NON-TECHNICAL SUMMARY

1.Advancing the knowledge and treatment of paediatric brain cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Brain tumour, Paediatric, Cancer, Treatment

Animal types	Life stages
Mice	juvenile, adult, neonate, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects' objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary objective of this project licence is to understand the origins and biology of paediatric brain tumours and to identify new treatments that can be translated into clinical practice.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Paediatric brain tumours represent the second most common cancer type to affect children but are also the most lethal. Of the 130 different kinds of paediatric brain tumour Ependymoma (EPY), Medulloblastoma (MB) and Choroid Plexus Carcinoma (CPC) are the most common and deadly solid cancers. Part of the reason for this is that treatment has not changed for more than 40 years and remains an aggressive regime of gross or partial resection surgery, radiotherapy and often chemotherapy and still results in a 30-50% death rate. Of those that do survive, the impact of such a harsh treatment program means that in the majority of cases, these children will be significantly impacted for the rest of their lives, and only 1% will achieve a college level education. Ependymoma and Choroid plexus carcinoma are also resistant to current chemotherapies and inevitably recurrence of these tumours occurs.

It is widely understood that childhood brain tumours comprise many distinct diseases each with different origins, prognoses and challenges. It fits, therefore, that each tumour type would require a different method of treatment. In order to determine the most effective treatment there is a need to first understand the biology of the disease and to develop models that faithfully recapitulate their human counterparts.

An accurate model of sonic hedgehog subtype of medulloblastoma (SHH-MB) was developed in 2004 and used to identify new treatments that could be efficiently translated to children with this tumour. However, models of other brain tumour types, such as Ependymoma, WNT-medulloblastoma and CPC, did not exist until recently. Using cross species genomics, we have now generated mouse models of each of these cancers that do not require invasive methodologies, but form tumours *in situ*. We propose in this licence to utilise these models in furthering knowledge of the mechanisms involved in initiation and progression of each tumour type, and more importantly to enrol these models into our pre-clinical mouse hospital in order to identify new treatment options that can be translated into the clinic, and ultimately reduce mortality rates and the long term side effects to the child. We will continue to use our robust and reliable, orthotopic implant (in which cells are transplanted into the brain) and patient derived xenograft (PDX, in which cells taken from human tumours are implanted into the mouse brain) models, for each tumour type, in our pre-clinical mouse hospital to explore the impact of novel therapeutic methods alongside the standard-of-care treatment. Data produced from the genetically

engineered mouse models (GEMM), orthotopic and PDX models in this setting, will provide extremely strong evidence to support the progress of these treatment methods, into human clinical trials.

What outputs do you think you will see at the end of this project?

The research outlined in this proposal aims to make much needed progress in the understanding of the origins, biology and treatment of three of the most important forms of paediatric brain tumour.

Upon completion of this project, we expect to have generated and fully characterised new genetically engineered mouse models of two of these tumour types.

Further to this we will have generated models for exploring the roles of specific genes and gene mutations in normal and tumour development (tumorigenesis). Importantly these models will have been crucial in advancing knowledge of disease relevant biology.

New treatments of childhood brain tumours are needed. Alongside the aims within this project (to develop new and repurposed drugs that may be delivered through novel localised methods) the approach laid out in this project has a significant chance of advancing effective new therapies.

One of our most important outputs will be new treatments for each of these brain tumour types that are ready for clinical trials. These will be based upon their individual biology and are therefore, specific to and effective against their respective human diseases.

Publications originating from this project and all mouse models generated will be made available to the scientific community and could thus be important for scientific advancement of other research groups.

Who or what will benefit from these outputs, and how?

In the short term the outputs of this project will provide new information that will benefit the scientific and translational research community, through peer-reviewed publication of our work. This information will not only fill gaps in current knowledge and provide a basis for further investigations into the biology of these diseases but will also provide guidance for research into other types of children's brain tumour.

As some of the tumour types in these studies are rare and therefore, with access to samples limited, we have formed international collaborative networks, who will also benefit from sharing resources. The mouse models generated will provide powerful tools for further investigations and for testing of novel treatments. Our patient derived brain tumour atlas will be an informative and detailed resource that will benefit academic and medical communities, aiding in quicker and more accurate diagnosis of patient samples.

In the mid-term, our research strategy will enable direct translation of novel treatment options from mice to human clinical trials. This will provide significant evidence regarding the efficacy of the treatment in mice and as a result, increased confidence in its success in human subjects. Benefits at this stage will be seen by the translational research scientists, clinical scientists and a small number of patients.

Our long-term aim for this project is to see clinical practice in the treatment of brain tumours change, from the current aggressive and damaging standard of care, to an effective tumour specific treatment plan that not only improves prognosis but does so with fewer, or no, lasting side effects. Thereby

improving the quality of life for patients, and their families. Following curative treatment this will further benefit healthcare practitioners, by reducing the need for life-long care and alleviating the costs associated with long-term care of survivors.

How will you look to maximise the outputs of this work?

Maximising the output of this work will be achieved through open communication and sharing of our progress throughout this project with academic, clinical and lay audiences, using a variety of forums, such as teleconferences,scientific meetings and collaborative websites.

All scientific results will be published in peer-reviewed open-access journals in a timely manner, to ensure that the information presented is widely available. At the time of publication, we will also make available the wealth of complex sequencing data and functional maps, that will be generated from this research through supplementary files and by uploading to publicly available repositories.

Following characterisation and peer-reviewed publication of the mouse models generated in this project, mice will be made available, upon request, to researchers for non-commercial research.

The researchers associated with this project will be encouraged to present their findings at scientific conferences. This will enable wide dissemination of work and promotion of further collaborations.

As our research aims to generate more effective treatment options that can be translated from mouse to human clinical trials, we believe that establishing open communication with the public, and in particular patients and their families is critical. As a result, we have actively engaged in demonstrations and lay seminars and our website will include specific elements specifically designed for public and patient engagement.

Species and numbers of animals expected to be used

- Mice: 20377

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The overall aim of this project is to gain a better understanding of the origins and biology of 3 of the most important types of paediatric brain tumour and to develop new, effective treatments that can be translated to the clinic. Using the best models and methodology is critical in achieving this aim and for this reason we will use mice for our research.

Mice are commonly used as an animal model for brain tumour research due to the following factors:

- They have similar genetics to humans

- Their embryonic and post-natal development programmes are similar to that of humans
- They have a similar central nervous system (CNS) anatomy to humans
- Mice have the most comparable neurobiology and immune system to humans
- Mouse response to treatments are the most similar of all laboratory models.

Previous research shows that the mouse models used in brain tumour research to date have demonstrated many similarities to human brain tumours and are able to mimic very closely the progression of human disease. Non-mammalian models do not share such similarities and are unable to reproduce many of the features of human brain tumours.

In vitro (cell culture) systems cannot currently replicate the complexities of the mammalian organ systems, particularly the human brain and central nervous system. Further to this, regulatory and research bodies require the preclinical assessment of potential new therapies in animal models prior to their translation to the clinic.

The scientific community has a range of techniques that enable manipulation of the mouse genome, allowing us to generate models with which we can answer specific key questions regarding brain tumour biology. The models described throughout this project represent the optimal models for the study of human childhood brain tumours and for testing the efficacy of novel therapeutics.

The studies outlined within this project that are aimed at testing novel therapeutics will involve the use of adult mice. However, protocols aimed at exploring the mechanisms of disease will include animals of varying life stages. Each stage has been specifically selected because they are the most appropriate age for the study.

Typically, what will be done to an animal used in your project?

Many of the animals used within this project will develop a brain tumour. This may be induced by one of four methods:

1. Breeding of genetically altered animals by natural breeding behaviour. This may result in the birth of animals that will spontaneously develop a brain tumour as they age, due to an activated cancer-causing gene (oncogene) or gene deletion. Alternatively, the offspring of these animals may require use of a drug, either during pregnancy or soon after birth to have the same effect. Administration after birth will require an injection on two consecutive days, after which the animal will be left to age and will be monitored for tumour development. Some pregnant females may receive up to 6 injections during pregnancy, with agents that mark developing neural cells in order to study the origins of brain tumours.

2. Some animals may receive an injection into the brain whilst they are still a developing embryo. In these cases, a pregnant female will undergo a short surgical procedure to expose the uterus and the embryos injected through the wall of the uterus. Following the injection, the uterus will be returned to the abdomen of the mother and the surgical procedure completed by sewing up the abdominal wall. The female will then be cared for and allowed to deliver the babies naturally. The offspring, once born, will be aged until they develop a tumour.

3. A small number of animals may receive an injection directly into the brain within 2 days of birth, in order to cause a tumour to develop. This will be carried out under anaesthesia.

4. Some animals on this project will develop tumours following a surgical procedure to implant tumour cells directly into the brain. This will be done on a single occasion and under general anaesthesia. Animals in these studies will only be adult animals.

The majority of these animals will be monitored for tumour development using a non-invasive imaging method, which requires light anaesthesia and injection of a substance to enable visualisation of the tumour as it grows. This will be performed on a weekly/twice weekly basis until the animals either demonstrate symptoms associated with a brain tumour or until the tumour reaches a pre-determined size before symptoms occur. They will then receive treatment for the disease. The exact timing of this will vary between the different tumour types but is performed to ensure that the suffering of any animal is kept to a minimum.

Animals that are enrolled on a treatment study will then undergo one, or a combination, of treatments that mimic the experience of a human patient in the clinic. Some of these animals will receive, as part of their treatment, newly developed but thoroughly tested, drugs and some may be delivered in new ways. These treatment options include a surgical procedure to remove the brain tumour, carried out with extreme care and under anaesthesia. Resection surgery will take no more than 45 minutes per mouse. These animals will be allowed 3-4 days to recover from surgery before being given treatment using new or current chemotherapeutic agents and/or radiotherapy.

Chemotherapy will be delivered by a variety of methods including injections, orally, or in drinking water. They may also be delivered using newly developed methods such as a biodegradable product called hydrogel. The hydrogel can be mixed with any drug and injected into the space left by the removed (resected) tumour. This will be done immediately after the tumour removal, reducing the number of procedures the animal undergoes. Alternatively, a pump may be inserted under the skin of the animal that will deliver the drug directly to the brain through a cannula, which will be installed following the removal of the tumour. Treatment studies will last no more than 3 months and animals will be monitored throughout for signs of sickness.

What are the expected impacts and/or adverse effects for the animals during your project?

Many of the animals used in this project are not expected to experience suffering. On rare occasions mice undergoing some of these procedures will exhibit post-procedural symptoms indicating pain or infection. Topical or systemic treatments for these will be immediately provided and mice will be closely and regularly monitored.

Animals that are expected to develop a brain tumour are not expected to experience suffering from the procedures used to initiate tumour formation. On rare occasions an animal may experience pain, tiredness or a head tilt following the surgery to implant tumour cells.

All animals that are expected to develop a brain tumour will be monitored closely using non-invasive imaging, in order to determine if a tumour is growing. The majority of these animals will be enrolled onto treatment studies before symptoms associated with an established brain tumour develop. However, some animals will experience symptoms including:

- Gait problems including laboured movement, wobbly movement or limb dragging.
- Excessive tiredness.
- Seizures.
- Symptoms associated with hydrocephalus (domed head, hunched posture, head tilt or twitching).
- Weight loss of up to 20% (typically this is recovered within 7 days).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals used within this project (~75%) will experience a moderate level of severity. The remaining animals (~25%) will be expected to be in the mild or subthreshold category.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although *in vitro* cell culture methods can be used to test the transformative effect of gene mutations on particular cell types, this system cannot recapitulate the complex microenvironment (i.e. the arrangement and physiology of many different types of cells) that exists in tissues and organ systems. Our scientific approach requires the use of cell types that are susceptible to cancer, at specific time points during development and animals remain the most informative model, as they recapitulate the diversity of cell populations, complexity of human development and the crosstalk between tumour and stromal (non-tumour) cells in human cancers. Our careful use of human genomic and in vitro cell culture assays (most notably to test signalling elements and novel therapies) has capacity to triage cancer causing lesions, dramatically reducing the number of animals used in exploratory genetic models and markedly increases the efficiency with which we develop cancer models.

Animals are required to achieve our aim as regulatory and research bodies require preclinical assessment of potential therapies in animal models before their translation to the human clinic. In spite of this we will continue to use cell culture methods, such as drug sensitivity studies, and in vitro

radiation and chemotherapy combination studies to optimise the selection of agents and minimise the numbers of animals used in testing potential therapeutic agents to those that have shown the most promising effects.

Which non-animal alternatives did you consider for use in this project?

In the careful design of our research project, we considered the use of methods that would minimise the need for animals, such as cerebral organoid (3D cultures of mixtures of brain cells of the appropriate type) cultures. However, such systems do not always model the complex nature of the organ development or the biology of cancer.

Where possible we will use alternative research approaches that do not involve the use of animals. In particular we will use in vitro methods, including culture of patient derived cells and the generation of iPSCs (induced pluripotent stem cells), to screen potential therapeutic agents for efficacy against tumour cells.

Why were they not suitable?

Although the use of cell culture methods will enable us to reduce the use of animals, they cannot fully replace them as they do not model the complexity of the organ or the tumour. Organoid, cell culture and iPSC systems lack many of the features that accompany a human brain tumour, such as a functional blood-brain barrier, the diverse cell populations and the immune system. The fact that we require the use of specific cancer susceptible cell types at specific developmental stages and that regulatory bodies require the preclinical assessment of novel therapies in animal models prior to translation to human trials, dictates that we must use animal models to achieve our aims. It is therefore, critical that we use the best models and methods for this research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our use of *in vitro* (cell culture) methods reduces the number of animals required for the *in vivo* investigation stage of this research. Furthermore, each of our mouse model experiments has a careful statistical design that is aimed at minimising the use of animals while ensuring robust and meaningful statistical end points. These animal numbers are selected in collaboration with highly qualified statisticians and are based on our extensive experience with brain tumour mouse models.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In designing the experiments described within this project we aimed as much as possible to reduce, replace and refine our use of animal models. In order to achieve this, whenever possible, we will use cell culture methods to replace or reduce the number of animals used in studies. For example, in trials of novel drugs, we will first determine how efficient the drug is in cell lines that have previously been generated from an animal model. This will be performed using a series stringent downstream analysis methods. These *in vitro* results will help indicate how and whether a mouse study should be performed.

Where mouse model experiments are required, we have used a careful experimental design that allows us to minimise the use of animals, whilst achieving the maximum amount of data and maintaining reliable statistical end points.

In many of our animal models we have included the use of a bioluminescent reporter (a gene that makes the tumour cells glow) to enable visualisation of the growing tumour or its therapeutic response over time. As a result, we will be able to reduce the number of animals required to achieve both growth and survival data. The bioluminescent information can also be used to determine a point at which a tumour is established but is not large enough to cause symptoms, indicating the correct stage to start treatment studies. This also reduces the severity of the overall experience of the mouse.

We have also worked closely with a senior biostatistician, to develop and implement an experimental design that enables the adjustment of mouse numbers used in a particular group, according to the latest information.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise the number of animals required in our project we ensure the use of the most up to date laboratory methods for processing materials collected from animals used in this licence. By doing this we are often able to achieve the maximum amount of data from smaller samples. In this way we can split samples collected from one mouse into downstream numerous applications. For example, one piece of tissue can be used to generate fresh cells for culture, frozen samples for molecular analysis and fixed material for histology.

By employing standardised SOPs for our experimental design, particularly in our novel treatment studies, we can use data from control animals in one study, as controls in another (within the same tumour type) and thereby reducing the number of animals required in this project. Where needed pilot studies will be performed, which will inform the design of subsequent studies, potentially enabling the reduction of numbers.

Where possible, our genetically engineered mouse strains will be maintained as homozygous in order to reduce the breeding needed to generate mice of the required genotype and to optimise the efficiency of offspring carrying the appropriate alleles for the experimental purposes.

As part of a good standard of practice, each experiment will be preceded by the writing of an experimental study protocol which will outline our objectives and methodology and will include statistical endpoints. All of these will ensure that we are using the optimal number of animals to achieve the aims of this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the only species that are employed in our protocols. In particular, we will use genetically engineered mouse models (GEMMs) that replicate three of the most important human paediatric brain tumours; Ependymoma, Choroid Plexus Carcinoma and Medulloblastoma. These strains have been specifically generated to carry the genetic mutations that lead to tumour formation in the human diseases. In this project we will use these strains to explore the biology of the disease by inducing tumour formation using a variety of methods including conventional breeding, *in utero* injection or injection of agents. Animals in these studies will be maintained under normal conditions until a specified time, at which point material will be collected and analysed as previously described. These methods are all designed to result in no more than a temporary discomfort to the mice. These models may further be used in the preclinical assessment of novel treatments, as they most closely recapitulate the human condition.

Orthotopic implantation of tumour or patient derived cells, for use in treatment studies, will be carried out in immune compromised CD1 nude or NOD SCID Gamma mice (NSG). These intracerebral transplantation models are necessary to avoid rejection of human material and to enable rapid tumour growth for treatment studies, as these cells are expected to engraft and induce tumours in transplanted mice. The methods involved in assessing novel treatments can result in a more severe experience for the mice and so to reduce the number of animals enrolled in such studies, we have refined our workflow to include initial testing of leading agents using a subcutaneous implantation model. Subcutaneous tumour models are well documented in literature for use in such studies, but as they lack the blood-brain barrier they cannot be used to replace the need for orthotopic implant models in the final test of a novel therapeutic.

The majority of our mouse models utilise a bioluminescent tag that enables the real time monitoring of tumour development. Using this allows us to limit the suffering for the mice by providing a guide for progression to development of clinical signs, and thereby a humane endpoint by which to ensure suffering is kept to a minimum.

We will minimise suffering by adhering to the best practice guidance, currently the NCRI guidelines for the welfare and use of animals in cancer research. Every protocol proposed in this licence is the most refined for the purpose and designed to cause the minimum distress and suffering to the animals.

Why can’t you use animals that are less sentient?

Mice are the most relevant species with the least sentience that we can use to carry out the research proposed in this project. Their short lifespan (approximately 2 years) allows for studies in which disease

progression can be monitored throughout development to humane endpoint, mimicking far closer the disease progression in humans. Further to this, the short gestation time (~3 weeks), extensive published knowledge and the array of techniques that enable manipulation of the mouse genome, allows us access to genetically modified animals in which we can explore the effects of genes on normal brain development and tumour formation in a species where the process is similar to that in humans. Less sentient species do not follow this same developmental program. Non-animal models cannot recapitulate the complex context of tissues in which cancers develop, particularly in the brain where the blood-brain barrier and functional immune system are key features, or the complexities of the tumours themselves. These features are critical for understanding the impact of potential novel therapeutic approaches.

The advancement of knowledge and development of concepts to improve human and animal health and well-being requires the use of living animals. Exhaustive literature searches in brain tumorigenesis show that our tumour systems are the most accurate models for the study of these diseases. The use of our preclinical mouse hospital in the testing of new treatments includes the use of combinatorial approaches, including irradiation and chemotherapy is critical as it allows the assessment of novel agents in context of treatment actually received in human clinics. This is the best approach to find new therapies that will succeed in the clinic and will further reduce the number of animals needed to achieve clinical impact.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our procedures will be regularly assessed throughout the project in order to ensure that they are being performed in the most refined manner. Refinements will be routinely made over the course of the project through constant advice from veterinary and husbandry staff, as well as through regular liaison with clinical practitioners. For example, we will work closely with the NVS to look for a less aversive inhalation anaesthesia in order to reduce stress on the animals.

If needed amendments to the licence will be applied for, for example, if new procedures are needed to improve the welfare of animals.

Within our last licence period we have made several refinements to our procedures, in order to ensure that we are using the most refined method for the study and reduce suffering to the mouse. For example:

- We have worked closely with practicing clinical neurosurgeons to refine our surgical procedures, including the use of biopsy scissors in order to resect tumours and a fine cauterisation pen for stopping bleeding following resection. Both of these refinements have resulted in fewer losses.

- The use of osmotic minipumps to deliver chemotherapeutic agents is more invasive, however, by using a pump that can remain in place for one week, we are able to reduce the number of injections that a mouse may receive and thereby reducing handling and stress for the animal. In order to reduce stress on the mouse even further the pump is implanted under anaesthesia and pain relief is provided.
- Finally, the use of oral gavage to deliver tamoxifen to pregnant dams has been shown in the literature to carry a reduced risk of embryo loss.

