components. Animals will be trained and habituated to testing and sample collection to reduce the impact of fear of novelty or restraint. We will use pain relief and rigorous pain management where ever this is feasible, and will aim to shorten the period of pain assessment to the minimum required to achieve experimental objectives.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

We will use NC3Rs guidance on positive reinforcement training, handling and restraint, anaesthesia and analgesia where relevant. We will also adhere to published guidance on best practice in behavioural testing from the Laboratory Animal Science Association (LASA). Animal housing and husbandry will at least meet, and may exceed, that required under the ASPA.

When publishing our work we will use the ARRIVE guidelines to ensure that we make all the relevant information known to others to help refine further studies.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will continually review our procedures throughout the time course of the study, and seek less harmful alternatives whenever these are avat at birth, or maternal strategies, make extrapolation between species unreliable. Therefore, we need to study these species to be able to understand the full impact of early mother-young separation. In order to develop improved methods to manage young ruminants, and to mitigate any potential adverse consequences, we need a better understanding of the impact on neonatal animals, and through to adulthood, of early life events.

NON-TECHNICAL SUMMARY

234. Understanding the mechanisms underlying chronic obstructive pulmonary disease (COPD)

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

The aim of our work is to better understand the processes driving chronic obstructive pulmonary disease (COPD). Despite much research to date, we still do not understand what triggers and drives disease forward well enough to develop better therapies to stop or reverse this – current therapies merely help manage the disease, and this represents a huge unmet clinical need.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

COPD has recently emerged as the third leading cause of premature death globally (World Health Organisation data). COPD causes an enormous health and socioeconomic burden, and this burden is growing due to the lack of research into better treatments, when compared to e.g. cardiovascular disease, where mortality is falling because intensive research has led to better treatments for patients.

The processes that drive COPD are poorly understood, but chronic inflammation is clearly very important. This Project focuses on the role of a cellular protein, REDACTED, which we know plays a role in other lung diseases, and is a key driver of a range of diseases that feature inflammation. This suggests REDACTED could be an attractive drug target in COPD, and this work will test whether blocking REDACTED activity could be a valid therapeutic strategy to develop drugs for more effective COPD treatment.

What outputs do you think you will see at the end of this project?

This work is expected to provide new insights into how the lungs can be regulated. It will provide us with an understanding of the pathways that contribute to the perpetuation of disease and repair processes, which are associated with chronic obstructive lung disease. The development of novel therapeutic strategies requires an advanced understanding of the roles and mechanisms of action of cells and proteins that are altered in disease.

This work will help provide that, and the new information we discover will be disseminated as widely as possible to other researchers via scientific publications (in journals and at scientific conferences), so they can build on this knowledge.

We will also widely engage with the public, both directly (e.g. school visits) and through social media, to help educate more people about the importance of maintaining healthy lungs. The important long-term benefit of this work is that these studies will help identify and validate new approaches that can be used to treat or better manage COPD, and alleviate the burden of disease and disability.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

In the short to mid-term term (within Project timescale), the Project will benefit REDACTED researchers including partner organisations, with a focus on understanding the disease process in COPD. In the medium term, the new information and insights about COPD will be beneficial to researchers internationally (academic and industrial) who have an interest in lung disease and inflammation in diseases, because we will publish our findings in open-access journals so that others can follow our work or use our data to inform their own research.

We anticipate that in the long term, this Project will benefit COPD patients, since there is currently significant interest and progress in developing REDACTED-targeted compounds as future drugs to tackle disease, and our research could highlight that COPD may be one such important therapeutic avenue.

Our public engagement work, which arises directly from our scientific research, will also benefit COPD patients in REDACTED in spreading greater awareness about their condition and state-of-the-art research that is underway to help them. These activities will also benefit schoolchildren in this region, as greater awareness of the importance of lung health and prevention of tobacco product abuse will contribute to future health outcomes.

How will you maximise the outputs of your work?