We aim in this licence to determine treatment regimens that reduce exposure to anaesthesia but that result in a better prognosis for the mice and ultimately for human patients.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Work in this licence will be undertaken in accordance with the principles set out in the Guidelines for the welfare and use of animals in cancer research: British Journal of Cancer (2010):102: 1555-1577 and the guidelines published by the NC3Rs, which are updated regularly with the best current practice.

All surgical procedures will be performed under the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) and blood sampling will be performed as recommended in the NC3Rs guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We currently follow updates provided by the National Centre for the 3Rs through receipt of electronic and printed media and through regular attendance at our Institutes AWERB committee. Throughout this project we will

- communicate constantly with veterinary, NACWOs and husbandry staff,
- receive updates from the NC3Rs and
- will attend NC3R and scientific conferences.

These approaches will allow us to be aware of the most recent advances in the field and will enable us to implement these into our research in a timely manner.

NON-TECHNICAL SUMMARY

2.Analysis of cell signalling in a zebrafish disease regeneration model

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

regeneration, stem cells, signal transduction, developmental biology, disease modelling

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the important roles that cell signalling plays during disease and regeneration. By understanding better how different signalling pathways interact we will be able to inform new clinical approaches.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A firm understanding of how cells communicate in a simple vertebrate will inform clinical approaches to disease and disability. Cell signalling molecules are the master regulators of cell behaviour and cell fate. This has made them popular targets for pharmaceutical strategies and the development of new medicines. A good example of how our work has informed clinical studies is in the understanding of an inherited childhood tumour disease. Our studies have shown how the disease functions in the initiation of cartilage tumours (osteochondromas). This understanding has led to the development of a drug for the treatment to suppress osteochondroma formation. Understanding the important roles that signalling plays in different disease states and during regeneration is our ongoing aim. This project promises to aid in the treatment of many degenerative diseases and in recovery from injury or surgery.

What outputs do you think you will see at the end of this project?

The outputs from this project will include publication of our study in highly respected journals, presentation of results at international scientific conferences and patents based upon our discoveries. In particular we will reveal new signalling pathways that identify and recruit regenerative cells. We will characterise how these pathways affect cell behaviour at the single cell level: How these signals control cell differentiation, cell shape changes, migration and proliferation. We will use genomic approaches to understand how global transcriptional changes affect these processes. All of these finding will enhance our ability to identify new protein targets for pharmaceutical intervention in a clinical setting.

Who or what will benefit from these outputs, and how?

The understanding of how cells communicate underpins much of our understanding of human disease. For example, mutations that affect signalling genes often confer cancer. One such gene is HER2 which when mutated may result in breast cancer. Genetic tests can now identify individuals that are susceptible to breast cancers long before the cancer forms. Herceptin is a commonly used treatment for breast cancers that was developed based upon our understanding of how HER2 acts in cell communication. It is difficult to predict at this point the specific clinical problems that will be impacted by our research as our studies focus on the basic understanding of cellular interactions. It is also difficult to estimate the time it will take for significant clinical milestones to be achieved based upon our basic research findings. However, it is likely that our results will at some point help clinicians to better understand how altered signalling results in different disease states. Many signalling molecules also make excellent targets for pharmaceutical intervention. By identifying new important interactions we will be providing pharmaceutical companies with novel targets for the design of inhibitors. Further beneficiaries of our research are pharmaceutical companies with which we have collaborated in the past. Such collaborations between academia and industrial partners is crucial for scientific, medical

and economic progress to be made. Finally, researchers in the fields of biology and chemistry will understand and act upon our findings in their own research domains.

How will you look to maximise the outputs of this work?

We are a highly collaborative research group with interactions both nationally and internationally. Our group has organised two international research conferences and our results have been published in over 50 research papers.

Species and numbers of animals expected to be used

- Zebra fish: 31,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish was chosen for this study because of its low sentience (neuronal complexity) and because is a vertebrate which has many of the same genes as humans. This project will involve working with all stages of the life cycle. This is because we would like to understand cell behaviour throughout the life course.

Typically, what will be done to an animal used in your project?

Most of the fish for this project will be used for breeding purposes. Typically, these fish mate naturally and lay eggs to establish the next generation. Most of these fish will be transgenic or carry mutations. We will also use fish to generate new transgenic lines. Typically, this involves adding genetic material to the eggs when they are at the one cell stage, then raising the fish normally. These two procedures will account for more than 95% of the animals used in this study. Of the remaining fish they will experience more invasive techniques such as being exposed to pharmaceutical treatments, or having small pieces of their fins removed. These invasive techniques are necessary to understand how cell signalling functions during regeneration.

What are the expected impacts and/or adverse effects for the animals during your project?

Although the vast majority of our animals lead healthy lives, there may be unforeseen effects on the health of the fish due to our experimental regimens. These include the formation of open sores, necrosis, ragged fins, very slow and irregular heartbeat or oedema, tumours, abnormal behaviour and weight loss. Animals that display these signs of ill health will be killed by a Schedule 1 method. Our protocols are designed to minimise suffering and if animals are in poor health or visible pain the experiment will be aborted.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals will experience only mild severity. A small proportion (less than 2%) may experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The study of the role of combinatorial cell signalling involves different tissues and the complex extracellular milieu that is present in living organisms.

Which non-animal alternatives did you consider for use in this project?

Our project builds upon the knowledge gleaned from in vitro studies. As this project develops, we will seek to move experimentation into in vitro systems. We will do this through collaborations with tissue culture laboratories.

Why were they not suitable?

In vitro studies do not allow us to identify new signalling events from unexpected sources. The complex interactions that occur between multiple tissues cannot be recreated in an in vitro system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This project relies on analysis of mutant and transgenic fish in the heterozygous and homozygous state. Strains are usually maintained by crossing heterozygous carriers to wildtype stock (an outcross). To obtain a reliable and consistent number of fish, one must have a sizeable colony of identified heterozygous carriers. These are usually obtained by random crossing of pairs of fish which means that we can only estimate the number of fish that are needed. Furthermore, sex ratio inequalities make it difficult to know how many fish are needed: often the ratios of male to female are as low as 1:10 in a given tank. Thus to be sure that enough pairs can be tested to obtain enough carriers, a large number of outcrossed fish must be raised. Maintenance of mutant and transgenic strains makes up the majority of the number of fish used for this project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will try to minimise the number of animals used by careful experimental planning, but as these experiments are exploratory in nature it is difficult to precisely predict the number of animals needed for this project. Where applicable, we will write a individual study plan for each experiment including: a statement of the objective(s); a description of the experiment, covering such matters as the experimental treatments, details of the experimental material, and the size of the experiment (number of groups, numbers of fish or embryos/group); and an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and with the treatment differences that are to be estimated). When ever possible we will seek to move experimentation into in vitro systems. We will do this through collaborations with tissue culture laboratories.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have a highly successful breeding program that is a model for zebrafish facilities around the world. For experiments, we only perform the necessary number of experiments to obtain publishable (significant) data. Our protocols are designed to minimise suffering and if animals are in poor health or visible pain the experiment will be aborted.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish (Danio rerio). Most of the animals used in this project are simply being bred which is a regulated procedure.

As the embryos develop ex utero, experiments and harvesting embryos can be done without harming the parent. Zebrafish are an extremely tractable system and techniques such as transplantation, injection of genetic material and GFP analysis are standard in the laboratory. The transparency of zebrafish allows one to follow the behaviour of labelled cells (i.e. green fluorescent protein) over long periods of time. Chemical modifiers are easily applied by addition to the media. Some of our study involves analysis of regeneration: In our bone crush assay, a single ray in the tail fin is crushed: this damages as area no larger than 0.01mm2 and containing approximately 50 cells. This damage is not visible to the naked eye. Tail excision in adults involves removing 0.2 to 0.6 cm from the tail and is visible. The tail is very thin, and the total weight of the tissue removed is 2-4 milligrams. In comparison a fish weighs 1-2gms. Thus although with adult tail amputation damage is visible, it is still a very small amount when compared to the entire animal. Fish repair damaged fin tissue rapidly and these types of injuries occur regularly in nature.

Why can’t you use animals that are less sentient?

We use zebrafish (Danio rerio) for our research because it is the least sentient vertebrate model system. This model allows us to study complex cell behaviour involving different tissues (e.g. skeletal tissues) in a simple organism. Most of our research is done in immature life stages, however it is sometimes necessary to confirm important results in older life stages to draw more general conclusions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Procedures that may cause distress to the fish are performed under deep anaesthesia. After procedures fish will be closely observed and monitored for any signs of distress. If a fish is showing signs of distress then the experiment is stopped and the protocol will be reviewed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are many useful resources on the NC3Rs website (e.g. webinar July 2020: “Best practice in experimental design)”. Zebrafish husbandry publications include Zebrafish by Christiane Nusslein-Volhard and Ralf Dahm in Practical Approach Series (OUP) and The zebrafish book: A guide for the laboratory use of zebrafish Danio* (Brachydanio) rerio by Monte Westerfield, Institute of Neuroscience, University of Oregon. The new ARRIVE Guidelines 2020 will also be strictly adhered to (https://journals.plos.org/plosbiology/article?id=10.1371/journal.pbio.3000410)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs regularly holds online workshops and events aimed to improve experimental procedures with a focus on the 3Rs. We continually review and refine our protocols with discussion between our researchers,our NACWOs and our NVS.

Home Office

NON-TECHNICAL SUMMARY

2.Angiogenesis in health and disease

Project duration

1 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

angiogenesis, skeletal muscle, remodelling, sarcopenia, hypertrophy

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We have identified novel approaches to regain control over blood vessel growth that is lost in many diseases, allowing us to better understand the cells and molecules involved in regulation and devise more targeted interventions. Much of this work has been successfully addressed, but Covid-19 lockdown prevented the final experiments needed to complete studies for 2 PhD students, so we wish to have a short-term licence to continue the current licence aims, objectives and procedures.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

An adequate, but not excessive, blood supply is critical to health
. Hence, numerous pathologies arise as a consequence of disrupted vessel growth.

What outputs do you think you will see at the end of this project?

The aims of the work are expected to be realised, given that this is a licence intended to complete the final experiments in a series already started before interruption by Covid-19 lockdown. We will continue to generate outputs aimed at wide dissemination of the results including posters and oral communications at scientific meetings, peer-reviewed articles and reviews, research seminars and public engagement events.

Who or what will benefit from these outputs, and how?

Cell and molecular biologists, physiologists and biomedical scientists will benefit from these outputs in the short term. Public understanding of science is part of the long-term goal. Adoption of the findings may influence clinical practice and aid in rehabilitation medicine.

How will you look to maximise the outputs of this work?

Immediate beneficiaries are other researchers in the field, or other fields of biomedical research; patients with relevant pathologies and/or clinicians attempting treatment; society as a whole due to the social value of new knowledge, which may in time form the basis of economic benefit. Benefits will be utilised to inform better diagnosis and new treatments, or improved quality of life, based on these pre-clinical data; intellectual gain will accrue from dissemination of new knowledge, e.g. publishing in scientific journals and informing other research; these data will complete publications begun under the current PPL. The timeline of benefits will be varied: immediate benefits will be the provision of essential data to inform the next stage of the project; short to medium term benefits will accrue from published

papers to inform the scientific field; long term benefits may include major discoveries based on this original work, but the nature of scientific research cautions against making unrealistic goals on this score. Benefits will be maximised by use of data as the basis for subsequent grants, thereby continuing the process of knowledge expansion, and where possible by exploiting the intellectual property rights in conjunction with the University legal department.

Species and numbers of animals expected to be used

- Mice: 36
- Rats: 48

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using animals previously demonstrated to exhibit similar mechanisms of muscle hypertrophy/atrophy as seen in humans, which will allow us to explore new ways of supporting exercise tolerance in conditions where mobility is limited.

Typically, what will be done to an animal used in your project?

For some animals, they will be put to sleep and one hindlimb muscle removed; this may occur in humans following disease, cancer or a traffic accident.

What are the expected impacts and/or adverse effects for the animals during your project?

We take care to administer pain relief after surgery, and the animals recover very quickly - indeed, they have been observed hanging upside down on wire cage lids within 24 hours, suggesting there are no serious impediments to locomotion and routine activity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All surgery is classified as being of moderate severity; 20 years experience has suggested little difference in animal response among categories.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

By careful monitoring of outcomes, we have managed to reduce the duration and intensity of muscle activity required to elicit vessel growth, have refined the interventions to reduce the discomfort, but as we are investigating a complex integrated response have not yet found a suitable alternative to use of whole animal models. As this project seeks to complete two PhD studies interrupted by Covid-19, it would be inappropriate to adjust any procedures at this stage.

Which non-animal alternatives did you consider for use in this project?

N/A

Why were they not suitable?

Biology is inherently complex, and development of sustainable therapy cannot rely on simplistic models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have many years experience using these animals with these or similar interventions, and seek to use the minimum number that will provide robust data: ambiguous findings arising from the use of inadequate sample size to allow appropriate statistical analysis would be a waste of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have previously engaged the services of biostatisticians to ensure were using adequate, but not excessive numbers of animals. Our long experience in conducting such experiments has demonstrated the validity of this approach, in that our findings have been replicated by other laboratories around the world.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We always attempt to derive as much useful data from each animal, to both maximise the benefit derived from each animal used but also to minimise the use of additional animals. This may take the form of tissue samples used for two different analyses, or measurements made under terminal anaesthesia followed by ex vivo experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use a model of inducing muscle hypertrophy that is consistent with the extent of compensatory growth seen in a number of clinical conditions, without inducing pathological responses as seen in some alternative methods. For development of obesity and complications we use a strain of rat that spontaneously develops this condition.

Why can’t you use animals that are less sentient?

We have demonstrated over a number of years that the biological responses we are studying are conserved among mammals, but there is little evidence to suggest less sentient animals would have the same response. As the therapeutic goals are aimed at muscle dysfunction most typically experienced in adult life, using immature stages would be inappropriate as we know there are mechanisms aiding recovery that are lost with age. The response we are studying are part of a dynamic remodelling process, and hence require chronic intervention, beyond the scope of anaesthetic insensitivity.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is the final stage in an established research program, so further adjustment to procedure would invalidate much of the data generated from animals used so far, so would violate our commitment to upholding the 3Rs principles.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow current advice from the Home Office regarding regulatory procedures and advice, and follow current standards laid out by reputable biomedical science journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to relevant sources of reliable animal welfare advances, such as Understanding Animal Research and the National Centre for the replacement, Refinement & Reduction of Animals in Research, and communication with local named veterinary surgeon and animal care staff.

NON-TECHNICAL SUMMARY

3.Antibody-based therapeutics for cancer

Project duration

5 years 0 months

Project purpose

- (a) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (b) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop new medicines that modulate the body's own response to cancer to provide better and safer treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Although in recent decades a lot of progress have been made in prevention, diagnosis, and treatment of cancer, it is still the second leading cause of death globally, accounting for an estimated 9.6 million deaths in 2018. In the same year, approximately 17 million new cancer cases were reported. Due to the aging population, genetic factors, and unhealthy life-style choices, the cancer burden continues to grow globally. This exerts a tremendous physical, emotional and financial strain not only on individuals and their families, but also on communities and national health systems.

Currently available cancer treatment options are often invasive, painful and damaging to the patient, these include surgery, chemotherapy, and radiotherapy. In recent years, a novel class of therapeutics which directly engage and modulate patient's immune system to fight cancer has been introduced to the clinic. These new drugs, predominantly antibodies, have shown great potential in a percentage of patients with particular types of cancer and for whom other therapeutic options had been exhausted. However, these new drugs have failed to change the overall outlook in which only half of cancer patients will survive for 10 years or more after cancer diagnosis. It is important that new medicines are found that can treat patients with cancer, without causing further harm.

What outputs do you think you will see at the end of this project?

The main outputs of this project licence will be the development of novel therapeutics for the treatment of cancer.

One of our antibody is currently being tested in clinical trials and another is in advanced stages of pre-clinical development. The studies performed within this project will help us to define which diseases can be targeted with these drugs, which dosage is the most indicated, and what other drugs could be used in combinations to have a stronger anti-tumour effect.

For our programs that are at earlier phases of development, we will gain the necessary knowledge to validate their targets and potentially obtain antibodies or antibody-based therapeutics that could progressed to clinical development.

Who or what will benefit from these outputs, and how?

At the moment, many cancer patients have a poor prognosis and their disease continues to progress despite being treated with current medicines. This project will provide the supporting data to develop novel therapeutic antibodies that will benefit patients either as stand-alone therapies or in combination with other agents, increasing response rates and ultimately being able to bring about effective disease control in a greater number of patients. This would benefit not only individual patients, but also communities and national health systems.

How will you look to maximise the outputs of this work?

Our findings will be presented at national and international scientific conferences and meeting as posters and talks, and eventually published as scientific articles and patents.

The results of the accompanying clinical trials will be included in the entries to the ClinicalTrials.gov and/or published in the scientific journals.

Species and numbers of animals expected to be used

- Mice: 12500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project, we are developing antibody-based therapeutics against cancer.

Mice are used in oncology studies because of well understood genetics, availability of well validated tumour models, and relative ease of manipulation of the immune system. As tumour growth is a relatively long process, we will be using young but fully adult mice (6-12 weeks old) so that their immune system is fully matured and can resemble the human situation.

Typically, what will be done to an animal used in your project?

In this project, we will be administering therapeutic agents to mice challenged with tumours, using predominantly subcutaneous (implanted under the skin) and occasionally orthotopic (implanted to relevant organs) tumour models. In rare occasions, when needed for the subsequent steps, mice could be pre-treated before implantation of the tumour.

When using subcutaneous tumour models, mice will be tagged usually by the implantation of a chip for identification purposes, then partly shaved on the site of injection and injected with cancer cells or fragments under brief anaesthesia. After recovery, tumours will be allowed to grow while the mice are being monitored. When the tumour is established, usually by 6-15 days, treatment will commence. In most cases mice will be dosed with intraperitoneal injection (through the wall of the abdominal cavity) 2-3 times a week for up to 3 weeks. On some occasions, treatments may be administered more often and via other routes e.g. orally or intravenously. During the study mice will be observed, weighed and tumour size measured non-invasively usually 3 times a week. The studies will be terminated when enough data on the anti-tumour effects of the treatments have been collected and no additional scientific knowledge could be obtained, usually no more than 5-6 weeks after tumour implantation.

When using orthotopic tumour models, the tumour cells will be implanted surgically into the relevant organs, e.g. liver, kidney capsule, or pancreas, under anaesthesia. The surgical wound will be repaired by suturing and mice will be allowed to recover from anaesthesia under observation. After that, mice will be monitored, weighed, and the tumour growth estimated by palpation. When tumours are established (depending on the model, between 5-20 days after tumour implantation), mice will be treated with antibodies, cells and/or other compounds, and monitored as described for the subcutaneous models, with the exception of tumour growth being estimated/measured by palpation.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals used in this project will be bearing a subcutaneous tumour and will be dosed with antibody-based treatments. Growth of tumours implanted subcutaneously are expected to have only mild adverse effects, unless it undergoes ulceration or necrosis (death of tissues), with the latter expected only in rare cases. Ulcerations will be graded and closely monitored; mice will be humanely killed within 48 hours from the appearance of a grade 3 wound (a full thickness skin loss with shallow tissue damage).

Physiological responses to the treatments such as tumour growth and antibody mediated biological activities may result in some adverse effects. Antibodies are usually very well tolerated, but their administration could lead to temporary mild adverse effects such as weight loss or piloerection. These effects usually resolve within 2 days from appearance.

Orthotopic implantation of cells might results in temporary mild pain as in most cases it requires surgery and suturing; these will however be ameliorated by the administration of anti-inflammatory drugs and analgesics. Orthotopic tumours may in some cases metastasize more easily to other sites causing behavioural changes and weight loss that will be regularly monitored and alleviate whenever possible, for example with provision of food supplement on the cage floor.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In this project, individual procedures are expected to result in only mild adverse effects in most mice. However, most experiments will include more than one treatment/procedure which will result in a cumulative level of severity likely to be moderate for all the animals used in Protocols 1, 2 and 3.

Most mice used under Protocol 4 will experience procedures only under terminal anaesthesia, thus they are expected to be classified as non-recovery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer cells co-opt many immune cells, including macrophages, neutrophils, T-cells and non-immune supportive cells such as fibroblasts or endothelial cells that build blood vessels, to suppress the immune system and create an environment which supports the growth of tumours. In this project, we will be developing antibody-based therapeutics that re-invigorates immune cells in the tumour micro-environment so that they can fight cancer.

The intricate interaction between cancer cells and the immune system within the tumour, but also systemically, can only be modelled properly in an animal setting.

Which non-animal alternatives did you consider for use in this project?

It is possible to model some properties of the tumour micro-environment in 3D cell cultures such as spheroids or organoids. They are usually very simple and composed of a single cell type derived from human or animal tumours. They allow for medium throughput screening of drugs that directly affect growth of tumour cells.

It is also possible to study cancer in human tumour explant cultures. These are derived from the patient resections and are the best representation of human disease tissue. They are, however, very difficult to obtain, the amount of tissue is generally small thus allows only to study a limited number of conditions/treatments.

Why were they not suitable?

3D culture systems are very simplistic. In most cases, they include only single cell type (cancer cells) and as our test molecules will be targeting immune cells, they cannot be used directly in this model. We and others are however, developing 3D culture systems that in future might include more cell types including at least some immune cells.

Patients explants are complex models, which however cannot be maintained in culture for more than just a few days. Some aspects of anti-cancer immune responses often take a week or more to fully develop and therefore cannot be studied in this system.

Both models also lack interactions with other immune system organs such as lymph nodes, bone marrow, and spleen that play an important role in anti-tumour immunity.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We are currently developing a similar number of oncology drug candidates as during the course of 2017-2018, when around 60 studies a year were performed under the previous licence, using an average of 2500 mice a year. We foresee a requirement for a similar number of animals being needed to support these programs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To ensure we use the minimum number of animals, Experiments will be carefully designed, taking into account the expected outcomes and statistical analysis of the data. Power calculations will be performed using the NC3R's Experimental Design Assistant, Gpower3.0 or other relevant software. Data previously generated in-house and literature searches, together with pilot experiments, will help to have preliminary information that will be used in the experimental design.

Sources of variability will be controlled whenever possible (cage identity, sex, age, operators etc.). Animal assignment to experimental groups will be randomized and experiments will be performed on comparable numbers of male and female mice to account for possible sex bias in the responses. If there is a known gender difference in the response to the model then the appropriate gender for the type of study will be used.

For each model, the incidence of the tumour uptake can affect the number of mice used per group. Whenever possible, we will use models with an incidence close to 100%, using low incidence models only when no alternative can be found or there is scientific evidence that these are the best models to study a specific mechanism.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All our antibodies and related molecules undergo extensive characterization of their activities in a suite of cellular and tissue assays in vitro. Only a small number of selected candidate molecules (usually from 2 to 5) is used in animal experimentation.

To further reduce the number of used mice, we will maximise the amount of data obtainable from each single experiment. Whenever possible, for example, we will obtain preliminary information on the levels of the drug in the mouse blood post injection while testing its general tolerability. This may allow us to identify any dose-related issues with a molecule and help us to optimize the dosing regimens. Additionally, we may collect tissues at the end of the experiment and test bio-distribution of our compounds and possible pharmacodynamic effects on mouse physiology.

We have also recently introduced a micro-sampling method for blood collection from tail vein for plasma isolation. Using this method, we can collect blood from the same animals over multiple time points and generate data using a reduced number of animals compared to standard blood collection methods. Following this refinement, we were able to reduce the number of mice used in this protocol by half. We will also optimize the tumour biopsy sampling technique, to reduce the number of mice needed to analyse the tumour micro-environment.

Additionally, collecting mouse tissues and performing *ex vivo* experiments will allow us to further reduce the number of live animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse models of cancer have been widely used in the development of our understanding of tumour immunology and have successfully predicted the mechanism of action and the therapeutic utility of new medicines. There is a large body of literature from which we can source information to help us define

the most efficient means of obtaining scientific data from these models while causing the least harm to the animals.

Why can’t you use animals that are less sentient?

In this project, we will investigate therapeutic interventions that modulate the immune system to fight cancer. Many of the targets for these interventions (both particular cell types and proteins) are not present in non-mammalian species. For this reason, mice with their very well understood genetics and immunology, plethora of well-established tumour models, and developed technologies to manipulate their genome are currently the species of choice for oncology research.

As tumour growth is a relatively long process, we will be using young but fully adult mice (6-12 weeks old) so that their immune system is fully matured and can resemble the human situation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be housed in a state-of-the-art animal unit where a high standard of environmental enrichment is provided to animals. Animals will be housed in groups to allow for social interaction. However, when required for animal husbandry purposes, they might be housed singly but not for longer than 8 weeks and enhanced environmental enrichment will be provided.

When appropriate, suitable analgesia and anaesthetic regimes will be used to minimize animals suffering. Where novel agents are administered, the duration and frequency of monitoring will be increased to ensure that no animal will suffer unduly. Humane endpoints will be continuously evaluated for each model and refined wherever feasible.

All studies will be reviewed internally by the Project Licence holder and the personal licence holders involved before commencing to ensure that experiments are aligned with the Licence and reflect the implementation of best practices.

All the compounds used in animal studies will undergo extensive quality control checks and where possible, we will use drugs sourced at clinical grade. Tumour cell-lines will be free from infectious contaminants, confirmed by external tests for various rodent pathogens.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The "Guidelines for the welfare and use of animals in cancer research" published in the British Journal of Cancer 2010, the PREPARE guidelines and our Campus Animal Usage guidelines will all be used to assist with the planning and of experiments. The “Guiding Principles for preparing for and undertaking aseptic surgery” (LASA 2010) guidelines will be followed for surgical procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All staff involved in the design and implementation of animal experiments in line with this project licence will be encouraged to participate in relevant tumour modelling conferences, courses and workshops to stay on top of current trends in the field.

Additionally, they will register on the NC3R mailing list to ensure communication of best practices. After action reviews will occur internally and in consultation with the named people to ensure best practice is implemented at all times.

Home Office

NON-TECHNICAL SUMMARY

5. Arabian killifish; a novel animal model for investigation of embryo development and infection

Project duration

5 years 0 months

Project purpose

(a) Basic research

Key words

Arabian killifish, zebrafish, transgenic fish, mutant, CRISPR/Cas9

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult, pregnant
Arabian killifish, Aphanius dispar	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Zebrafish are currently used as models for embryo development and infection studies. Arabian killifish have characteristics with potential to make them a better model for these studies. The aim of this project is to produce genetically altered zebrafish and Arabian killifish from which naturally spawned eggs and embryos will be collected. These will be used for development and infection studies to compare the two models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The zebrafish embryo has been a very important model organism for studying development and infection because of the large fecundity and accessibility for high resolution microscopic imaging due to its small size and transparency. However the zebrafish embryos start moving after 15 hours, therefore to trace the cellular and tissue events in the embryo in later embryonic stages, it requires anaesthetics and in such condition, physiological responses are often compromised. On the other hand, the Arabian killifish embryos do not move for the first 4 days therefore it is more suitable for longer tracing of the cell and tissue behaviour. In addition, the yolk of the Arabian killifish is far clearer than the one in zebrafish facilitating higher resolution imaging in many tissues. In case when we use the model for infection studies using human pathogens (e.g. Candida albicans), it is ideal to infection at human body temperature, however zebrafish embryos cannot survive this temperature. We found that the Arabian killifish embryos can survive and develop normally to the hatching stage at 37'C making the model more suitable for studying the behaviour of human pathogens. To establish the Arabian killifish model and to clarify common and distinct features of its cell behaviour and imaging capability, it is necessary to create similar GA animals in two species and compare the performance as model systems. For infection experiments, we will focus on human opportunistic pathogen, Candida albicans. C. albicans normally live in the human body without harming the host. However, when the host health condition is compromised, such as during immunosuppressive treatments, C. albicans is no longer suppressed by immune cells and becomes a life-threatening pathogen. However, the invasive process by C. albicans and its interaction with cells at diverse body sites is not well understood due to the difficulty of imaging infection in vivo. In this project we will modify the activity of the host immune system using our model species and pinpoint the key interactions that make host tissues able to resist or become susceptible to colonisation by C. albicans.

What outputs do you think you will see at the end of this project?

(c) Publications: we will published a few high impact papers reporting importance of our new model system, Arabian killifish, as a model for infection at human body temperature. These papers will include: a description of normal development of the Arabian killifish embryo, technical papers reporting

the method for infection experiments using Arabian killifish, and the molecular mechanisms of infection by Candida albicans and the host response in the Arabian killifish.

(d) Transgenic fish resource: We will establish useful transgenic fish lines in the Arabian killifish. These fish embryos grow with all-over fluorescence or in specific cell-types within the embryo (e.g. immune cells, muscle or brain) therefore the shape, position and size of the body and tissues can be easily visualised under fluorescence microscope. These fish lines will be available for researchers all over the world. The zebrafish is currently a very popular model animal for testing infection and drug screening in both academic institutions and in pharmaceutical industry. As the Arabian killifish has similar advantage for imaging and high through put drug screening, and it can be applied with human body temperature, this system would provide an alternative tool for basic research and drug screening in the research community.

Who or what will benefit from these outputs, and how?

5. Academic researchers: They will have the benefit of using a novel infection tool which is applicable for in vivo live imaging at human body temperature. The researchers who use mice as a model due to the right temperature and many other similarities to human infection will be interested in this model as a replacement system, as this model can do similar temperature experiment in a transparent embryo that provides real-time visual information of infection. Zebrafish researchers will also be interested as this fish permits all experiments that zebrafish can, and it can be done at 37'C. The first few papers will be published in the first 2 years. Then our TG fish lines will become publicly available. Therefore by the end of the 5-year license, many researchers will be using our fish as a model system.

6. Pharmaceutical industry: This model can be used for drug screening and testing. This industry currently uses mice, zebrafish and cell culture systems all of which have disadvantages compared to the Killifish model. We aim to discuss collaborations for its use as a drug-screening system with the aim of starting such research within the 5-year period.

How will you look to maximise the outputs of this work?

(1) Publication: We aim to publish the Arabian killifish model system for Candida infection in a high impact journal to advertise the system to relevant research community. We aim to advertise the system in conference and media as well.

(2) Collaboration with other academic groups: We aim to establish a few collaborations with other research groups and increase the user of the Arabian killifish infection model.

(3) Collaboration with industry: We will seek for collaboration with industry and apply the Arabian killifish system for drug testing and screening of anti-fungus.

Species and numbers of animals expected to be used

Zebra fish: 5000
Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish: We will use zebrafish embryos because they are small and transparent therefore are suitable for microscopic observation. Among fish species, zebrafish is the best fish for our study because important tools and protocols are most enriched than for any other fish species. These tools include transgenic fish, mutant fish, genes, antibodies and associated protocols.

Arabian killifish: We will also use the Arabian killifish embryos to complement our study on zebrafish. Though zebrafish is the most suitable model fish for studying infection in developing embryos, they cannot survive at human body temperature. Therefore, for conducting essential experiments that might be affected by temperature, we will use the Arabian killifish as another model fish.

The life stage: We will keep all life stage of the fish just for maintaining the fish in the aquarium. However, when we conduct experiments for collecting data, we will only use the embryonic stages (fertilisation to the stage when the fish start independent feeding). All of these embryos used for experiments will be terminated before independent feeding. The time of independent feeding is 5dpf in zebrafish. But the time in the Arabian killifish can vary between 10 and 12 days depending on the temperature (28 to 37'C). Therefore with 28'C, the latest date of termination is 12dpf and with 30'C or above, the latest date will be 10dpf.

Typically, what will be done to an animal used in your project?

We will collect eggs from the zebrafish and the Arabian killifish from natural spawning. These eggs will be injected with DNA or RNA to create genetically altered fish (F0 generation). These fish will be raised to adult. To select the founder fish that are indeed genetically altered, we will collect eggs from natural spawning and examine either fluorescence under microscope or presence of DNA sequence by embryo PCR. The fish identified as genetically altered will be maintained in the aquarium. These fish will lay eggs by natural spawning. We will collect these eggs, raise them to embryonic stages (stages from fertilisation to the independent feeding) and use these for our experiments. These experiments include general characterisation of the embryo development and injection of a Candida albicans and observe the process of infection and reaction of the host cells (e.g., immune cells) under microscope. All experiments will be finished before independent feeding and the embryos will be all terminated before independent feeding.

What are the expected impacts and/or adverse effects for the animals during your project?

Injected constructs may cause death or developmental abnormalities before fish reach the stage of protection. Harmful genetic alterations in embryos may be evident as altered morphology prior to hatching.

Some genetic alterations may result in a harmful phenotype during post-hatching development, observed as; failure of larvae to inflate their swim bladder, difficulty swimming, altered morphology, abnormal behaviour. Any larval fish showing any of these signs will be euthanised immediately at pre-independent-feeding stage.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity in these animals would be mild. Injected embryos may show some morphological abnormalities and these will be terminated at embryonic stages. Only healthy embryos will be raised to adult. The transgenes that we use are considered as not harmful. Therefore we consider the process to generate and maintain these GA animals have not more than mild severity.

What will happen to animals at the end of this project?

Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Unless we use animals we cannot obtain a realistic understanding of cell and tissue behaviour. Alternative methods would be cell culture methods, but such methods use one or limited number of cell types and do not reflect the true, complex in vivo environment. In real fish embryos, all key tissues exist and interact with each other in a spatio-temporal manner. In this living environment, realistic alteration of the cell and tissue behaviour in an infected or genetically altered condition will become visible. Such information is indispensable for us to learn the important process of cell dynamics in normal and infected cells, tissues and embryos.

Which non-animal alternatives did you consider for use in this project?

We could consider cell culture systems. Cultured cells (e.g. human or mouse fibroblast cells, macrophage or neutrophil cell lines) would provide host cell response to pathogens such as Candida albicans. Therefore it can be useful for learning cellular response to infection.

Why were they not suitable?

Cell culture method would not allow us to see a true in vivo response to infection, including cooperative action of different type of immune cells, skin cells, neurons, livers and blood cells. Such complex response is only seen in the in vivo system such as fish embryos. Therefore such alternative system is not suitable for us to learn realistic host-pathogen interaction.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Zebrafish: We will keep about 100 fish/line with 10 lines (total 1000 fish), and make new generation every year for 5 years making the total number roughly to 5000 fish.

Arabian killifish: Same as above.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are highly specialised in generating GA fish lines. With our hand, we can minimise the fish to raise for making new GA fish (100 fish/line).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We aim to further improve efficiency of breeding. Currently we obtain about 30 eggs from each Arabian killifish tank containing about 30 fish. It might be possible that they may lay more eggs if we could provide a better spawning chamber and modifying feeding protocol. We will try such pilot studies using the WT strain. As for zebrafish, the protocol is highly established therefore further improvement of breeding is highly challenging.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal models: Zebrafish and Arabian killifish.

Methods: Generating GA fish lines by microinjection, maintain the line and collecting eggs/embryos from natural breeding. These are all highly established and refined methods. In zebrafish, these methods are already established all over the world. In the Arabian killifish, the fish is similar to medaka killifish (ricefish) therefore similar protocol for microinjection is applicable and confirmed as very efficient (not causing adverse effects and can generate GA animal with high efficiency).

Our new model, Arabian killifish, has a strong potential to contribute in refinement of the imaging method. In zebrafish, embryos start to move at 15hpf onward therefore it requires anaesthesia for live imaging. However Arabian killifish embryos do not move for the first 4 to 5 days therefore imaging can be achieved without anaesthesia. This provides a longer time span for imaging without causing any potential harm by anaesthesia.

Why can’t you use animals that are less sentient?

We use fish embryos for experiments because they are vertebrate models which have similar tissues and body pattern to human. But they are also small and transparent allowing live microscopic observation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will keep updated novel technologies for microinjection, CRISPR/Cas9 and transgenesis from literature and conferences. This may further improve efficiency to generate GA animals (meaning that we might not need to raise 100 founder fish/line in future). We will also be updated in fish husbandry information and technology including maintenance of water quality, food quality, feeding scheme, detection of health issues, population density and enrichment of the aquarium.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the latest scientific papers and presentations from conferences for generating and maintenance of the GA fish.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow NC3Rs webpage, attend 3Rs conference and follow relevant publications.

Home Office

NON-TECHNICAL SUMMARY

6.Assessing metabolic effects of diabetes and metabolic disorders in the heart and other target organs

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Heart, Metabolism, diabetes, magnetic resonance imaging, stem cells

Animal types	Life stages
Mice	adult, juvenile
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the interplay between metabolic processes and tissue and organ function in health and disease, with a particular focus on how the development of diabetes affects liver and cardiac function. Damage to a tissue or organ can impair metabolic energy generation and vice versa. By understanding this interplay, we can develop therapeutic approaches to minimise or correct the damage caused by dysfunctional metabolic processes. As part of trying to understand these processes, we will develop new methods for non-invasively imaging them via MRI.

A retrospective assessment of these aims will be due by 03 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Metabolism underpins the function of all organs of the body and generates the energy needed for the heart and other organs to function. The heart is critical to maintaining the supply of blood and oxygen to the body, so that damage to the heart muscle, caused by a heart attack or an increased workload due to high blood pressure, reduces blood flow and energy generation in other organs. These effects are part of the reason why cardiovascular disease is responsible for 27% of all UK deaths. In the UK there are more than 100,000 hospital admissions each year due to heart attack resulting from a blocked artery. This means that part of the heart muscle is not fed with the oxygen and nutrients that it needs, heart cells die and that part of the heart muscle is replaced by a scarred region that doesn't beat properly. The rest of the heart therefore has to work harder to compensate. Recent developments in clinical practice have meant that many more people now survive a heart attack, which is either treated surgically (via stenting to open the blocked artery) or with drugs, but in some cases the damage to the heart is so severe that the heart no longer functions well enough. Currently over 900,000 people in the UK are living with heart failure. By understanding what causes the heart muscle to die and how we can prevent or reduce the damage, we can increase survival and reduce the number of people for whom the damage is so great that the heart begins to fail. Additionally, sometimes patients who are admitted with a heart attack have received damage that is unlikely to recover if treated surgically, but are operated

upon nevertheless. This exposes them to an unnecessary risk of life-changing or life-ending complications, such as stroke, ventricular fibrillation, or cardiac rupture, and it is often usually only realised in the surgical setting of the catheter laboratory that there is nothing that can be done. We are investigating the use of advanced MRI methods with injected compounds to determine whether or not the heart tissue at risk is still viable for surgery, or if it is dead and will not respond to surgical treatment. Also, by identifying exactly which areas of the heart require treatment, we are also investigating whether we can rescue the damaged region of the heart by treatment with stem cells, either injected directly into the heart or attached across the scar to form new viable tissue.

Damage to organs such as the liver and pancreas can alter the supply of sugar and fat in the blood and mean that the heart and other organs cannot generate sufficient energy to work efficiently. By far the most prevalent metabolic disease is diabetes, and its precursor known as metabolic syndrome. There are over 3.5 million people diagnosed with diabetes in the UK and this is estimated to rise to over 5 million by 2025. Worldwide it is estimated to affect 8.5% of the global population. The most common two forms of diabetes are type 1 and type 2 diabetes, of which 90% of people with diabetes have type 2 diabetes. Both type 1 and type 2 diabetes are associated with elevated levels of sugar in the blood and this, over time, leads to complications including vascular problems, high blood pressure and high cholesterol. These are major causes of coronary heart disease, which is recognized to be the cause of death for 80% of people with diabetes. Yet it remains difficult to exactly assess the degree of damage to the heart in diabetic patients, and to understand, non-invasively, what damage has occurred, or is at risk of occurring, or could be prevented in an individual patient. Metabolic syndrome and type 2 diabetes are associated with obesity, which is becoming increasingly prevalent, and which is also linked with sleep apnea, a common breathing disorder that affects many people whilst they sleep. It is thought to affect 2-4% of the population and, in turn, has been shown to increase the risk and severity of type 2 diabetes independent of age and obesity. In diabetes, there is a mismatch between supply of fat and sugar to the heart and other organs, and the ability of those tissues to take up and use those fuels. This results in reduced tissue function and the build-up of unwanted and potentially toxic by-products. We are investigating why this happens and whether we can use drug molecules to restore a more normal metabolism, thereby preventing the development of further organ dysfunction.