REDACTED

Species and numbers of animals expected to be used

Mice: 5,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

This project is very simple and does not involve procedures required to replicate or 'model' a human disease in an animal. Instead, we will answer our scientific questions by using animal cells and tissues after their death, via sacrifice of the animal by a humane method. However, since we need to compare the results of experiments using both normal (wild type) and genetically altered (for example lacking REDACTED) animals, we do need to breed and maintain these animals in the laboratory, and to test them to see if they are normal or REDACTED-deficient (by painlessly removing a piece of ear tissue).

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

The procedures are all related to the breeding and maintenance of the animals, and classified as mild in severity. Once culled humanely, appropriate tissue/organs/body fluids will be harvested for the purpose of laboratory experimentation.

Therefore, possible adverse impacts relate only to the housing of animals, testing whether they are normal or genetically altered, and maintaining them in the laboratory for periods up to 15 months.

We do not expect adverse effects on the animals as part of this project, but we will monitor the welfare of animals on a daily basis, and ensure that any unexpected discomfort or suffering is ended as quickly as possible, by humane killing if necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

The procedures are all related to the breeding and maintenance of the animals, and all expected outcomes are classified as mild in severity. All of the animals are expected to be classified as Mild.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Genetically altered animals allow us to investigate definitively the effect of a molecule we think may be a good drug target – by testing the way cells and tissues of the body function in the absence of that

protein.

The reason animals are required for these experiments is due to the multidimensional nature of lungs and therefore lung disease. It is not just certain types of cells (for example airway lining or muscle) that contribute to disease, but how they interact with each other in the complex internal environment of the lung. It is often not possible to duplicate these interactions in anything other than that of intact mammalian tissue, and our experiments will involve using pieces of lung tissue that incorporate these complex interactions.

What was your strategy for searching for non-animal alternatives?

Human cells and cell lines will be used wherever possible, to complement and validate our experiments that use mouse tissues. However, human lung tissue is not available in amounts needed to answer our scientific questions regarding complex interactions that occur between different types of cell within the lung, therefore we need to use mouse tissues as a model for the human organ.

In addition, human tissue that is genetically altered to lack certain molecules we need to study is not available, therefore using genetically altered mice, which are readily available, is the best way for us to selectively study the effect of molecules such as REDACTED.

Why were they not suitable?

As explained above, the reason animals have to be used in these experiments is due to the multidimensional nature of lung disease. It is not just particular cells that contribute to disease, but interactions between many different cell types in the particular arrangement and structure we see in the lung. It is not possible to duplicate these interactions in anything other than that of an intact mammalian system. Also, we cannot study the impact of lack of important molecules such as REDACTED in human tissue, since this requires genetic alteration, not feasible in humans but already performed in mice.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

To ensure the minimum numbers of animals are used we will only use sufficient animals necessary for valid statistical analysis (so that our results are clear and reliable). We have estimated the numbers of animals required based on size of effect that we have seen in pilot studies, and using well-accepted statistical prediction models based on these observations. A dedicated BREATH statistician is involved in aiding design and analysis of experiments.

Experiments will be performed on cells, tissues and organs collected from humanely killed animals, rather than using mouse models of disease that involve multiple licensed procedures on living animals. Not only does this mean that we can address our scientific goals in a project that does not cause significant harm to animal welfare, but also means we can minimise animal use by often using multiple cells or tissues from each animal in different experiments.

Efficient breeding strategies (generating only genetically altered, and not normal animals) will be explored as a further approach, to reduce animal numbers used. However, we must first test that this does not compromise normal physiology (e.g. inflammation responses) of the cells and tissues, and therefore experimental outcomes. Thus, we have not incorporated number reduction assumptions that are dependent on such approaches into the estimate presented here.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

We have already designed this Project based on not only a significant body of scientific literature, but further on the basis of convincing pilot studies in our laboratory, using surplus animal tissue accessed according to 3Rs principles.