What outputs do you think you will see at the end of this project?

Our research will provide valuable insights into the mechanisms behind damage caused by metabolic abnormalities. It will also develop new techniques for imaging this damage, these abnormalities, and their response to treatment. Our work will be published in peer-reviewed journals and presented at national and international conferences. New MR technology and techniques will be shared with other users in the field, in publications and at conferences and workshops, and translated to clinical MRI scanners in the local hospital.
The co-PIs have published over 200 papers which have been cited over 5000 times. One PI is part of the organising committee of our Metabolic Health network which promotes dissemination of research between clinical and pre-clinical departments. She is also an active member of Diabetes UK and is able to discuss her work with the clinical community and patient groups at the annual meeting of the society. Another PI is part of the BHF-funded Regenerative Medicine Network and her work is presented to the BHF community at their annual meetings. The third PI is an active member of the International Society for Magnetic Research in Medicine and his team regularly present at meetings of the society. All PIs are members of the British Society for Cardiovascular Research and encourage members of the group to present their results at the annual meetings of the Society. One PI works in the MR using at the local Hospital and so developments in MR imaging will be directly translated into

the clinic, which we anticipate could be done within 12-18 months.

Where we are exploring pharmacological therapies, we look first to see whether we can repurpose an existing drug to minimise adverse effects and so that potential therapeutic benefits can be rolled out more rapidly. For example, we are studying the effect on the diabetic heart of a drug which currently going through phase 3 clinical trials for anaemia and which could be directly repurposed for treating diabetic cardiomyopathy. Similarly, we have shown that daily treatment with a dietary supplement increased glucose oxidation in the diabetic rat heart. Where there are no existing drugs, we work in collaboration with colleagues in the Department of Chemistry, whose work focuses on the discovery of new drug targets and mechanisms, and the translation of these findings into new clinical candidates. We have clinical Fellows within our research team who undertake clinical studies linked to our preclinical work.

Our collaborator in the Department of Materials has an excellent track record in product commercialisation and has won awards for his innovative products. He is thus ideally placed to take forward successful tissue engineered scaffolds.

Who or what will benefit from these outputs, and how?

The immediate impact will be the sharing of new knowledge and techniques with the scientific research community. This will stem from presentation at conferences worldwide and the high impact publications that will come out during the project duration. Previously our research has been published in the national press, and future work will be promoted in a similar way, so that the public will be aware of our work, and an increased understanding of the links between diet, diabetes and heart health may influence lifestyle choices. Research into the effects of particular diets, such as a high fat diet or a ketogenic diet, could result in changes to clinical advice within the lifetime of this licence.

The design of new MR imaging techniques and hardware will be able to be put into clinical use immediately in the MR research unit at the local hospital. Whereas MR imaging is used routinely in the clinic, MR spectroscopy is still largely a research tool. Research into the effects of re-purposing drugs for improving cardiac function in diabetic patients or following a heart attack would be able to go directly to phase 2 clinical trial, since any adverse effects of these drugs would already be known. Nevertheless, it would take around five years for a drug to be validated through phase 2 and 3 clinical trials. For novel drug compounds, testing in animal models, determining appropriate dosage levels and safety testing in a phase 1 clinical trial would add a further five years to the process. Work in the BHF-funded regenerative medicine network includes feasibility studies in large animal models, so that advances in stem cell therapy could be tested by collaborators within the network. Unlike novel drugs, stem cells do not need to be tested for toxicity and so advances in stem cell therapy could advance to phase 2 clinical trials in the same way as repurposed drugs.

How will you look to maximise the outputs of this work?

We work in close collaboration with other research groups in the field and share our knowledge through Diabetes UK, the British Heart Foundation Regenerative Medicine Network, the International Society of Magnetic Research in Medicine and the British Society for Cardiovascular Research. It is difficult to publish unsuccessful approaches but new data archives such as Data Brief are making this more feasible.

We have collaborations with companies which provide hardware for imaging scanners and with the diabetes research company Novo Nordisk which funds research and Fellowships. From time to time we have students from the Doctoral Training Centres which have links to the pharmaceutical industry.

Species and numbers of animals expected to be used

- Mice: 1700
- Rats: 3350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

As metabolism and energy generation are linked to the function of the organs of the body, we need to study these effects in a living animal. In order to study how damage to the heart can change the way the blood and oxygen are delivered to the rest of the body, or how metabolic diseases such as diabetes can stop the heart working efficiently, we need to use rodent models which have a four chambered heart and respond to changes in metabolism in a similar way to that in humans. The bulk of our work is done in young adult animals. However, for development of deteriorating organ function and/or metabolism, animals may need to be kept for sufficient time to allow the changes to develop. In some cases we may study juvenile animals, for example to investigate the effects of the onset of diabetes in young adults. We will use genetically altered animals which have a mutation which causes a change to the way the body metabolises fats and sugars. For example, we use animals with a mutation in the leptin receptor so that they continue to eat even when they don't need to and become obese and diabetic. We also use an animal which is used to model muscular dystrophy, as we have found these animals don't respond to insulin as they should.

Typically, what will be done to an animal used in your project?

A wide range of experiments are described in this project. The majority of experiments will be performed in wild-type rodents although we may use genetically altered animals where we want to investigate the role of one particular gene or pathway in the way the body handles fat and carbohydrates or in the development of diabetes or of heart failure.

Protocol 1: In most cases, animals will undergo terminal anaesthesia for removal of the heart or other organs while the heart is still beating. This will ensure that organ function, metabolic proteins and circulating metabolites are representative of the levels *in vivo* as many of these deteriorate very rapidly when the heart stops beating. Animals may be fasted overnight, prior to anaesthesia, as this results in more consistent data since there is no risk of one animal having eaten more recently than other. In some cases, before it is killed, the animal will be given an injection of a substance such as insulin which will cause a change in the way the body handles fats and carbohydrates. Tissue from these animals will be used for *ex vivo* experiments such as a) whole organ perfusion to measure the rate of uptake and metabolism of fats and carbohydrates, b) measurement of oxygen consumption by isolated cells or c) molecular biology to measure levels of genes and proteins.

Protocol 2. A lot of our *in vivo* work involves imaging or spectroscopy to measure function and metabolism of the heart and liver. The early stages of the process development are done using ‘phantoms’ designed to mimic live tissue. However, we need to image live animals where we are measuring heart function so the final stages of method development will use animals. These may be imaged on several occasions but generally no more than once or twice per week and no more than 10 times in total. These animals may have an injection under anaesthesia to deliver contrast agents or drugs to increase the heart rate temporarily. Under this protocol we may image genetically altered animals which are predicted to have problems with heart or liver function as a result of, or resulting in, impaired metabolism.

Protocols 3 and 6. As diabetes is a metabolic disease, we are particularly interested in the changes induced by obesity and diabetes at various stages of the disease. Diabetes can be induced in animals using a compound called streptozotocin (STZ) which kills some or all of the insulin-producing cells in

the pancreas. To induce type 2 diabetes, animals are fed a high fat diet for 3 weeks and then have a low dose of STZ. This model mimics the early stages of the disease as these animals become obese and show increased levels of glucose and insulin in the blood. To induce type 1 diabetes we give a higher dose of STZ which kills the majority of insulin-producing cells so these animals have very high levels of glucose and low plasma insulin. We may also use genetically altered animals which become diabetic where these give a more appropriate phenotype for the question we are asking. The animals will have blood samples taken at intervals to determine development of the disease and may be imaged using techniques developed in protocol 2. Some animals will be given a drug in their food or drink or, if necessary, by injection to establish whether this changes the disease progression. At the end of the experiment we will take tissue for *ex vivo* experiments as in protocol 1.

We also use animals with diabetes on protocol 4 as we know that diabetic patients are at greater risk of heart failure after a heart attack and we are trying to establish why this happens and how to prevent it. In these animals, we will ensure that the diabetes is established and stable before proceeding to further experiments.

Protocols 4 is a surgical protocol designed to mimic the impaired heart function resulting from a heart attack caused by a blockage of the coronary artery. The animals may be kept for several weeks to allow the changes to the heart to develop. They will probably be imaged to measure the changes to heart function and may be given a modified diet or drug treatment to determine whether this improves organ function and/or substrate metabolism. This treatment could include injection of stem cells into the heart muscle or attachment of a tissue-engineered scaffold across the damaged area of the heart to study the effect of adding new, healthy cells or tissue on the function and metabolism of the heart. Again, at the end of the experiment we will take tissue for *ex vivo* experiments as in protocol 1.

Protocol 5 is used to test which tissue-engineered scaffolds survive best after being implanted in the body, but without the complex surgery needed to access the heart. These animals will have scaffolds implanted under the skin in areas of the back where the scaffold does not affect movement. The animals may be imaged to measure the development of blood flow into the scaffold.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will be used for method development on our imaging protocol. These animals will by anaesthatised several times, although normally this will be no more than once a week. However, the animals may become averse to the anesthesia over time.

Animals which undergo surgery to induce a heart attack may die during or after surgery. Once they have recovered, they rarely show signs of pain or abnormal behaviour or weight loss. We may keep these animals for up to six months as the heart gradually remodels after the surgery and we are interested to see whether therapies such as treatment with stem cells will mean that the heart function does not deteriorate so much over time.

We use animal models of diabetes which will have increased thirst and urination. The type 2 animals will become obese whereas the type 1 diabetic animals may show some weight loss. For most projects,

the animals will be diabetic for up to a month, but if we are looking at a potential therapy that takes longer to take effect we may keep the animals for longer. We use diabetic animals on our surgical protocol to induce a heart attack as we are investigating why diabetic patients recover less well. These animals may not recover from the surgery as well as wild-type animals and will be monitored particularly carefully.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We do a lot of experiments using the *ex vivo* perfused heart or isolated mitochondria. These animals will be on protocol 1 and will generally only undergo terminal anaesthesia. Some will have an overnight fast so that levels of metabolic substrates are not affected by a recent meal. Some animals will be used for method development on our MRI protocol and undergo general anaesthesia with administration of substances but no other interventions. These animals will predominantly have a mild experience although some on the imaging protocol may become averse to the anaesthesia and have a moderate experience.

Our type 2 diabetic model does not routinely result in more than increased weight gain and increased thirst and urination. We ensure that these animals have sufficient water and are on absorbent bedding and so many of these animals will have a mild experience. In some cases, higher levels of blood glucose will mean that the animals have a moderate experience. The GAA models of type 2 diabetes may develop increased levels of blood glucose and have a moderate experience.

The type 1 diabetic model will mean that animals develop high glucose and low insulin and these animals, either STZ-induced or GAAs, will have a moderate experience.

Animals which undergo surgery for myocardial infarction will have a moderate or severe experience, depending on how quickly they recover from the surgery and whether they progress to heart failure. Mice recover less well than rats and are more prone to developing life-limiting heart failure. Diabetic animals on this protocol are more likely to develop severe adverse effects.

Based on this previous experience, and the number of animals on each of our protocols, overall we expect around 50% of animals to have a mild experience; around 40% of animals to have a moderate experience and 10% of animals to have a severe experience.

What will happen to animals at the end of this project?

Killed

A retrospective assessment of these predicted harms will be due by 03 March 2026

The PPL holder will be required to disclose:

What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We study the interplay between organ function and substrate metabolism, with a particular emphasis on the heart. To obtain relevant measurements of heart function it is necessary to use an animal model with a four chambered heart like the human heart. As metabolism and contraction of the heart are inextricably linked, it is essential to study metabolism in the intact beating heart. Impaired delivery of metabolic fuels, due to decreased heart function or an imbalance such as is seen with diabetes, will mean that the organs of the body cannot function properly. This may, in turn, cause a further change in the metabolic balance of the body which could feed back to damage heart or liver function. As a result, these effects need to be studied in animals over time.

Which non-animal alternatives did you consider for use in this project?

We use mouse HL1 cells, a cell line that behaves like mouse heart cells, to determine the mechanisms behind effects observed in our *in vivo* studies. We also use this cell line to explore new theories before taking experiments into animals. We have developed a protocol to make the cells insulin-resistant and have found that these provide a good *in vitro* model of the changes we see in the diabetic rat heart. For example, we used these cells to investigate molecular changes occurring in diabetic animals after a heart attack, which lead to one of our recent publications. As it is not easy to get human heart cells, we use human stem cell-derived cardiomyocytes to help us determine whether effects seen in rats or mice are likely to also occur in humans.

In order to minimise the number of rodents used for developing cardiac imaging sequences at an early stage of the process, we are using an "eMouse", developed by collaborators, that generates a 'heart beat' and signals to mimic the movement due to breathing. We can mimic biological tissues, by adding chemicals to the gel, which has enabled the creation of "blocks" of tissue with much closer MR properties to certain tissue types of interest. This improves our ability to robustly test hardware and software prior to using it in animals.

Why were they not suitable?

The insulin-resistant HL1 cells provide a useful model but they only enable us to understand what is happening in heart cells in a monolayer, isolated from other cell types and from the mechanical stresses encountered by cells in the heart. We can generate engineered heart tissue, which is a 3D construct where the cells contract against flexible posts, and this is a better model of the environment cells encounter in vivo. However the cells retain a very immature phenotype and do not behave like a true adult heart cell. We are working to mature the cells and to adapt the insulin resistant model we use in the HL1 cells. Nevertheless, these cell systems can only ever provide a part of the picture when one is studying the complex metabolic interplay between different organs in the body. In addition, the heart contains many other cell types in addition to the beating cardiomyocytes. For example, after a heart

attack blood flow to part of the heart muscle is cut off so that the cells do not get enough oxygen or nutrients to continue beating efficiently. We can mimic this in our cell models. However the dying cells send out signals to the body's immune system and this attracts immune cells to the damaged region. Some of these immune cells are beneficial and others are not, and it is much harder to mimic the effects of this immune reaction in a dish. Non-beating cells in the heart, called fibroblasts, start to change and reinforce the dying muscle, forming a stiff scar and changing the workload on the rest of the heart which again it is hard to reproduce in a model.

Similarly, although the "eMouse" is extremely valuable for testing new hardware and software for MR imaging, it cannot provide the imaging problems associated with blood flow and movement due to breathing and does not provide any cellular or functional information.

A retrospective assessment of replacement will be due by 03 March 2026

The PPL holder will be required to disclose:

What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have been working with rodent models of disease for many years and use the information we have from previous studies to determine the number of animals we think will be needed for particular studies. Based on our current and planned funding, we know which types of experiments are proposed for the next few years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We take statistical advice from experienced researchers in the field, combined with our own previous experience of working for over 15 years in this area. We use statistical power calculations to estimate the number of animals we need in each experiment to detect metabolic and/or functional changes. We have developed new statistical methods that are unique to MR experiments that others in the field now use, which increase statistical power. Where we are testing a new drug compound, after appropriate *ab initio* calculations, we will use a small number of animals to determine the dose of drug to give before undertaking the experiments with sufficient animals to determine whether the drug has the effect we predict. In all cases we aim to pick the animal model which provides consistent results in our experiments, to reduce the number of animals we need.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use MRI to measure cardiac function and metabolism on the same animal over time as the disease progresses. The MRI does not affect the animals adversely and allows us to reduce the number of animals required to follow the disease progression. We can measure substrate metabolism *in vivo* in the heart and the liver in the same animal, further reducing the number of animals needed; and we have refined our *ex vivo* heart perfusion measurements so that we can measure metabolism of both glucose and fat in one heart where previously we would have needed to use of two animals.

Where possible we use cryoinjury in the rat to provide a damaged region of heart tissue. The previous ischaemia/reperfusion protocol meant the animal was kept under anaesthesia about 90 minutes and also resulted in a large variation in tissue damage. The new protocol comprises placing a liquid nitrogen-cooled probe on the heart tissue for 10-15 seconds and means that the animal is under anaesthesia for about 30 minutes. This protocol produces a more reproducible infarct size and therefore results in fewer animals being used. It is also a refinement because the animals are under anaesthesia for about 30 minutes rather than 90 minutes.
However, the type of damage does differ from that resulting from a blocked artery and so in some cases we have to use the previous protocol where we block the blood flow through the artery, either permanently or for just under an hour.

We have been using omics-based technology to investigate the metabolic changes occurring in diabetes or after chemotherapy. We have discovered that the high rate of reproducibility and low error measurements from these mass spectrometry-based techniques have allowed us to decrease our numbers needed to find the information we need.

Where possible, we use tissue or organs from control animals not required for the designated study, or animals that do not fit the criteria for the designated study, for method development on other studies, such as imaging protocols or *ex vivo* mitochondrial analysis.

A retrospective assessment of reduction will be due by 03 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use rats and mice because the hearts and other organs are structurally and metabolically close to the human heart. Although we have to generate disease models for our experiments, we use non-invasive techniques wherever possible, for example we feed high fat diet to elevate plasma free fatty acids and give therapeutic compounds in drinking water if applicable. We use a model of cryoinjury to induce damage to the rat heart but maintaining an open artery, as is seen clinically, because this generates more reproducible results, thereby reducing the number of animals needed, and exposing animals to a shorter period of anaesthesia than required for ischaemia/reperfusion. For experiments to design cell scaffolds for heart repair, we first test whether these are tolerated by the body, by implanting them in a pocket under the skin, before we progress to the more invasive surgery to attach scaffolds to the heart.

We use genetically altered animals (GAAs) when we are investigating the role of a specific gene in a disease pathway or to mimic a particular aspect of a disease. In general, mutations in metabolic pathways may cause the animal to gain or lose weight but do not cause significant pain or suffering. If the disease phenotype may deteriorate with age we will use the animals before they reach that point.

Why can’t you use animals that are less sentient?

In order to examine changes to metabolism and organ function in disease, we need to use a model that matches the human physiology, rather than a non-mammalian system. For some of our experiments we take a wild type animal and terminally anaesthetise it before imposing metabolic changes on an isolated organ. For these experiments, we need to perfuse the heart in a system which mimics the delivery of oxygen and substrates and for this we need a heart from an animal the size of a mouse or rat. Similarly for our MR experiments we need enough tissue to get a measurable signal from the heart. These experiments would not be possible in a species that is the size of a fish.

For most of our *in vivo* experiments, we look at how a disease such as diabetes or a heart attack changes the function of the heart over a period of weeks and we cannot keep an animal terminally anaesthetised for that length of time.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have purchased a Mouse Monitor from Indus Instruments that includes a heating pad and records ECG, body temperature and pulse oxygenation from both rats and mice. We use this to monitor animals during surgery and it has been very useful whilst establishing the cryoinjury model, as we can detect changes on the ECG which can indicate whether that the damage to the heart is too severe for the animal to be safely recovered.

We've introduced double-HEPA filtered air handling systems as much as possible into our workflows, both MRI and otherwise. As well as protecting operators, these will have positive beneficial effects on rodents undergoing procedures: as well as increasing sterility, there is a lower likelihood of airborne scents being communicated between animals.

A dedicated rodent echocardiography machine has been purchased for cardiovascular research, which is

more efficient for scanning animals than human systems previously used, and therefore can achieve better results with less time under anaesthesia for each animal.
This will be particularly useful for screening animals after myocardial infarction or aortic banding where the surgery can give variable results. Where the surgery is unsuccessful or the effect is too severe, the animal can be removed from the study at an early time point. Similarly, we monitor blood glucose levels regularly, using a pinprick sample of blood and a glucose monitor. Again, where an animal is not sufficiently diabetic or blood glucose levels are too high, the animal can be removed from the study at an early time point.

In order to observe breathing motion of the animals in the MRI scanner, we have previously used an induction loop across the chest. This loop is effective, but the signal it provides can be obscured briefly during each MR pulse. We have recently installed a small warm plastic balloon, to be placed underneath the animal, that enables more robust monitoring of breathing, thereby increasing scanning efficiency and decreasing the time the animal is under anaesthesia.

We have close links with the cardiac groups at the Wellcome and other imaging groups in the University and discuss techniques and share hardware and software advances between the groups. We liaise with the veterinary staff and keep up-to-date on LASA guidance to minimise harms.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the NC3Rs experimental design assistant when planning our experiments and will follow the LASA guidelines on aseptic surgery. We will keep up-to-date on advances publicised in the NC3R newsletter which provides information on the most refined techniques, such as new guidelines on non-aversive methods of picking up animals, single-use of needles and blood sampling. We will adhere to updated ARRIVE guidelines on reporting work with animals as now required by many journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The PPL holder or a designated representative attends the departmental 'gold standard meeting' each term at which the 3Rs are discussed. Members of the team attend workshops and courses run by the NC3Rs and all staff receive the NC3Rs newsletter from the Home Office Liaison team. Relevant advances from these outlets and from reading the literature are discussed at the weekly lab meeting.

A retrospective assessment of refinement will be due by 03 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

7. Assessing novel genetic therapies in neurological disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

gene therapy, neurodegeneration, genetic brain disorders, molecular therapy, genetic rodent models

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To develop and test new genetic therapies for currently untreatable brain disorders.

A retrospective assessment of these aims will be due by 26 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Faulty genes are a significant cause of severe brain disease, especially those affecting children. We are currently undergoing a revolution in how we understand and envisage treating highly debilitating genetic disorders of the brain. The focus of this work is on childhood onset neurological disease for which there are no current effective treatments. Genetic brain diseases are often lifelong, affect a considerable number of individuals globally and place a huge socioeconomic burden on families, carers and health services. Childhood onset brain disorders are especially costly with regards to treatment, lost earnings, care and support for children and adults. The revolution in genetic medicine now means that we are diagnosing these diseases and their underlying genetic causes very effectively. However, this is not matched by treatment options and it remains the case that there is no effective therapy for the majority of severe brain disorders. That said, advances in gene therapy (replacing or fixing a faulty gene) offers the option of developing genuinely transformative treatment options. The reason that genetic approaches to therapy has such potential is that they offer to fix the root cause of the disease rather than just some of the symptoms. The goal of this programme of research is to develop and establish the effectiveness and safety of gene therapy across a number of significant brain disorders. For this we use rodents in which the equivalent gene that causes brain disease in humans had been disrupted or inactivated. Assessing the impact of gene therapy drugs in such animals allows us to predict the extent to which the gene therapy is likely to be safe and effective in people with severe brain disorders.

What outputs do you think you will see at the end of this project?

This project will provide vital new data on the potential utility of gene therapy in pediatric onset neurological indications. Based on our work to date, it can be expected that outputs include publications, public dissemination, patent applications and lead molecules for preclinical and clinical development.

Who or what will benefit from these outputs, and how?

There is currently intense research in the genetic therapy space and any early publications on innovative therapeutic approaches or tractability of disease phenotypes will be of significant impact in the short to medium terms (1-3 years). Data generated by this project will allow us to refine our approaches to hone in on the most likely effective interventions in childhood onset severe brain disorders. The longer terms benefit of these outputs, especially patents and therapeutic molecules will be new treatment options in hitherto untreatable pediatric disorders. We have a track record in this area with genetic therapies we have developed being destined for first in human gene therapy trials. Beneficiaries include patients of childhood genetic brain diseases and well as scientific and medical researchers in this fast moving field.

It is expected that the innovative genetic therapies proposed will facilitate the rapid advances being in this sphere of translational research and will have direct potential for very rapid (in drug development terms) therapeutic impact. In addition, the parasite therapy is a highly innovative therapeutic approach which is much earlier in terms of translational development but has the potential to deliver therapeutic cargoes that are difficult to deliver by established methods. It thus has the potential to treat patients with mutations in very large or complex genes or even multiple genes.

How will you look to maximise the outputs of this work?

It is vital to the ethos of the laboratory that we work in collaboration with other laboratories both within and without the research institution. We have established links with laboratories across the UK and internationally with whom we share new knowledge, techniques and ideas. This informal 'peer review' process enables us to interrogate paradigm and experimental designs, enabling us to target those experiments we feel will generate the most useful and transferable.

Species and numbers of animals expected to be used

Mice: 10000
Rats: 1800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will require the use of animal models that exhibit the clinical features of patients with neurological disorders under investigation. As our focus is on assessing potential treatments for pediatric and juvenile-onset disorders, we require the use of rodents at neonates, juvenile and adult stages of development. Rodents used in this work are genetically altered to model genetic brain disorders, with rats and mice being well suited for assessing cognitive (learning and memory) and functional outcomes.

Typically, what will be done to an animal used in your project?

Experimental animals will be enrolled in therapeutic studies. Animals will be assigned to a treatment group and novel genetic therapies administered, typically via a single injection. Animals will then be monitored for clinical signs of neurological disease to assess whether the therapeutic intervention impact aspects of the disease. Tests may include assessment of activity, walking, learning and memory, anxiety or functions such as breathing control.

What are the expected impacts and/or adverse effects for the animals during your project?

The therapeutic agents being tested are known as gene therapy and target the root-cause of the diseases under investigation. As such, there is an expectation that the therapy may be highly impactful in ameliorating the clinical features of the disease. We expect that the therapy may result in correcting highly debilitating features of neurological disease including motor function (control of muscles), breathing control, seizures as well as higher level brain functions such as cognition. It is possible that we will observe unexpected adverse effects due to the novel therapeutic agents. Where these occur, experiments will be stopped immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the majority of the work the severity will be in the mild to moderate range, especially in neurological

disease models where the main clinical feature is intellectual disability. In some instances, the rodents will model very profound neurological disease and in order to assess the impact of gene therapy in these instances, the procedure will be considered severe.

What will happen to animals at the end of this project?

Killed

A retrospective assessment of these predicted harms will be due by 26 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The neurodegenerative diseases under investigation in this project are complex conditions exhibiting a range of physical, neurological and learning impairments. We aim to test the impact of gene therapy on these complex aspects of neurological disease. As such it is not possible to model these conditions in isolated systems such as single cells grown in a dish. Therefore, the use of animal models is unavoidable when investigating these disease types.

Which non-animal alternatives did you consider for use in this project?

We have made significant efforts to replace experimentation on live animals to investigate complex neurological disorders. This includes the use of neuronal and other stable cells lines for the testing of genetic therapies at a cellular and molecular level. We also study gene structure and sequences using human post-mortem tissues. We collaborate with groups working on human-derived cell lines from patients with intellectual disability disorders.

Why were they not suitable?

None of these alternative approaches enable the assessment of gene therapy on key neurological features that characterize childhood-onset neurological disorders such as intellectual disability or motor control. Instead, the therapeutic potential of agents in neurodevelopmental and childhood-onset disorders require the study of an intact nervous system as they involve combined problems in brain circuitry, connectivity, neurochemistry and brain cell physiology which develop over time. It is only by creating accurate genetic models of these disease which closely mimic the major features of the human condition, that one can study how these processes interact. Moreover, whilst cellular level assays are used to test whether pharmacological and genetic interventions can rectify disease at the single cell level, it is only by testing these at the whole brain/animal level that one can truly assess whether these translate to improvements in behaviour, learning or corrected brain development.

A retrospective assessment of replacement will be due by 26 May 2026

The PPL holder will be required to disclose:

> What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from yourexperience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The principles of our experiments are twofold. One is to characterise the development of the disease in the nervous that underlies Rett syndrome and related disorders so that we can identify avenues of potential therapy. This mainly includes the use of genetically altered animals and wild-type controls to provide tissues necessary for investigation outside the animal, such as neurochemical, molecular, electrophysiological and anatomical profiling. The second is to utilise this knowledge to develop and test the efficacy and safety of therapeutic interventions. Whilst as much of this as possible is done at the cellular level, for instance testing genetic therapies in cultured cells, Rett syndrome is fundamentally a nervous system disorder and for this we need to test putative therapies in the whole animal.

Our research conducted using animal tissues (electrophysiological, biochemical and morphological assays and genetic and pharmacological interventions) is based on the minimum number of animals required to produce sufficient biological replicates for robust statistical comparisons. Our use of cultured cell systems enables the preparation of multiple cell-based assay systems from a smaller number of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have developed cellular assays to characterise the properties of our molecular therapies prior to any animal work. This acts as a triage even prior to any pilot rodent study. Where organismal level work is required, we will use the minimal numbers to achieve robust scientific outcomes. All experiments are conducted according to the ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For experiments on living animals, our previous experience has shown that 15 animals in each control and experimental group will provide a 90% chance of detecting a significant change in respiratory, motor and other behavioural phenotypes. We employ the services of a professional biostatistician to advise on all areas of our gene therapy work.

Pilot experiments on a small sample of animals (maximum n=5) will be conducted to select appropriate drug doses and for viral studies, to assess effectiveness of transgene expression.

A retrospective assessment of reduction will be due by 26 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of experimental procedures will be performed on mouse models of RTT. In additions, mouse models of CDKL5, Syngap, Pten deficiency, Angleman syndrome and other NDD models will be used during this project. We intend to develop gene therapy treatments for RTT which will inform our approach in developing gene therapies for other conditions. Whilst RTT-like phenotype is severe in rodents, our experienced and knowledgeable scientists will closely monitor the animals and will take the following steps to ensure that pain, suffering and distress are kept to a minimum.

We have adopted a revised phenotype scoring system which we use at least weekly to assess, in a semi-quantitative and objective fashion, the onset and development of RTT-like symptoms in mice and rats. We have refined the scoring system so that there are now two separate instruments - while sharing most of their criteria, one is deployed to assess the phenotype of the mice for use in analysis, and the other is deployed to assess whether welfare-related actions are required, including closer monitoring, a vet-supported husbandry package, and clearly-defined humane endpoints.

Male Mecp2 mutant mice have an early-onset phenotype that becomes progressively more severe. They are therefore not kept alive long enough to become severely symptomatic unless required for a specific experiment. Treated mutant mice used to provide tissue for cell culture and other ex vivo experiments are euthanised while still presymptomatic.

Neonatal dosing is used to assess early genetic interventions in NDDs. Our breeding strategies generate mixed litters of GA and non-GA animals. We have therefore adopted a rapid genotyping protocol to identify mice with the appropriate genotype and avoiding unnecessary injection of the wildtype mice. For this approach it is necessary to conduct tail biopsies.

Gene therapy is generally considered an irreversible treatment in that, once delivered, the treatment cannot be withdrawn. Part of our programme of works is to develop safety features whereby a pharmacological agent can be used to turn down/shut-off the transgene expression at the earliest sign of any adverse effects. This is a safety feature for translational purposes but is also a refinement during preclinical testing of gene therapy cassettes to mitigate against potential adverse effects in mice.

Use of rat models: In addition to mouse models, rat models of CDKL5 deficiency, SynGAP deficiency and Fragile X syndrome will be assessed. Models of these disorders show less overt outward phenotypes (motor, autonomic and peripheral phenotypes) and are therefore more dependent on detecting more subtle behavioural phenotypes that are more clearly expressed in rat models. In terms of refinement, this enables the finer grain testing of therapeutic interventions in domains (e.g. cognitive) that are most pertinent to the disorders in patient. It is a key scientific objective to assess whether cognitive features are reversed by genetic therapies targeting Rett syndrome and for this reason we wish to extend experiments into rat models which enable the assessment of more robust behavioural outcomes. For SynGAP knockout rodents, the phenotype is severe in hemizygous male animals. In limited proof-of-concept experiments, we wish to establish whether early genetic intervention can ameliorate the onset of these overt phenotypes in male animals. As a refinement, we would aim however to progress the study to heterozygous females as quickly as possible. All rat studies will be in collaboration with groups within the centre that have existing extensive expertise in dosing, maintaining and phenotyping rat lines.

We aim to also test an unconventional approach to deliver therapeutic protein to the brain by delivering engineering attenuated strains of Toxoplasma that can secrete the MeCP2 protein into neurons. Having shown that this approach is effective in delivering MeCP2 to neurons in vitro, we reply on experiments in mice to show that the approach has therapeutic application in vivo in terms of establishing whether this delivery approach can impacton RTT-like phenotypes.

Why can’t you use animals that are less sentient?

The use of genetically-modified mice is frequently the only viable strategy for studying neurodevelopmental genetic disorders. Indeed, they are especially well suited for studying single-gene disorders of brain in which accurate genetic mouse models recapitulate many of the cardinal features that characterise the disorder in humans. Intellectual disability is characterised by impaired cognition and at present this can only be tested in the live animal. However, we have developed sensitive assays for changes in motor function that can detect nervous system abnormality at a very early stage (at 4-8 weeks). This enables us to follow the trajectory of the disorder phenotype from an early stage and assess whether therapeutic interventions affect the onset and development of disease-like characteristics rather than simply testing for the reversal of established and more severe symptoms.

RTT is a severe neurological disorder and is diagnosed once patients develop overt symptoms. The aim of the research is to develop effective therapies for RTT. As such, animals are therefore required to develop overt RTT-like signs in order to test the impact of putative therapies. Protocols 5, 8 and 8 are categorised as severe for this reason.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As detailed in the project plan, we have implemented a very rigorous monitoring system for our Mecp2 rodent lines. This include regular detailed monitoring of welfare and an escalation of monitoring frequency and enhanced husbandry (bedding, soft food etc) as the phenotypes progress as well as

clearly defined humane endpoints. Any of studies involving surgical or invasive intervention will adopt appropriate pain management and post-operative care. For mouse lines that have a propensity for benign tumours, only young mice will be maintained unless on a dosing procedure. In these cases, mice will be monitored frequently and with clear humane endpoints upon tumour discovery.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on the Operations of ASPA - https://www.nc3rs.org.uk/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our technical staff are members of professional bodies (Institute of Animal Technology, Royal Society of Biology) and take part in continuing professional development to ensure their knowledge is as current as possible. Regular updates from bodies such as the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) and Understanding Animal Research (UAR) mean new developments and best practices can be evaluated and implemented where they might improve animal welfare without inhibiting the integrity of the research. Regular communication with our veterinary staff will ensure techniques are reviewed and refined where necessary and appropriate.

A retrospective assessment of refinement will be due by 26 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

8. Assessing Novel Treatments for Endometriosis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Endometriosis, Preclinical model, Fertility, Drug therapy, Inflammation

Animal types	Life stages
Mice	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aims are to gain a better understanding of endometriosis and to assess the efficacy of new treatments to prevent disease growth and recurrence.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Endometriosis is a debilitating condition that affects an estimated 176 million women worldwide. In endometriosis, cells similar to the lining of the womb grow elsewhere in the body, typically in the abdomen around the ovaries and the bowel. These endometrial-like cells respond to female sex steroids with a chronic inflammatory reaction that is the leading cause of pelvic pain and infertility. Often dismissed as women's troubles, a lack of research and funding means sufferers can live in severe pain, unable to work or socialise. Current drug therapies carry side effects, are not suitable for patients seeking pregnancy and endometriosis often recurs upon discontinuation of drugs. There is a scientific and clinical need for a better understanding of endometriosis development/recurrence and the assessment of new treatments/delivery systems.

What outputs do you think you will see at the end of this project?

New information

It will increase our understanding of the disease. In particular, it will provide new information in relation to the local peritoneal environment (the abdominal area surrounding the lesions) in disease progression and following treatment with novel compounds. In this programme of work, we will also look to develop and investigate a model of recurrence and utilise this model to assess treatments.

Specifically, lesion size, hormone production, inflammation and metabolic pathways known to exacerbate the disease will be studied. This work should increase knowledge about the effect of new treatments and modalities on endometriosis development, progression and recurrence. It is anticipated that these treatments and delivery methods will reduce lesion formation and/or prevent their regrowth, thus providing important information with the aim to progress these compounds to the clinic for patients.

Information in relation to novel drug delivery platforms, including the suitability of hydrogels, will also be assessed. These modalities have yet to be studied as a local delivery system within the peritoneal cavity, where lesions are usually found. Surgery will be performed at similar times of the day to avoid body clock effects on inflammation, adhesion and local repair.

By monitoring the reproductive cycle via vaginal lavage and cytology, drug effects on reproductive function will also be determined. This measures the integrity of hormone signalling, that may indicate local verses systemic drug release. It will also show if contraceptive effects are reversible when treatments are discontinued.

Publications

Our research spans across many different scientific fields, including: endocrinology, pharmacology, pharmaceutics and material science. We plan to submit articles to high impact, open access journals, such as the British Journal of Pharmacology and the Journal of Controlled Release.

There is limited previous research on endometriotic lesion recurrence; therefore, this research is very novel. Publications will demonstrate validity of our model of recurrence as well as the effect of novel and/or localised treatments.

There is also a sparsity of hydrogel imaging research within the peritoneal/abdominal cavity, which would be of interest to drug delivery scientists studying diseases within that area of the body.

Products

If proof of concept is successful and lesion weight or endometriosis recurrence is significantly reduced, novel treatments and/or hydrogels could be considered as a possible, and viable, treatment option within the clinic.

Who or what will benefit from these outputs, and how?

Scientific community

Studying the local lesion environment with or without drug treatments would enhance knowledge about the cause of endometriosis and its development, progression and recurrence. This information would benefit other researchers within the same field as well as the general scientific community and general public.

Translation for clinical benefits

Successful placement and efficacy of the hydrogel-based delivery system could have clinical benefit for women with endometriosis. Introducing a localised drug delivery system as opposed to oral or injection-based treatments could reduce the severe side effects that often occur with systemic dosing, such as: weight gain, headaches, depression, reduced bone density and acne. Current intra-uterine devices carry risks of ejection from the body, infection and piercing of the uterus that would be mitigated by the hydrogel. By localising drug release, women receiving this treatment could have the option to conceive, which is not feasible with current hormonal therapies. Targeted delivery would therefore improve patient compliance, reproductive health and would also reduce the need for multiple surgeries. This would significantly cut healthcare costs, which are currently estimated at £8.2billion/annum in the UK alone, by saving the need for referrals, specialist centres, additional treatments and lost working time. The clinical benefit of these new medicines would be more long-term, beyond the lifespan of this project licence.

How will you look to maximise the outputs of this work?

We are collaborating with other research groups concerned with the peritoneal/abdominal cavity, regenerative medicine, imaging experts, gynaecologists and material engineers. This collaboration will allow for hydrogel formulation, live imaging and analysis of suitability for the clinic. This will provide

information on both drug release to endometriotic lesions as well as the prevention of adhesions, which commonly occur within this area of the body, particularly after surgery.

To avoid publication bias, we are committed to publishing all findings from this project, both positive and negative. Outputs will be maximised through publication of abstracts, papers, conference presentations, patient public involvement and public engagement activities.

Species and numbers of animals expected to be used

- Mice: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We require our chosen model to undergo an oestrous cycle, the equivalent of a human menstrual cycle. Hormonal changes, particularly in oestrogen, are essential for disease establishment and progression. We also wish to monitor if our chosen localised treatments disrupt this oestrous cycle. Therefore, it is necessary that the chosen animal is a sexually mature mammal. As a group, we have chosen to utilise mice.

Typically, what will be done to an animal used in your project?

There are two main categories of animals used within this project: donor mice and recipient mice.

Donor Mice

Donor mice will be humanely killed in order for their uterus to be removed and sectioned into small pieces. In order to analyse which phase of the oestrous cycle these mice are in, a vaginal wash will be conducted on these mice prior to being humanely killed.

Recipient mice: disease establishment

In all cases, recipient mice will undergo surgery under anaesthesia. The uterine fragments from the donor mice will be stitched onto the peritoneum of the recipient mice, where lesions commonly form in humans. Recipient mice will undergo a small incision of the skin and muscle layer in order to gain access to the cavity. Prior to surgery, these mice will be injected subcutaneously with opioid-based pain relief. The wound will be cleaned with betadine solution and their eyes will be treated with lacri-lube to prevent dryness/irritation. Recipient mice will then be split into key groups: systemic vehicle, systemic treatment, localised vehicle and localised treatment. Vehicle will be the same solution the chosen drug is suspended in. Mice that are treated systemically with treatment or vehicle will undergo repeated administration throughout the project. Depending on the drug type, this will be given either by injection or orally. Recipient mice given localised vehicle or treatment will not need these repeated doses as a

hydrogel will be administered during surgery. Some mice will have small volumes of blood taken to analyse drug exposure levels. A proportion of these animals will be humanely killed at specific time points to allow for extensive analysis of the lesions as well as the surrounding area.