We have used data from pilot studies to ensure we can measure clear results in our experiments, and performed statistical calculations in order to reduce our estimates of animals needed.

We will continue to liaise with a dedicated statistician, formally linked to the Project, throughout to ensure that experiments are designed efficiently.

We will also use NC3Rs Experimental Design Assistant tool where appropriate, and refer to appropriate recommended experimental design texts.

Finally, we will use the information obtained from our animal experiments to inform our experiments using human cells, and vice versa. This will ensure that we only perform the most scientifically useful experiments, and reduce the overall number of experiments that require animal tissues.

What other measures apart from good experimental design will you use to minimise numbers?

Our estimate of animal numbers required is based on a breeding strategy that generates normal animals (wild type) as well as those genetically altered by full or partial loss of a gene function. Although this provides the different types of animals we require to make scientifically meaningful comparisons, it is possible that we may not need as many ‘normal’ comparators as the genetically altered animals (because ‘normal’ tissues may serve as controls for several experiments). In this case, we will explore whether it is possible to reduce the number of animals required for breeding by mainly pairing genetically altered animals. This alternative approach could potentially reduce animal numbers used, provided this does not compromise normal behaviour of the animal cells and tissues, and therefore experimental outcomes.

We will inform other workers within the Institution (and external collaborators) when culling animals, so that surplus tissues can be made available to other studies (external to this Project) according to 3Rs

principles. An example of this would be knee joints, which could be used to provide ‘control’ standard tissues for ongoing work within our Institute focused on joint disease.

Importantly, we will perform ongoing weekly review of study data generated, to ensure experimental objectives are reached and thus stopped at the earliest possible checkpoint.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

The current project will use tissues from normal ‘wild type’ and genetically altered mice, a model widely used in the scientific community. Our laboratory experiments will use cells and tissues taken from animals following humane sacrifice. Prior to this, we will breed and maintain the mice for a period of up to 15 months in our licensed facility, and will take small biopsies (usually by painlessly removing some ear tissue) to identify the mice as normal or genetically altered. We therefore expect that there will be no significant animal suffering associated with this project, and we will monitor animals in our care carefully and daily to minimise any unexpected harms. Any unexpected suffering that may occur will be minimised by pain relief where appropriate, and comfort will be maximised by measures such as increased bedding, ensuring warmth and providing easy access to food and water.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

We must use mammals for this work, since the physiology of other animals would be too far removed from that of humans to generate any data that would be instructive to the study of human disease.

Mice are the small mammal model of choice due to the availability of genetically altered animals with particular characteristics that enable researchers study the importance of particular molecules and genes, to test whether these molecules and genes would make good targets for new drugs to treat disease. In this case our major focus will be on testing whether a molecule called REDACTED is likely to be a viable drug target for COPD.

Since COPD is a disease that develops in humans over a long period and is associated with maturity/advancing age, it is important that adult, fully developed animals are used for this study. We will maintain mice in the laboratory up to a period of 15 months, approximating to human middle age.

Only procedures associated with breeding will be used in this project, minimising potential for significant animal suffering. Tissues and cells will be harvested and utilised in experiments after humane sacrifice by an approved method.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

Significant welfare costs to animals are not expected in this project, since only procedures associated with breeding and maintenance of normal and genetically altered mice are included. Health of animals will be carefully monitored by experienced staff on a daily basis, and we do not expect significant adverse characteristics of the genetically altered animals, with which we already have considerable experience.

For genetic testing, techniques with least impact on animal welfare will be utilised will be used to minimise possible infection,

Mice kept to middle age (up to 15 months), could show signs of ageing, such as skin sores (which will be resolved with pain relief creams), or excessive growth of teeth (which will be clipped if necessary).

Other refinement measures will include environmental enrichment, increased bedding, maintaining warmth and easy access to food and water.

If welfare costs are greater than expected as normal for a mouse of this age, then such animals will be humanely culled by staff trained and assessed as competent.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

The NC3Rs website hosts a wide range of resources, including online videos, dedicated to refinement through such means as optimised experimental design, and housing/husbandry. https://www.nc3rs.org.uk/3Rs-resources.