Recipient mice: established lesions and disease recurrence

In order to analyse drug effects on established lesions or lesion recurrence, these recipient mice will undergo two surgeries. They will undergo the surgery as detailed above to establish endometriosis within the animal. These animals will then be allowed to recover for a period of 2 weeks. After this time, the animal will undergo a second surgery which is almost identical to the first. Some of these animals will have their established lesion removed, whilst others will not. Treatment will start at this stage, with the same groups still applying: systemic vehicle, systemic treatment, localised vehicle and localised treatment. Animals receiving localised vehicle or treatment will be given the hydrogel at the time of the second surgery. Animal receiving systemic treatment or vehicle will be given either repeated injections or oral doses. Some mice will have small volumes of blood taken throughout the experiment to analyse drug exposure levels. Vaginal wash will also be performed to determine drug effects on reproductive function. A proportion of these animals will be humanely killed at specific time points to allow for extensive analysis of lesion regression or recurrence.

Live imaging

Recipient mice from each of the two procedures described above may also undergo non-invasive, live fluorescent imaging. This will allow hydrogel localisation, lesion growth and recurrence to be monitored.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts of both protocols is the development of endometriotic lesions, which have been shown to establish within roughly 2 weeks after induction. As the model of endometriosis proposed within this project has been used and verified in the previous project licence, it has been shown to be well-tolerated by the animals, with no outwards sign of pain or distress.

Drugs previously tested within this animal model appear to also be well-tolerated by the animals with no visible adverse effects. Drugs that have yet to be tested within this model are well characterised within the literature.

Localised drug delivery vehicles being used within this project, namely hydrogels, are also well-characterised within the literature and appear to not have a toxic effect in numerous cell types/lines. This will be verified with our cells of interest within the laboratory prior to commencement of any animal work.

Daily vaginal wash was well-tolerated by the mice when performed for up to 4 weeks under our previous licence.

A potential impact of protocol 2 is aberrant wound healing due to second surgery. However, this will be assessed in a small pilot study to see potential adverse effects and their duration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Donor animals used (~20%) are humanely killed using Schedule 1 (mild).

Recipient mice (~80%), the maximum expected severity is moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Endometriosis is a complex disease with a relatively poorly understood cause. Past research has shown that the cause of endometriosis has a hormonal, immune and inflammatory element. Therefore, in order to correctly analyse the effects of localised treatment, an animal model is the only viable option as it takes into consideration all of these options. Work using cells or individual organs fail to account for all of these components.

Which non-animal alternatives did you consider for use in this project?

Prior to animal work, primary cells as well as cell lines have been utilised to monitor the effects of these drugs as a solution and within a hydrogel. Cells of interest and surrounding cell types were studied. Cell-based experiments on how to investigate cellular regrowth are also being investigated.

Studies investigating drug release from the hydrogels are being conducted within the laboratory, using media similar to the peritoneal/abdominal fluid.

Why were they not suitable?

Whilst methods involving primary cells and cell lines gave information on drug efficacy in cellular models, it does not provide detailed information on these drugs effects on interacting cell types and the complex environment surrounding the lesions. Laboratory methods used to monitor drug release only takes into account the diffusion of the drug. It fails to account for degradation of the hydrogel by enzymes and shear stress.

For this, we need a more complex, animal-based system to be able to monitor how these drugs are effective and can prevent disease progression/recurrence.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Working alongside a trained statistician, we utilised data acquired from previous animal work conducted within this group to calculate the minimum number of mice needed per treatment group and lesion number per mouse to find a biologically relevant reduction in lesion weight. Lesion weight was used as it is the most useful and clinically relevant measurement in the studies. This analysis allowed us to account for variation than can occur both between and within mice. It allowed a study with best chance of detecting meaningful outcomes to be designed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have utilised the NC3Rs experimental design tool in order to design our animal-based experiments. This allowed us choose appropriate groupings and blind the studies effectively. This design tool has also helped us identify any potential nuisance variables and how to avoid them. By doing this, we are reducing the likelihood of experimental replication, thereby reducing the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Donor uterus is segmented into many fragments (typically 12-15 pieces), therefore, fewer donor mice are required than recipient mice. Typically 3 lesions can be induced within a single recipient mouse. This reduces the numbers of recipient mice needed to see an effect of the drugs on lesions.

We have conducted pilot collaboration work to determine whether fluorescently-tagged hydrogels can be monitored within the peritoneum using live imaging. This pilot study investigated two different types of fluorescent tags. We humanely killed a small cohort of animals, from there, we conducted the study as planned in the protocol. This study confirmed that the hydrogel can be imaged within the mice, which means there is a reduced need for sacrifice at specific time points.

We will also conduct a small pilot study, which will involve analysing wound healing from dual surgery. This will provide information on the rate of wound healing and will ensure that dual surgery is feasible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using a mouse model to mimic endometriosis. This model requires both donor and recipient mice. Donor mice are humanely killed to allow for their uterus to be removed and segmented into small pieces. These segments are then stitched on to the peritoneum of recipient mice. This particular model will be used as it is one of the most well-established models of endometriosis within the literature. Previous work in our laboratory found that this method produced fluid-filled cysts that are characteristic of the disease. The cysts were also found to be responsive to hormones, which is also one of the main disease characteristics.

For the recipient mice, this technique requires a small incision on the ventral area, limiting pain and potential harm to the animal. From previous work, the animals recover well with no obvious adverse effects in relation to pain or distress and in the vast majority of animals we did not observe any changes in weight or normal behaviours.

Our previous work demonstrated that following surgery the lesions develop naturally without supplementing animals with hormonal treatment. We also conducted ovariectomies (removal of ovary function) in our original work to prove hormonal dependence of lesion development. These previous studies have allowed us to further refine our methodology and both steps have been removed from our studies.

Why can’t you use animals that are less sentient?

We require the mice for this project to be sexually mature mammals, as changes within the oestrous cycle are important to monitor and can affect lesion establishment, growth and recurrence. Therefore, using immature life stages or less sentient animals, i.e. non-mammals, is not scientifically appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be allowed to acclimatise to their environment to reduce any distress. Animals will also be trained to become accustomed to regular and appropriate handling.

For each step appropriate controls are in place to minimise any adverse effects for the animals and humane endpoints are clearly defined. Animals will be monitored by both the research group and the unit staff.

Animals will receive appropriate pain relief pre- and post-operatively. However, non-steroidal anti-inflammatory drugs will be avoided as the inflammatory response is involved in disease development.

Following surgery, animals will be allowed to recover from anaesthesia in a temperature controlled incubator. Surgical wounds on the animal will be subjected to after-care such as betadine solution to prevent infection. Lacri-lube will also be administered to each animal to prevent eye dryness and irritation whilst anaesthetised. Following recovery, animals will be closely monitored, weighed regularly and observed for any signs of distress or pain. We have also refined our animal handling techniques in line with current guidance.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the best practice guidelines highlighted within the document 'Responsibility in the use of animals in bioscience research' which is published by the NC3Rs.

We will also be following the best practice guidelines published by the NC3R concerning: blood sampling; grimace scale; how to pick up a mouse; housing and husbandry; procedures with care and rodent welfare hub.

We will comply with local practices and keep up to date with newsletters and bulletins sent by the animal unit.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult with our named information officer in order to stay knowledgeable in advances of the 3Rs. As well as this, we will keep up to date with any relevant literature on the 3Rs or published papers from the NC3R to ensure our work will always be within the recommended guidelines. We will also keep up to date with any news and bulletins provided by the animal unit in which we are undergoing our research.

Home Office

NON-TECHNICAL SUMMARY

9. Autoimmune and inflammatory diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Autoimmune, Inflammation, Arthritis, Inflammatory bowel diseases, Therapy

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify and investigate novel molecular targets and mechanisms and develop new medicines for the treatment of autoimmune and inflammatory diseases.

A retrospective assessment of these aims will be due by 08 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Despite the progress in the discovery and development of medicines, there remains a significant unmet need in the treatment of autoimmune and inflammatory diseases. Such diseases contribute to more than 100 serious chronic illnesses involving almost every organ system in the human body, affecting an estimated 7-9% of the world population, and this incidence has been rising by 3-9% over the last few decades. Women account for 80% of those individuals with autoimmune diseases (Invernizzi et al., 2009). For example, women account for 80–95% of patients with primary Sjögren's syndrome, systemic lupus erythematosus (SLE), and about 60% of arthritis patients are women (Beeson, 1994). Autoimmune diseases present a group of common and highly disabling long-lasting conditions with similar features making diagnosis and treatment extremely difficult, which are among the world's leading causes of death. Autoimmune and inflammatory diseases are frequently associated with additional serious healthcare issues, including severe pain, fatigue, depression, anxiety, chronic morbidity presenting a considerable burden on healthcare systems. In addition, a patient with an autoimmune disease such as rheumatoid arthritis or IBD, is significantly more likely to develop others, leading to more complex healthcare needs and lives that are considerably more challenging.

Autoimmune and inflammatory diseases such as rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), inflammatory bowel disease (IBD), Sjögren's syndrome (SS) and psoriasis are all characterised by a breakdown in function of the immune system and/or activation of pathological mechanisms that remain poorly understood. These diseases vary greatly in the tissues and/or organs they affect and how they are presented, with some being limited to a particular tissue and others affecting the entire body. Through the assessment of information obtained from individuals living with autoimmune and inflammatory diseases, identification of the biological mechanisms and specific genes involved can be identified as novel approaches for treating such diseases. The use of animal studies is

fundamental for the validation of these mechanisms and genetic targets to support the research and development of potential new medicines.

In addition, the production of autoantibodies in autoimmune diseases has a profound involvement in the development of pain associated with such diseases. Cellular responses involved during acute inflammation leading to activation of the immune system, trigger mechanisms involved in pain signalling. However, recent studies suggest that the pain associated with autoimmune diseases such as RA develops in the absence of inflammation and is primarilly driven theough the production of autoantibodies (Wilderbrand et al., 2016). Although there is a large variety of autoimmune disorders with different symptomologies, pain appears to be a common factor in most of these conditions. The pain associated with autoimmune diseases is considered as one of the leading causes of comorbidities such as depression, resulting in a significant impact on quality of life and disease burden.

Increased understanding of the immune system and the mechanisms involved in the development and maintenance of autoimmune and inflammatory diseases has resulted in the important discovery of many effective treatments that manage the symptoms, but have little or no effect on the underlying causes of the disease. In addition, with undesirable adverse effects and a high proportion of non-responders associated with current treatments, there still remains a high unmet need to develop new medicines that are effective against multiple autoimmune and inflammatory diseases, offering a significant improvement over currently available treatments.

What outputs do you think you will see at the end of this project?

This licence supports a wide range of methods to enable the identification and evaluation of inflammatory and immunological systems involved in autoimmune diseases, to enable the investigation and development of potential new medicines to act against those diseases. The information generated from this work will enable scientific programmes to increase understanding of how mechanisms could drive development and maintenance of disease or why a condition may not heal or resolve. Studies targeting the identified and validated biological mechanisms will enable the effectiveness of therapeutic agents to be tested and developed as new medicines. This will provide information on common mechanisms that underlie different systems and disease indications (to enable subsequent expansion of research into a wider range of disease indications when mechanisms in common exist). It is also anticipated that results generated from these studies will be shared through scientific meetings and literature to further increase scientific knowledge and understanding in this field.

Who or what will benefit from these outputs, and how?

The information generated from this work will contribute to the development of new medicines to address the unmet medical need and improve the lives of people suffering with autoimmune and inflammatory disease.

Early research and discovery efforts will continue with the identification and validation of new disease related targets, which will form the basis of continued discovery and development of novel and effective therapies to benefit patients and increase knowledge available to the scientific community. Patient

benefit will occur over the longer term due to the long timescales involved to develop new medicines. The wider scientific community will benefit from published work presented at scientific meetings and in scientific journals to further increase knowledge and understanding in the field.

How will you look to maximise the outputs of this work?

It is expected that the information generated from the work carried out under this licence will be included in scientific publications as part of the process of investigating and validating new disease mechanisms and targets, and developing new treatments for disease. Where work is considered to be 'pre-competitive' (e.g. method development or model validation work), whereby it does not contain information that is subject to intellectual property constraints, it will also be considered for publication. In addition, the company also supports the view that publication of unsuccessful approaches ('negative data') is a valuable scientific output from properly conducted research, and this type of data would not be excluded from a publication strategy.

Information generated using this licence is maintained in a long-term, secure company database, that is continually available to other internal company researchers. Therefore, data will be recoverable in the future, even after likely project and personnel changes, and the information will be a valuable future resource to reduce the need to repeat and re-establish expertise in a field of research.

Species and numbers of animals expected to be used

- Mice: 13,500
- Rats: 2350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is the aim of this project to identify and develop new medicines to treat diseases affecting the immune system. Prior to performing in vivo experimental models under this licence, in silico and in vitro human and animal models are regulary employed to study biological responses and mechanisms related to the human disease. In vitro biological cell based assays are reproducible, reliable, robust and biologically relevant enabling the screening of many compounds to identify those with the desired biological effect for progressing in vivo. Currently, animal models cannot yet be replaced in all pre-clinical research as they are required to provide basic information relating to the function of specific mechanisms and targets, and for assessing the activity of potential new treatments in complex, integrated systems only found in living animals. For most of the proposed work an established immune system is required that is able to respond to a challenge and/or develop disease symptoms, and is suitable to investigate the roles of genes of interest that may be involved in human disease. For rodents, this would typically require animals of at least 8 weeks of age. Animals may be genetically altered resulting in developing

diseases naturally (spontaneous), and/or can be treated (induced) to develop the required response and/or relevant disease symptoms which are similar to those observed in humans. Animal models are essential for providing such conditions, as they present with many similarities regarding the features and characteristics of the human disease they intend to reproduce, therefore there is a high level of translation between species. The recognised similarities validates rodents as highly relevant and extremely valuable model systems for the work proposed in this licence. The animal models used for this work have been developed to be the least severe, and are well characterised and validated to investigate the role and function of mechanisms and pathways involved in immunological and inflammatory changes. The processes involved in disease states are extremely complex, thus new treatments need to be tested in a whole living animal to ensure effects produced on immune responses are accurately predicted. Within this project licence, it is proposed to use adult rats and mice with mature immune systems to test the effectiveness of new treatments.

Typically, what will be done to an animal used in your project?

An animal used under this project licence will typically experience the following.

Protocol 1 (Tissue supply)- Animals will not undergo any disease induction, and will be used to supply tissues and/or fluids to support work performed in culture (e.g. ex vivo). Under this protocol, animals will be humanely killed to allow blood and/or tissues to be collected. As part of this protocol, animals may receive either a single or repeat course of drug treatment prior to collection of samples. Drug levels and/or markers of treatment effects in the blood may also be measured. At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 2 (Mechanistic challenges) - Animals will be injected (typically on a single occasion) with an inflammatory agent (e.g. LPS) to produce an inflammatory/immune response that could lead to moderate suffering and last up to 7 days. An animal could receive either a single or repeat course of drug treatment throughout this duration. The effect of any given drug treatment on the inflammatory/immune response produced will be assessed by measuring drug levels and/or markers of treatment effects (i.e. cytokines) in the blood. Animals will be weighed and general health assessed daily throughout the study duration. At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 3 (Immune responses) - Animals will be injected (typically on a single occasion) with an antigen (e.g. KLH) to produce a primary immunisation response. A second injection (typically on a single occasion) may be provided to produce a secondary immunisation response (e.g. DTH) that could lead to moderate suffering and typically last up to 14 days. Animals could receive either a single or repeat course of drug treatment during this duration. The effect of any given drug treatment on the inflammatory/immune response produced will be assessed by measuring drug levels and/or markers of treatment effects (e.g. antibodies) in the blood, measurement of tissue responses (i.e. ear swelling), and/or via imaging capabilities (e.g. MRI). Animals will be weighed and general health assessed daily throughout the study duration. At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 4 (Mouse arthritis) - Animals will receive a single injection of an initial sensitising substance (e.g. collagen/antibody cocktail) followed by a further single injection (boost) of a secondary inflammatory agent (e.g. LPS) up to 1 week later to induce arthritis. Animals will start to show signs of

joint swelling in all paws within 2-3 days following the second injection which could last up to 3 weeks which could lead to moderate suffering. Animals will be weighed and general health assessed daily throughout the study duration. Animals are likely to receive either a single or repeat course of treatment during this duration. The effect of any given treatment on the arthritis produced will be assessed by measuring drug levels and/or markers of treatment effects (e.g. antibodies) in the blood, physical observations (i.e. paw swelling) and/or via imaging capabilities (e.g. MRI). At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 5 (Rat arthritis) - Animals will receive an initial single injection of type II bovine collagen usually combined with an adjuvant (e.g. IFA) followed by a further single injection (boost) 7 days later of type II collagen combined with an inflammatory agent (e.g. LPS) to induce arthritis. Animals will start to show signs of joint swelling in the hind paws within 5-7 days following the second injection which continues until day 21 post initial collagen injection that could lead to severe suffering. Animals will be weighed and general health assessed daily throughout the study duration. Animals are likely to receive either a single or repeat course of drug treatment administered during this duration. The effect of any given drug treatment on the arthritis produced will be assessed by measuring drug levels and/or markers of treatment effects (e.g. antibodies) in the blood, physical observations (i.e. clinical scores, paw swelling) and/or via imaging capabilities (e.g. bio-luminescence). At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 6 (Mouse colitis) - Animals will receive either a single injection of T cells (adoptive transfer model), or antibody (e.g. aCD40), or will be administered with a chemical substance (e.g. DSS) in the drinking water, to induce colitis. Animals will typically start to show symptoms of colitis (e.g. body weight loss) 2-3 weeks following T cell transfer or 2-4 days following either antibody or chemical administration. Animals will be monitored daily and general health assessed. Animals will be weighed every other day until disease symptoms are observed, then every day thereafter. Animals could receive either a single or repeat course of drug treatment during this duration. The effect of any given drug treatment on the colitis produced will be assessed by measuring drug levels and/or markers of treatment effects (e.g. proteins) in the blood and/or faeces, or physical observations (i.e. endoscopy). At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for further analysis.

Protocol 7 (Mouse Lupus) - Animals that are genetically altered (e.g. mouse strains NZB/W F1 and MRL/lpr)) will either spontaneously develop lupus symptoms, or animals will have a single injection of a disease accelerator (e.g. pristane) or an immune trigger such as an adeno-virus (e.g. Ad-IFN) to initiate lupus development. Genetically susceptible mice and those challenged with an accelerator will typically start to show lupus symptoms (e.g. protein in the urine, enlarged lymph nodes, enlarged spleen, arthritis) from 2-6 months of age, while those challenged with adeno-virus will show symptoms from 6-12 weeks of age. Animals will be weighed and general health assessed daily throughout the study. Animals could receive either a single or repeat course of drug treatment during this duration. The effect of any given drug treatment on the lupus produced will be assessed by measuring drug levels and/or markers of the treatments effects (e.g. auto-antibodies) in the blood, and/or via imaging capabilities (e.g. MRI). At the end of the study, animals will be humanely killed, and further blood and/or tissues may be collected for furtheranalysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals exposed to an inflammatory/immune challenge agent (protocols 2 and 3) are likely to experience short lasting local or systemic inflammatory and/or immune responses, although certain models may be associated with weight loss (e.g. 5 - 10% of highest achieved body weight) lasting for a few hours or several days after. Additionally, adverse effects such as hunched posture, piloerection, subdued responsiveness, ocular-nasal discharge and diarrhoea may be observed, although these usually subside and animals recover within a few hours/days depending on the challenge agent and model used.

Animals that develop arthritis (protocols 4 and 5) may display signs of weight loss (e.g. 5 - 15% of highest achieved body weight), hind limb swelling and/or loss of weight bearing, reduced mobility, scabbing at the injection site, and may experience some degree of pain during the development (e.g. 5-7 days following boost) and maintenance (e.g. up to 21 days from initial collagen injection) of arthritis symptoms.

Animals that develop colitis (Protocol 6) may display signs of weight loss (e.g. 5 - 20% of highest achieved body weight), develop diarrhoea, hunched posture, blood in faeces (e.g. DSS model), swelling and reddening of skin, especially around the eyes, and may experience some degree of pain

Animals that develop Lupus (protocol 7) may display signs of weight loss (e.g. 5 - 10% of highest achieved body weight), develop protein in the urine, enlarged spleen, enlarged lymph nodes, skin rash, arthritis, and may experience some degree of pain.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Experience during work under previous licences indicates that at least 25% of animals are expected to show no more than mild effects following treatment. Up to 60% of animals will likely, experience a cumulative moderate severity, or at least a period of moderate severity at some point during experiments. Up to 15% of animals will likely, experience a cumulative severe severity (e.g. rat CIA model).

Protocol 1 is non-recovery (100% of animals), Protocols 2-4 will be moderate (40% of animals), Protocol 5 will be severe (up to 40% of animals may enter severe category, but all attempts will be made to work within the moderate severity), protocol 6 is moderate (40% of animals) and protocol 7 is moderate (up to 100% of animals have the potential to enter moderate severity).

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 08 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this programme of work is to identify and develop new treatments for extremely complex human conditions that affect many organs and/or systems in the body that have many different causes (e.g. hormonal, genetic, cellular). While it is possible to reproduce some aspects of these systems and study certain aspects of these functions in isolation (e.g. in vitro), the complex processes and interactions that work in different ways and at different times, either alone or together, cannot be completely and accurately replicated outside of the whole animal. The immune system is a very complex, highly coordinated network of specialised organs and cells that protect the body from potential harmful substances (e.g. bacteria, virus, infection), which can respond quickly and efficiently (i.e. immune response) to eliminate such harms. These responses involve several cell types (e.g. white blood cells) and signalling proteins (e.g. cytokines), and consist of a sequence of events that are common across mammalian species, and hence results from experiments carried out in rodents can be compared and translated to humans. Responses are coordinated to identify potential disease causing organisms (e.g. a virus or other pathogen) and/or damaged tissue, and act to alert and recruit other cells and signalling molecules and/or activate processes that can lead to structural changes in tissues and organs. An inefficient or malfunctioning immune system can result in the body mistakenly begins attacking its own healthy cells, tissues and organs leading to autoimmune diseases that may be restricted to certain organs (e.g. Lupus) or involve a particular tissue in different places (e.g. rheumatoid arthritis).

Additionally, investigations into disease states that are the result of altered or mis-functioning immune mechanisms, or investigations into highly organised body systems require the use of mature functioning tissue(s) that cannot currently be fully replicated, grown or kept alive outside animals (ex vivo). Rheumatoid arthritis (RA) is an example of an autoimmune disease primarily affecting joints of the hands and feet resulting in inflammation, pain and reduced function. The underlying cause of the disease is unclear, however due to the nature of the immune response and the structure of the joints/tissues involved, it remains too complex to replicate the cellular responses, tissue damage, symptoms and course of the disease in a plastic tube. Whilst a wide range of information from isolated cell systems is generated as part of the initial investigatory process to further increase our understanding of the basic mechanisms and how potential treatments target or affect many functions, understanding the integrated response in a whole animal with a physiology that is common with humans is vital to direct potential medicine progression to human clinical trials.

Which non-animal alternatives did you consider for use in this project?

Various in silico and in vitro assays are used to predict and/or investigate whether a novel therapy can directly effect isolated cellular processes involved in immune diseases. For example, cells and/or tissues may be isolated from naïve, diseased or challenged animals for use in biological assays. Cell

populations may be isolated from tissues and cultured as cell suspensions, or tissue pieces may be cultured in plastic tubes as explants or organoids. Models using types of isolated human and animal cells have been developed and widely published in the scientific literature, and are being increasingly used as part of the development of new medicines. Currently, the vast majority of these models use flat cultures of cells growing on plastic that have a limited level of complexity, and are only capable of addressing specific questions. The continued development of organoids (e.g. intestinal epithelial system) and three-dimensional (3D) modelling systems (e.g. gut-on-a-chip) have enabled some of the challenges of investigating the cellular interactions to be addressed, however, the full level of complexity required to replicate the human disease situation are yet to be achieved.

Why were they not suitable?

Despite much progress over the last few years, the three dimensional (3D) systems such as gut-on-a-chip and joint-on-a-chip are limited in their availability and they do not model the complex processes of the immune system. Immune responses involve the integration of genetic, molecular and cellular factors, across multiple systems. Additionally, systems using cells are not yet adequately able to model potential drug absorption, distribution, metabolism and elimination (ADME) properties throughout the body resulting from the administration of a therapeutic agent passing through organs such as gut and liver to enable delivery to the target organ/tissue. Thus, these non-animal systems are not yet fully characterised and/or validated to provide confidence in the clinical relevance of data generated from using them. While these models provide great value in predicting the potential effects of a novel therapy, Given this level of complexity, there are currently no suitable alternatives to assess the efficacy of a novel therapy on the ability to produce a desired or intended result, without the biological changes seen in the animal models.

A retrospective assessment of replacement will be due by 08 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from yourexperience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated number of animal that are likely to be used over a five year period are based on the experience of related work and projects previously supported under licence authority within the company. There is an anticipated steady rate of projects likely to require information that cannot be gained from non-animal alternatives. Also considered in these estimates is the likelihood of changes to research priorities as a result of continuing scientific advancements in many areas of science. Because

we are familiar with the types of models that are likely to be used and know the resources that we have available we can estimate the number and type of studies that will likely be required over the life cycle of a licence.

We use accepted statistical principles based on the main readouts from each model together with knowledge of the variability those readouts to inform on animal numbers required per type of study to produce statistically useful information.

The number of animals to be used under this licence has been estimated through previous experience and the anticipated requirement, over a five year period, to identify and develop novel therapies/therapeutic agents for the treatment of autoimmune and inflammatory diseases. The animal models used under this licence have been developed and optimised with statistical input to ensure they have sufficiently powered robust and reproducible endpoints, using the minimum number of animals to make informed decisions.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experimental work is planned with the input of statisticians to ensure that experiments provide high quality data using the minimum number of animals. Experimental treatment group size will either be based on existing data, or small trial (pilot) studies will be carried out to establish the variation of the biological system and associated readouts being investigated. Understanding the variation and what constitutes a meaningful biological response to a treatment allows a statistician to calculate treatment group sizes that are used to ensure that statistically meaningful comparisons can be made between treatment and control groups. These design principles aim to reduce the possibility of experiments not generating decision making data, potentially resulting in repeating work and hence using more animals.

In addition to statistical support, all studies conducted under this licence will undergo internal peer review in order to ensure that all aspects of experimental design are suitable for the study being proposed.

Where the biologic effect of a new therapeutic agent or control treatment is being tested, the blood or tissue levels of that substance and the associated biological response will be measured from the same animal. This allows the direct comparison of treatment levels and treatment effects to be made, and reduces the number of animals required overall. Animals will be randomly assigned to experimental groups using a random number generation system. This will reduce bias in a design that could compromise the value of generated data and potentially lead to more animals having to be used if work were to be repeated. Additionally, for subjective readouts that require a person to make a judgement, bias in data interpretation will be avoided by using experimental blinding. Thus, those involved in making those assessments will not be influenced in the interpretation of readouts by knowing which treatment had been given to animals.

These robust study design measures will maximise the likelihood of generating non-biased experimental results, and limit the number of animals required to generate high quality decision making data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Before performing any work under this project, cell assays (e.g. in vitro) will be performed to determine the activity of the test agent on the relevant mechanisms. Where a new model is required or an additional endpoint is to be implemented within an existing model, initial pilot studies will be undertaken to optimise the conditions and measures will be taken to ensure the maximum level of information (e.g. via serial sampling) is obtained using the least number of animals. Model performance will be continuously monitored and opportunities to reduce variability will be implemented with help from a statistician. To reduce variation in biological readouts we will ensure that our facilities provide a constant optimal environment suitable for the species, and the number of personnel involved in making any subjective experimental measures will be minimised. By controlling variation in biological readouts, we aim to ensure that the minimum possible animal group sizes are used to achieve the scientific objectives of the study.

A retrospective assessment of reduction will be due by 08 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will take a staged approach to studies, minimising the risks to scientific objectives and animals:

Blood and tissue supply (Protocol 1)

Aspects related to understanding particular mechanisms and/or process involved in inflammatory and immunological processes are evaluated initially through cell assays performed in tissues provided from non-recovery studies (Protocol 1). Additionally, materials (e.g. T cells) will also be provided for other in vivo models under this licence (e.g. adoptive T cell transfer model of IBD).

Acute challenge models (Protocol 2)

Following confirmation and validation of a mechanism and/or target in cell assays, initial in vivo validation will be performed in an appropriate challenge model (Protocol 2). These models display certain features of human autoimmune and inflammatory diseases, however they do not develop

disease-like symptoms and have a short duration, causing less harm than the disease models. They are used to provide further understand of the specific effects of new targets and/or mechanisms in vivo, thus limiting the number of compounds tested in the disease models.

Immune response models (Protocol 3)

Once initial validation of the mechanism and/or target has been determined, further evaluation may be performed in immune response models (Protocol 3) to assess their effects on specific immune responses related to a particular disease, without the need to induce a chronic disease state and the associated harms to animals. The selected models will allow us to explore how altering certain processes and/or functions with effective treatments can modify the immune responses being produced. The information provided form these models will provide further understanding into the mechanism of action of the target, and will provide evidence to support progression into more complex, disease-like models.

Arthritis models (Protocols 4 and 5)

The selected arthritis models (Protocols 4 and 5) represent many of the features of rheumatoid arthritis (RA) and are extremely useful for investigating mechanisms and processes involved. However, no single model reproduces the human disease exactly. Therefore, prior knowledge of the targets and mechanisms being investigated are essential for model selection to assess effective treatments. The mouse CAIA model (Protocol 4) will be the preferred option due to the quick onset of disease symptoms, produced over a duration of no more than 12 days, causing the least harm to the animals. Only in specific instances where the testing of a particular mechanism and/or target is necessary, will the 21 day rat model be considered. This approach will provide all the required data while preventing prolonged harm to the animals.

Mouse colitis models (Protocol 6)

The mouse models of colitis represent many of the common characteristics of human inflammatory bowel diseases (IBD). While no single model reproduces the human disease exactly, the selected models are valuable tools for assessing effective treatments on the mechanisms and processes involved. The DSS model resembles key features of ulcerative colitis (UC), has very quick onset of symptoms produced over a short duration of 7 days, that resolves quickly, providing a simple, robust model. The adoptive T cell transfer model assesses long term colitis that requires a longer duration of 6 weeks for the required disease symptoms to develop, however this provides a wider, more detailed disease assessment to test effective therapies on specific targets and/or mechanisms involved. The approach taken will provide all the required data while preventing prolonged harm to the animals.

Mouse SLE models (Protocol 7)

Different mouse models for Spontaneous Lupus Erythematosus (SLE) will be used (Protocol 7), as a single model alone does not represent all the disease characteristics seen in human disease, required to assess effective treatments. The mouse strains we will investigate, develop mild symptoms of lupus spontaneously at approximately 3 and 5 months of age. The disease onsets can be accelerated and aligned to levels of proteinuria similar to the human disease, by using inflammatory accelerators, allowing us to minimise the period of time for disease development, thereby reducing the cumulative

harm of disease and treatment period. Prior knowledge of the target and/or mechanism to be tested is essential for appropriate model selection and prevent prolonged harm to the animals.

New models and Biostatistics

When new models and/or modifications to existing models are required, pilot studies will be performed to ensure the animal model is as refined as possible. The methods employed in each animal model will be suitably refined to ensure the animals are exposed to the least harm to achieve the scientific objectives.

Statistical support will be obtained at all stages of running an animal study, to ensure the least number of animals are exposed to harms to provide the required scientific data. Literature will be regularly assessed to ensure the most up to date models, methods and refinements are used.

Harms associated with each disease model have been minimised by reducing the duration of the model and/or disease and by setting clear humane and experimental endpoints. The humane endpoints consider all aspects of the physical signs or symptoms associated with the particular model and/or disease.

Why can’t you use animals that are less sentient?

Autoimmune and inflammatory diseases are extremely complex conditions affecting single or multiple organs of the body, often involving several systems simultaneously. Rodents are a relevant species as they provide many similarities with the mechanisms, systems and processes involved in human diseases that are not known to be active in less sentient species. To undertake the work proposed under this licence, rodents must have an immune system that has matured sufficiently that it consists of all the required functioning components. Therefore, this requires animals to be at least 6 weeks of age, but preferably in excess of 8 weeks of age. Due to the duration of the models to be used, it is impractical and unethical to keep animals anaesthetised for the duration of the required procedures and sample collection periods.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The models described within this licence will undergo continual review to ensure they cause minimum harm to animals, while maintaining scientific integrity. For example, the duration of model implementation will be continually reviewed to ensure that the earliest appropriate biological endpoint is used to achieve the scientific objective. Furthermore, the number and frequency of procedures will be kept to the minimum required to answer the scientific question.

For each inflammatory model, animals will be assessed daily and monitoring score sheets will be used to assess the welfare of the animal as the model progresses.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following is a list of the best practice guidance that we routinely follow.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs through regular referral to the NC3R's website, as well as other published literature. Furthermore, the establishment Named Information Officer (NIO) will facilitate the dissemination information in relation to any such advances. In accordance with any updates, we will review and revise the protocols within this licence to ensure they have been adequately considered, and where applicable, applied.

A retrospective assessment of refinement will be due by 08 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

10. Bacterial adaptations to host environments

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Respiratory tract, Bacterial infection, Therapeutics, Vaccines

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To be able to cause disease, bacteria must be able to thrive within their host. We aim to understand how different aspects of the host environment, such as the available nutrients and immune defences, can shape the processes of bacterial adaptation and evolution. We aim to harness the information gained to develop new therapies and vaccines for the treatment or prevention of bacterial disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antimicrobial resistance is an accelerating public health issue. We urgently need to identify new ways to treat drug-resistant bacterial infections. Understanding how bacteria capitalise on the opportunities provided by the host environment, and how they overcome the challenges presented, can help us to develop new strategies to combat infection. These might include developing drugs that prevent bacteria from utilising host resources, or therapies designed to promote aspects of immune defence that are key to eliminating bacterial pathogens.

What outputs do you think you will see at the end of this project?

This project will provide the following outputs:

- New understanding of microbial determinants of colonisation and virulence for important bacterial pathogens of the human respiratory tract.
- New information regarding how bacteria sense and respond to their host environment.
- Multiple research publications in peer-reviewed journals. We have a strong publication record as a lab and aim to publish from all our funded studies (typically 2-4 publications per year).

  Trained scientists. The skills learned from work on this project will be invaluable for the future research careers of the staff and students involved.

  In the long term, we would hope to generate novel therapeutics and/or vaccines for the treatment/prevention of bacterial diseases.

Who or what will benefit from these outputs, and how?

In the short term, the major beneficiaries will be the staff and students employed on the project, who will benefit from high quality training and exposure to a range of research methods. Both they, and the research community more broadly, will benefit from access to research findings in the form of published research papers that will stimulate further research. The research community will also benefit, in the short to medium term, from access to new experimental techniques that we will develop during this project, including those for novel experimental evolution systems and bespoke bacterial growth media that replicates conditions of the airways. In the long term, the public will benefit from access to new therapeutics or vaccines. In particular, people with cystic fibrosis would benefit from the development of novel therapeutics designed to increase the effectiveness of antibiotic treatment of infection.

How will you look to maximise the outputs of this work?

We aim to publish in open access journals to ensure maximum reach of our research and we also use pre-print servers (e.g. bioRxiv) to make our findings available at an early stage. We will publish a methodology papers to disseminate our work on developing novel culture media, and any data that is not used in primary research publications will be uploaded to Wellcome Open Research as a dataset. All our high-impact publications are accompanied by press releases to make the wider public aware of significant developments.

We have a number of active national and international collaborations and these will likely develop over the course of the project. For example, we have contacts in the pharmaceutical industry with whom we may wish to collaborate on the drug development aspects of the planned work.

Species and numbers of animals expected to be used

- Mice: 6800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We study bacteria that cause disease in the respiratory tract. We are interested in how the environmental conditions of the upper airways (the nose and sinuses) and the lower airways (the lungs) can influence bacterial evolution and determine the outcomes of disease. Of the animals with a respiratory tract sufficiently similar to that of humans, mice are the simples and therefore the most appropriate for our purposes. For most of our experiments, we use adult mice, as the disease course of an adult mouse infected with the bacterial pathogens that we use is very similar to that seen in humans. Occasionally, we use juvenile mice. Juveniles are useful for studies aimed at developing new vaccines, as we typically aim to vaccinate children and want to mimic that situation as best as possible in our models.

Typically, what will be done to an animal used in your project?

Most of the protocols in this licence aim to reproduce the clinical features of bacterial respiratory infection. These include asymptomatic bacterial carriage in the upper airways, pneumonia, chronic (long-term) lung infection and sepsis (infection of the bloodstream). These experiments range in length from 24-72 hours for a pneumonia or sepsis experiment up to >1 month for an upper airway carriage or chronic lung infection experiment.

In most cases, we can establish bacterial infection of the airways in mice by simply administering some bacteria suspended in saline to the nose of the animal and allowing the liquid to be inhaled. For sepsis, we administer the bacteria directly into the bloodstream by injection of a tail vein. For the induction of chronic lung infection, we embed bacteria into a jelly-like substance called agarose and then inject the agarose (as microscopic beads) directly into the airways. This requires surgery performed under anaesthesia.

Infected mice are monitored for signs of disease or may receive additional procedures. These would typically be either those designed to treat the infection (for example, administering an antibiotic or a novel drug) or those designed to help us understand how bacteria cause disease. An example of the latter would be administering substances that alter an aspect of host immunity, to see whether this alters the outcome of infection. Compounds are usually given in drinking water, are inhaled or are injected into the skin, muscles or blood.

We sometimes use mice that lack a particular gene (knock-out mice) or that express a new gene (transgenics) in order to study particular processes that occur during infection.

In addition to our work on understanding the processes that underpin disease, we also aim to develop new treatments and vaccines. Therefore, some mice undergo treatment with novel drugs and some are given novel vaccine formulations to determine if they provide protection against subsequent infection.

What are the expected impacts and/or adverse effects for the animals during your project?

Once infected with a bacterial pathogen, mice typically either remain healthy or slowly start to develop the characteristic signs of bacterial respiratory disease or sepsis. These include a loss of energy, mild weight loss and a hunched appearance. Once clinical signs are observed, we see either deterioration over 1-3 days, maintenance of mild symptoms for around 7-10 days or else rapid recovery. Weight loss is rare, but can occur, particularly in some of the longer term infection models.

Beyond the infection itself, the substances we administer to the animals and the routes and doses of administration do not typically cause lasting harm. They may alleviate the clinical signs of the infection or may hasten decline, but in either case, we have well defined humane endpoints and so terminate studies before animals suffer unduly.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

None of the protocols under this licence have a severity level higher than moderate. Our work on upper airways bacterial carriage (approximately 1/3 of our total animal usage) is typically mild in severity, although a small proportion of mice (<10%) may go on to develop symptomatic disease. Our work on pneumonia (1/3 of total animal usage) would be classified as moderate, with mice developing symptomatic infection but our humane endpoints preventing excessive suffering. Of all our models, the chronic lung infection model has the most adverse events, with mice experiencing a surgical procedure and mild/moderate weight loss in the days following. However, we use low numbers of animals under this protocol and published guidelines have refined the protocol to minimise adverse events. When performed correctly, mice under this protocol recover their weight and are alleviated of clinical signs within ~10 days of onset of infection.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mammalian physiology, anatomy and immune responses impact the nature of host-pathogen interactions in ways that can't be reproduced in a laboratory. This project licence is focussed on pathogen adaptations to host environments and the harnessing of that information to develop novel therapeutics and vaccines. Although we attempt to replicate the environment of the respiratory tract in the lab, that data generated are only useful if we can validate their relevance using animal models.

Which non-animal alternatives did you consider for use in this project?

In vitro systems (cell culture or bacterial growth media) offer some opportunities to replace animal use. We never use animals for early therapeutic screening and we use culture systems to study effects of individual host factors on bacterial adaptation and evolution. Performing preliminary work and basic mechanistic studies in vitro ensures animals are only used when alternatives are unsuitable for the research question being addressed.

Alternative infection models, that do not use rodents, include invertebrate species (for example, wax moth larvae) and human experimental models for the study of pneumococcal upper respiratory tract carriage. Human experimental systems are not appropriate for much of the work we undertake, such as disease studies or evolution experiments where bacteria may change in unpredictable ways over time. We use invertebrates for virulence screening and initial drug toxicity testing, before moving to mouse models with selected bacterial isolates or promising drug/vaccine candidates.

Why were they not suitable?