This site will be accessed regularly to search for updated resources. The applicant is registered with NC3Rs in order to receive regular newsletters and email updates, and the Named Information Officer also provides updates to users of the animal facility and to AWERB.

NC3Rs strategy for improving welfare of research animals is published:

Prescott MJ, Lidster K (2017) Improving quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156. doi:10.1038/laban.1217.

How will you ensure you continue to use the most refined methods during the lifetime of this project?

The applicant is registered with the National Centre for the 3Rs (NC3Rs) to receive email updates on new advances, and will also receive information through the Named Information Officer, part of the Animal Welfare and Ethical Review Board (AWERB) of the REDACTED.

Effective implementation of new advances will be discussed at regular (monthly) meetings where researchers involved in use of animals assemble, and at AWERB where appropriate. Project staff will

be trained in new advances so that these can be integrated into the normal work pattern of the project.

Explain the choice ofspecies and the related life stages

The project will use mice, from common laboratory bred strains.

The reason that we are using mice is because, as mammals, their physiology (how the body works) is broadly similar to that of humans, so that we might expect lessons learned by using these animals are likelyto be relevant to humans and human disease.

Another important reason to use mice in this work is because laboratory mice that are genetically altered to lack a certain molecule, are available to study. Such mice are extremely valuable to scientific investigation, as they allow us to study the impact of the absence of a specific molecule, normally present in cells, has on how the cell, tissue, organ or body system works. This is very important in predicting the outcome of blocking the molecule in question using a drug. In this case we will be mostly working with mice that lack a molecule we have found to be important in inflammatory diseases such as arthritis, called REDACTED.

We will use mice at adult stages, from maturity to advanced middle age. We will use these stages since these are the periods during a human lifespan that people are likely to develop, then show signs and symptoms of COPD.

We have not experienced or are aware of any adverse effects to the animals of lacking REDACTED in our project, but will monitor them daily in order to ensure any possible unexpected suffering is minimised. The project will use mice, from common laboratory bred strains.

The reason that we are using mice is because, as mammals, their physiology (how the body works) is broadly similar to that of humans, so that we might expect lessons learned by using these animals are likelyto be relevant to humans and human disease.

Home Office

NON-TECHNICAL SUMMARY

235. Understanding the progression of hypertensive heart disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What is the aim of this project?

To investigate the role of inflammation and elevated sympathetic nerve activity in the progression of hypertensive heart disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Heart disease is a major cause of ill health and the leading cause of death worldwide. Hypertension (consistently and abnormally elevated blood pressure) is a major risk factor of developing heart failure. Despite heart failure being a debilitating and fatal condition, the mechanisms involved in the progression of hypertension to heart failure are not well understood. This study aims to investigate the role of inflammation and sympathetic nerve overactivity in the progression of hypertension into heart failure. Understanding the causal mechanisms of the disease will allow identification of new therapeutic targets that will prevent disease progression. Furthermore, this study should help identify early markers of disease progression enabling early intervention. To achieve these goals, the study will combine research in humans and animal models of the disease.

What outputs do you think you will see at the end of this project?

We expect that this study will provide new information on the factors contributing to the progression of heart disease in response to high blood pressure. We expect the study will provide markers for the early detection of patients who are likely to progress into heart failure and require intervention (i.e. new diagnostic approaches). Finally, we expect that we will identify potential new treatment targets that could be used to prevent or slow disease progression. Depending on study outcomes, we expect to provide pre-clinical proof-of-concept data that will allow the repositioning of licensed drugs. Our findings will be published in open access PubMed-indexed peer-reviewed outputs.

What will be the impact of this proposed work on humans / animals / the environment in the short-term (within the duration of the project), in the medium-term and the long-term (which may accrue after the project is finished)?

Immediate benefits to scientific knowledge. The work carried out under this license will advance fundamental scientific knowledge of the progression of hypertensive heart disease. Our findings will be made available to other scientists and clinicians through publication in peer-reviewed journals and presentations at scientific conferences. We also aim to publish (using self-archiving tools) full datasets of the parameters measured in the disease models, for re-use by other scientists. In doing so, the study will provide a rational pathway for the discovery of new therapeutic targets. It will also provide further clinical validation of animal models of high blood pressure. The study will also provide educational

value by training a PhD student in pre-clinical and clinical approaches to medical research. We also aim to disseminate our findings to patients and their families via outreach activities.

Future potential benefits to patients. Long term, this project could be the first to deliver a safe and efficacious pharmacological treatment to prevent the progression of hypertension into milder variants of heart failure. This would benefit patients through improved health, quality-of-life and lengthened life-expectancy and reduce the socioeconomic burden caused by this disease. The likelihood of success is high, because during a previous programme of work, using the same animal model, we identified a new therapeutic target for treatment of drug-resistant hypertension that was subsequently validated in humans.

How will you maximise the outputs of your work?

As mentioned above, our findings will be published in open access PubMed-indexed peer-reviewed journals and will be presented at scientific conferences including clinical conferences. We also aim to publish (using self-archiving tools) full datasets of the parameters measured in the disease models, for re-use by other scientists. Lastly, we will contact the REDACTED media team to advertise published findings to a broader audience.

Species and numbers of animals expected to be used

- Rats: 160

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Describe, in general terms, the procedures animals will undergo, eg injections, surgical procedures. Include the typical number of procedures individual animals will undergo and the likely duration of suffering.

For approximately one third of the animals, the experimental studies will only involve the induction of a general anaesthesia. They will then be killed to enable the harvesting of tissue for analysis, never recovering from anaesthesia. Two thirds of animals may undergo one surgery under general anaesthesia and appropriate analgesia. Surgery will be performed using a strict aseptic technique and the animals will be given pain killers until they fully recover. Some animals may experience mild transient discomfort from drug administration and/or transient restraint for non-invasive measurement of blood pressure and blood sampling on more than one occasion. On separate occasions, some animals may undergo temporary sedation/anaesthesia to allow non-invasive measurements of cardiac function. These experiments are expected to last 12 weeks or less.

Expected impacts or adverse effects on the animals - for example, pain, weight loss, inactivity or lameness, stress, or abnormal behaviour - and how long those effects are expected to last.

Surgery under general anaesthesia and appropriate analgesia, is associated with post-surgical pain, and transient suffering or impairment of general condition. Most animals are expected to make an unremarkable full recovery from surgery within 3 days. Experiments are not expected to interfere with the animals' natural behaviours, some may cause only minor transient discomfort or stress, but are not expected to cause lasting suffering or harm. All animals will be killed humanely at the end of the study to enable tissues to be harvested forfurther analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per species)?

Approximately, one third of animals are expected to undergo mild severity, the remaining are expected to undergo moderate severity.

What will happen to the animals at the end of the study?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Rodents are the lowest animal order in which control of blood pressure is like humans.

What was your strategy for searching for non-animal alternatives?

A search of ATLA (http://www.atla.org.uk/), ALTBIB (https://toxnet.nlm.nih.gov/altbib.html) has returned no alternatives for achieving our experimental goals. We have considered humans, non-protected species, *in vitro* models (including organoids) and computer models.

Why were they not suitable?

Control of blood pressure takes place in the brain, one of the most complex organs. High blood pressure is believed to result from a combination of numerous factors. Thus, *in vitro* methods cannot reflect this complexity. The causes of the condition addressed in this project are not fully known and cannot be simulated in a computer model. Rodents are the lowest animal order in which control of blood pressure is like humans. Even though we will use humans in this research, the current technology available for human research is not refined enough to reveal the complexity of interactions we aim to study. Additionally, human studies can only establish correlations not causality; some of the tissue samples and interventional procedures required to confirm causality cannot be obtained/performed in humans. For these reasons, there is no replacement for use of animals in this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We carried out power calculations based on our data and published data.

What steps will you take to reduce animal numbers? Where applicable, what principles will you use to design experiments?

Experimental design and analysis were planned and discussed to prevent unnecessary replications. Clinicians, clinical physiologists, patient advocates and Pharma partners were consulted to ensure that data can support future clinical trials. Advice was also thought from mathematicians and statisticians.

What other measures apart from good experimental design will you use to minimise numbers?

We will measure as many outputs as possible from the same animals, particularly ex vivo. We aim to publish our full datasets after the study is completed so they can be re-used by other scientists.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Why are the animals, models and methods you will use the best to meet your objectives? Why will your approach cause the least pain, suffering, distress or lasting harm?

In this project, we will use a rat model of high blood pressure. These rats have naturally occurring mutations and spontaneously develop hypertension. The pathology in these rats is like hypertension in humans, they respond similarly to clinical interventions (e.g. anti-hypertensive drugs), and drug-targets developed in this model have demonstrated a similar role in the pathology as in humans. In approximately one third of animals, we expect to use ex vivo techniques to measure progression of hypertensive heart disease. In the remaining, we expect to use mostly methods that allow measurements of cardiac function in conscious freely moving animals. These methods include the latest refinements available and are not expected to cause prolonged pain, suffering or lasting harm.

Why can’t you use a less sentient animal, (for example at an immature stage, a less sentient species or using terminally anaesthetised animals)?

Because rodents are the lowest order in which blood pressure control is like humans. Further, control of blood pressure and cardiac function is significantly affected by general anaesthesia, therefore whenever possible, and welfare concerns can be addressed, physiological measurements must be performed in conscious animals.

What are you going to do to refine the procedures (for example increased monitoring, post-operative care, pain management, training of animals) to minimise the welfare costs (harms) to the animals?

To minimize welfare impact, all recovery surgical procedures will be aseptic. Animals may experience transitory discomfort or pain as they recover; thus, they will be given painkillers and post-operative care just like people in the hospital. All animals undergoing surgery are expected to recover quickly. In the unlikely event of post-operative complications, adverse reactions, or if any animal fails to recover and exhibit signs of pain, distress or ill health, testing will be discontinued, and animals will be humanely killed. After recovery, animals will be free of pain and able to exhibit all their normal behaviours. Animals will typically be housed in social groups, but some experiments may require single housing for a limited amount of time. In consequence, animals may experience mild transient anxiety. All animals will have enriched environments and will be handled frequently to reduce boredom and anxiety. Whenever possible, medicines will be administered via non-invasive methods. However, some animals may experience mild transitory discomfort from receiving an injection. If repeat drug injections or blood sampling are required, the routes and volumes will be suitable for their age and size and will be such that animals fully recover between interventions and will not suffer more than transient pain and distress and no lasting harm and there will be no cumulative adverse effect. As stress and anxiety affect control of blood pressure, all animals will be handled using non-stressful handling techniques. They will also be allowed to adapt to experimental conditions in advance of experiments to reduce stress and may be given food rewards.

What published best practice guidance will be followed to ensure experiments are conducted in most refined way?

https://nc3rs.org.uk/

How will you ensure you continue to use the most refined methods during the lifetime of this project?

We will regularly consult the NC3Rs website and published literature for latest advances in 3Rs. Advances will be discussed with NVS and will be implemented if they are deemed feasible, sufficiently validated, and do not compromise the robustness and the comparative value of the designed protocols and ongoing studies.

Explain the choice ofspecies and the related life stages

In this project, we will use a rat model of high blood pressure. These rats have naturally occurring mutations and spontaneously develop hypertension. The pathology in these rats is like hypertension in humans, they respond similarly to clinical interventions (e.g. anti-hypertensive drugs), and drug-targets developed in this model have demonstrated a similar role in the pathology as in humans.