Non-animal systems can replicate many important aspects of the host but can not reproduce every feature. When studying the processes of bacterial evolution, it is important to capture the full picture of the host environment as even small changes in environmental conditions can have profound influences on the way in which the microbes evolve. Similarly, if we aim to study key interactions between a pathogen and its host, we must consider that the interaction takes places in a host-specific context and that the outcome of the interaction may not be the same in a laboratory environment as it would be during an active infection.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have been working in this research area for 10 years and have experience of the mouse numbers required to complete comparable projects. We are able to accurately determine expected effect sizes (with variance) of interventions from previous work and we know the frequency at which adverse effects can occur in our protocols. The number of animals required has been determined based on our currently funded studies and the programme of work associated with each.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our funded studies are peer reviewed, including statistical analysis plans. We use the NC3Rs experimental design assistant for study design, powering our experiments to achieve a define primary outcome measure. Sample size calculations use estimates of effect size from preliminary data or published work. Common experimental designs include time-point analyses and survival studies. In the latter, we monitor disease progression using a sensitive disease scoring system, recording physical/behavioural changes in the animal and using time to progress to humane practical endpoints as a proxy for survival time. Kaplan-Meier survival analysis compares virulence of bacterial strains or treatment and control groups.

In time-point analyses, we assess microbe and host responses over an infection time-course. We first determine the key timeframe where the host-pathogen interaction under investigation can be studied, to reduce the number of time-points/mice needed in subsequent experiments. For acute infection, innate immune responses peak between 12 and 24 hours post-infection, and we avoid earlier or later time points unless there's a compelling need to include them. In chronic lung infection with *Pseudomonas aeruginosa* or URT carriage with *Streptococcus pneumoniae*, key interactions occur later and alternative time-points are prioritised. Longitudinal data are analysed by two-way ANOVA with correction for multiple comparisons.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The majority of animals used are purchased from external suppliers and we purchase only what is needed. When we breed mice, we use both sexes, where possible. Pilot studies are used to determine effective treatment doses or to identify appropriate time points for analysis. Our team work closely with departmental colleagues to share resources and we regularly provide mouse tissue for others when we don't require it ourselves.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mouse models of infection with human bacterial pathogens. These are predominantly respiratory infection models, although we occasionally use sepsis (blood infection) models when assessing therapeutic or vaccine efficacy. The procedures for induction of respiratory infection are generally minimally invasive, with bacteria in suspension applied to the external surfaces of the nostrils with a pipette, before natural inhalation by the animal. Light anaesthesia is usually administered, to minimise stress.

Following infection, mice develop either upper respiratory tract (URT) infection, which is usually asymptomatic, or lower respiratory tract (LRT) infection, which induces pneumonia +/- sepsis. We can control this process by variation of dose, volume and bacterial strain. We never induce LRT infection unless necessary. If we want to study colonisation, for example, we induce URT infection, as this model causes the least pain and distress.

Occasionally, we administer bacteria embedded in agar beads directly into the lungs of mice. This is a surgical procedure and is associated with a higher frequency of adverse events than our other models. For this reason, it is used sparingly and only where alternative models are unsuitable. The reason for doing so is that it mimics the high-density lung infection with *P. aeruginosa* that is often seen in people with cystic fibrosis. Alternative animal models do not reproduce this long-term infection with large numbers of bacteria.

In the infection models described above, we may treat animals with antibiotics or a novel therapeutic, or else we might promote or inhibit certain host or pathogen signalling pathways, to study their function. When this is done, we first determine appropriate timing and dosing of the intervention, to minimise adverse outcomes for the animals whilst ensuring we achieve the desired effect of the intervention.

Why can't you use animals that are less sentient?

This project investigates the effects of the respiratory tract environment on bacterial pathogen interactions with their host. Of the available model organisms with a respiratory tract similar to that of humans, mice are the simplest. We have to use adult mice for these experiments as the course of infection mimics human disease more closely than when juvenile animals are used. It is impossible to study microbial interactions over an infection time course in terminally anaesthetised animals.

The rationale for testing pathogen virulence, and drug/vaccine formulations in mouse models is well established and widely recognised as essential, when supported by appropriate prior in vitro studies. Use of mice as a model system for experimental evolution of microbes is less common, but we and others have demonstrated that it has advantages over in vitro systems.

Adult mice are the most appropriate choice for most of the work to be conducted under this licence. Disease progresses rapidly in infant mice and does not adequately reflect human infection. Aged mice are used widely in infection studies, but are not required for the experimental questions being addressed here. We will use juvenile animals in immunisation studies, as many vaccines are administered to humans in infancy.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I have worked with mouse models of bacterial infection for 10 years, over which time we have developed robust infection models, whereby mice progress through well-characterised, reproducible disease signs following infection. Hunching and pilo-erection are the first signs to develop and mice are monitored with increasing frequency as they slowly progress to a disease stage where they present with weight loss or behavioural change (reduced energy, minor changes in respiratory rate). We have defined endpoints that allow us to collect valuable information without undue suffering to the animal. The scoring system is sufficiently sensitive that the end-point is rarely missed.

Most experiments are performed with CD1 (for *S. pneumoniae* infection) or BALB/c (*P. aeruginosa* infection) mice and we can reliably predict time to reach humane endpoints, with some variation dependent on bacterial genotype or drug interventions. In our natural inhalation *P. aeruginosa* model, humane endpoints are rarely reached. Long-lasting, low-density lung infection is established and, after development of mild disease in early infection, mice are asymptomatic from ~48 hrs post-infection onwards.

Where disease progression is harder to predict (e.g. the agar-bead model of *P. aeruginosa* infection) we monitor weight regularly to prevent unnecessary suffering. The agar-bead model of chronic *P. aeruginosa* infection requires surgical procedures. Refinement in this model is based on published guidelines detailing appropriate surgical procedural refinements, choice of anaesthetic agent and post-

operative care. We consult the Named Veterinary Surgeon regarding anaesthetic and analgesic protocols and in questions regarding animal health.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Dosing and administration of agents, and withdrawal of blood, will be conducted according to LASA guidelines. Our disease scoring system was originally based on that of Morton (Morton DB, Nature, 1985, 317(6033):106) but has been updated to include more recent recommendations (Turner PV, Pang DSJ and Lofgren JLS, Comparative Medicine, 2019, 69(6):451). Animal monitoring will also take account of the mouse grimace score (Miller AL and Leach MC, PLoS One 2015, 10(9):e0136000). The agar-bead model was refined by van Heeckeren and Schluchter (van Heeckeren AM and Schluchter MD, Laboratory Animals 2002, 36:291-312), and more recently by Bayes et al (Bayes HK et al, Sci Rep, 2016, 6:35838).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Biomedical Services team advertise local and national 3Rs meetings, workshops and conferences. I have attended these and encourage my staff and students to do likewise. Important papers, posters and information leaflets are displayed in our animal unit, highlighting important work in 3Rs areas. I have an NC3Rs funded PhD studentship and have strong links with NC3Rs through my work on one of their funding panels. Our NC3Rs regional manager is in regular contact and on hand to provide support. We constantly aim to apply 3Rs principles to our research and work to implement refinements rapidly, as well as exploring alternative model systems in the laboratory.

NON-TECHNICAL SUMMARY

11. Beta cell metabolism and Vitamin B3

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

beta cells, vitamin B3, metabolism, metabolic stress, nutraceuticals

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to study how the metabolic stress response of beta cells (insulin producing cells) in the pancreas can be influenced by providing vitamin B3 precursors to increase nicotinamide adenine dinucleotide (NAD) provision.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to preserve quality of life and to lower disease risk during the course of life, we need to understand the mechanisms by which nutrients in our diet are used by biochemical processes in cells to maintain health. NAD (nicotinamide adenine dinucleotide) as synthesised from the vitamin B3 intake in the diet, is a compound that takes part in more biochemical reactions than any other vitamin-derived molecule. NAD links the intake of nutrients to the biochemical processes in the cell. We will study how the biochemical processes in beta cells, the cells that produce insulin in the pancreas, are affected by a diet high in fat or by supplementation with vitamin B3. As impaired beta cell function is an underlying cause of diabetes, this project will lead to a better understanding of diabetes and may give rise to new possibilities for its treatment.

What outputs do you think you will see at the end of this project?

This basic research project will lead to a better understanding of how mutations in the genes for NAD biosynthesis in beta cells can influence energy metabolism and glucose/insulin tolerance in mice. The energy metabolism of mice can be measured while the mice live normally in their cages. All these outputs will be obtained on a diet high in saturated fat and compared to a standard diet with lower fat content. The next step will be to study how the negative effects of a high fat diet can possibly be reversed by supplementation with vitamin B3 and its precursors. The effect of these precursors on islet function will be studied. To shine further light on the biochemical function of the beta cell, we will study which of several possible biochemical reactions is actually used in beta cells to produce NAD from vitamin B3 precursors and how these reactions interact with insulin secretion. As glucose is a major substrate for energy metabolism in beta cells, we will perform tracing experiments to study how glucose utilisation in the cell is affected by variations in NAD levels.

Who or what will benefit from these outputs, and how?

All knowledge gained from the project will be shared with the scientific and clinical community and published in peer reviewed journals (output expected during the project). Once the mechanisms of vitamin B3 metabolism on metabolic stress resilience in beta cells have been studied and better understood, the results will inform experiments to study human viable islets, a very rare resource, to examine the effect of vitamin B3 on human islet beta cell function (output expected during or slightly after the project). The long term benefit of the work will be a better understanding of the mechanisms by which dietary nutrients are used by cellular metabolic processes to maintain health. This will open new avenues to reduce metabolic disease risk for example in type 2 diabetes (output expected some 1-5 years after the project).

How will you look to maximise the outputs of this work?

Discoveries as well as negative results will be shared with the wider scientific and clinical communities through presentation at national and international conferences and publication in highly ranked peerreviewed journals. We will also share best practice of new techniques and newly developed protocols with collaborators. We will engage with the public through events organised by the establishment to showcase our research.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use genetically modified mice, which have mutations affecting the NAD metabolism in beta cells in the pancreas. These mutations will allow us to understand how metabolic stress can influence NAD levels in beta cells. Subsequently these mice will be studied to understand how vitamin B3 precursors can be used to ameliorate metabolic stress.
Adult mice of a specific age range (8-12 weeks of age) will be chosen to minimise variability.

Typically, what will be done to an animal used in your project?

Mice with a beta cell specific NRK1 mutation will be fed a high fat diet for 16 weeks to induce metabolic stress. Subsequently their energy metabolism will be assessed in the TSE Phenomaster System (9 days) and their glucose and insulin tolerance will be measured (2 hours each). At the end of the experiment tissues will be collected for further analysis.
Glucose and insulin homeostasis will be studied in for example in whole body NRK1KO mice compared to islet cell specific NRK1 KO mice. To achieve this, glucose, pyruvate and insulin tolerance testing as well as insulin and glucagon measurements will be performed (2 hours each, up to 6 measurements in total).
To reverse the effects of the high fat diet, mice will either be fed (for 16 weeks) or injected with vitamin B3 precursors and the effect of the precursors on glucose and insulin tolerance or hormone levels (glucagon and insulin) will be measured (2 hours each). At the end of the experiment tissues will be collected for further analysis.

To understand the biochemistry of vitamin B3 precursor incorporation into NAD metabolism and their influence on energy metabolism labelled substances will be injected to study their turnover and distribution in the body (up to 1 day). At the end of the experiment tissues will be collected for further analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Glucose/insulin tolerance testing and hormone measurements lead to transient pain during blood sampling (2min) when the initial tail incision is made and when subsequent blood samples are taken from the same incision over a period of up to 3 hours. To ameliorate this, a local anaesthetic will be applied before venesection. If tolerance testing or hormone measurements are repeated, mice will be resting for 2 weeks between measurements. For energy assessment in the TSE Phenomaster System mice have to adapt to the new environment, which might lead to slight weight loss in some animals. To ameliorate this an acclimatisation phase allows the mice to get used to the environment in their original litter groups before they are single housed during the isolation phase. The energy assessment itself is performed by measuring O_2 and CO_2 concentrations non-invasively while the mice live in their cages.
Mice will rest between TSE measurements and tolerance testing for a week. As high fat diet may lead to skin irritation soft bedding material will be used in the cages to prevent skin irritation from high fat diet.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 80% of mice will undergo a combination of procedures, like high fat diet, glucose and insulin tolerance testing and energy assessment or vitamin B3 precursor injection followed by glucose and insulin tolerance testing or mice will undergo glucose, insulin tolerance testing as well as hormone measurements. This will be classed as moderate severity.
The remaining 20% of mice will not undergo a combination of procedures and will be classified as mild.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use non-animal methods to identify and validate the vitamin B3 precursors that can be used to influence glucose and insulin metabolism in beta cells. While these are important studies, these conditions are artificial and cannot give an accurate picture of the effects in different organs and the whole body in mice or humans. Insulin is produced in the pancreas, but effects many different organs like muscle, liver and adipose tissue. Thus we use mouse models to study how vitamin B3 precursors can influence energy and glucose metabolism in different organs. Furthermore in mouse models specific genes of the biosynthetic pathway from vitamin B3 to NAD can be inactivated to examine their effect on biochemical pathways in vivo.
Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace *in vivo* animal use.

Which non-animal alternatives did you consider for use in this project?

In vitro data obtained from cell culture approaches has guided the proposed *in vivo* studies. We always conduct cell culture based experiments to justify the need to use animals.

Why were they not suitable?

Not all questions can be addressed in cell culture, there are no immortal cell lines available to study the complex interaction of alpha and beta cells in the pancreas. Pancreatic islet organoid cultures are still technically challenging.

Reduction

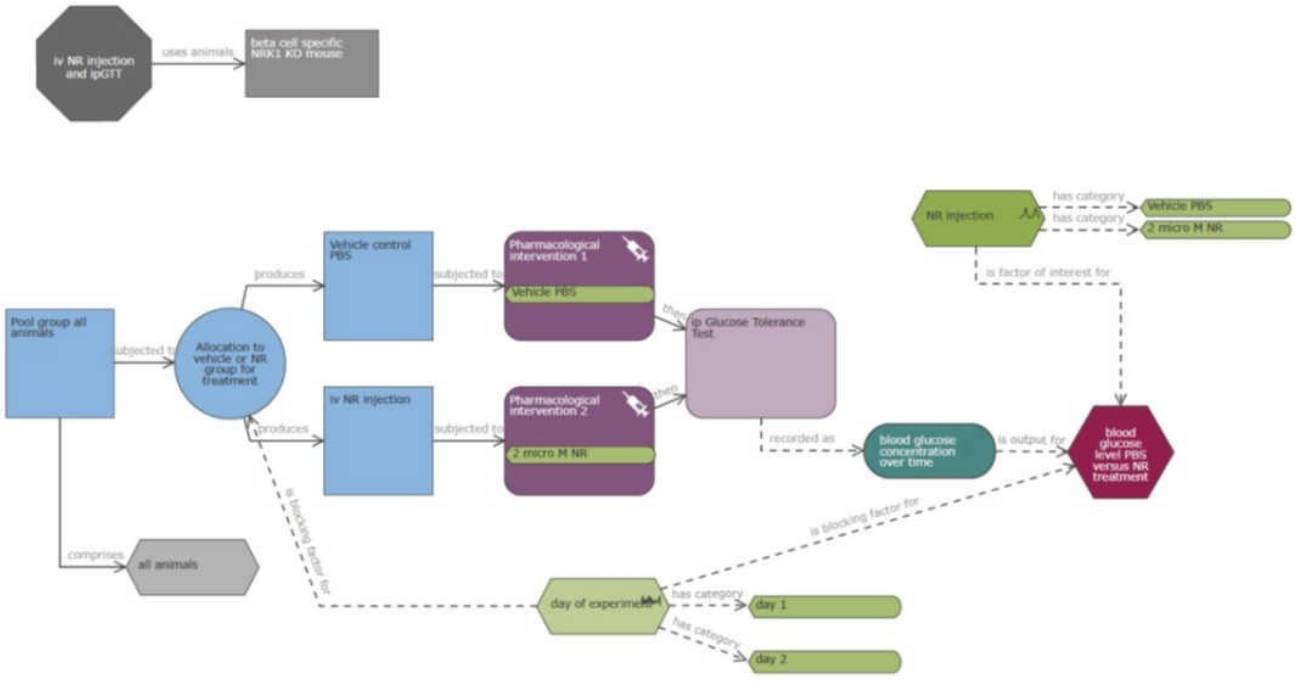
Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

When possible we will always use power calculations to determine the number of animals that should be used. For most quantitative experiments, animal cohort size will be calculated via power analysis. Expected effect size will be determined through consultation of the literature, cell culture based *in vitro* analysis or through small pilot experiments when possible.
We have used statistical methods to calculate how many animals we need to get meaningful data, depending on how many different vitamin B3 precursors and how many mutations of the NAD pathway we will look at. We will carefully consider which vitamin B3 precursors will be tested sequentially, for example if nicotinamide riboside has an effect on glucose tolerance, only its building blocks nicotinamide and riboside will be tested as opposed to testing all possible combinations of vitamin B3 precursors in all different mice with mutations of the NAD pathway, thus reducing the number of animals being used.
We aim to characterise the first step of NAD synthesis, using a NRK1 beta cell specific KO mouse. We aim to investigate about 4 different vitamin B3 precursors per year. We will study high fat diet and vitamin B3 supplied in the food as factors that influence glucose and energy metabolism.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs' Experimental Design Assistant to design experiments (protocol2, example) and taken advice from researchers who have performed similar research projects in the past.



We aim to reduce animal numbers by applying methods to reduce subjective bias, and undertaking appropriate statistical analysis without compromising the scientific objectives. When possible, experiments will involve a factorial design that will maximise the information obtained from a minimal number of animals. Furthermore non-

invasive energy metabolism assessment and subsequent glucose or insulin tolerance testing can be performed on the same animal over a period of time, thus reducing the number of animals used. As importantly, at the end of all *in vivo* experiments, islet cells and several other tissues will be isolated and a large proportion of the scientific output will be generated from these tissues in further *in vitro* experiments for example primary cell culture, protein analysis, metabolomics and genetic studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to estimate variability and perform power calculations to calculate sample sizes.
Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.
We always strive to generate the most effective breeding strategies to ensure that we obtain mice of the desired genotype with minimal animal wastage. If we are unable to estimate an effect size from our *in vitro* data, the literature, or our collaborators, we will conduct small pilot experiments.

All tissue surplus to requirement will be stored and made available to collaborators within the institution and beyond.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse models to study how vitamin B3 and its precursors influence glucose tolerance and energy metabolism while the mice receive an obesogenic diet. The high fat diet used is a very gentle way of generating metabolic stress and allows us to study how metabolic stress can be ameliorated by supplementation of vitamin B3 and its derivatives.
We will use a mouse model with a beta cell specific mutation in vitamin B3 metabolism, this will allow us to study how beta cells in the pancreas are affected by metabolic stress. The mouse model has no harmful phenotype.

To measure the energy metabolism of mice *in vivo* we employ the TSE Phenomaster System. While the mice live in their home cages, CO_2 production, O_2 consumption as well as food and drink intake can be monitored without any disturbance to the animals.
Even though vitamin B3 precursors are well tolerated and usually have no adverse effects, we will use pilot studies to help us to develop dosing regimens for vitamin B3 precursors if administration is not oral to further minimise risk of adverse effects.

Why can’t you use animals that are less sentient?

Mice are the least sentient species that will allow us to achieve our objectives.
We need to study glucose and energy metabolism in adult mice as this is what most closely resembles what occurs in humans. We have chosen to use mice over other less sentient species such as Danio rerio (zebra fish) and Drosophila melanogaster (the fruitfly) as mice and humans share 97.5% of their coding DNA sequences.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Through advice of colleagues performing similar work we are aware of refined methods for glucose and insulin tolerance testing as well as hormone measurements in diabetes research. Treatment doses, duration and route of administration for vitamin B3 precursors will be evaluated in relation to physiological concentrations in the blood, the literature and from previous experience in our group. These measures minimise the possibility of adverse effects.
Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.
We are fortunate to have excellent colleagues both in Academic groups and within the REDACTED with extensive, relevant animal procedure experience, including diabetes models, from whom we can learn refined techniques. Our team will undergo extensive training on dead animals and require to be authorised by REDACTED before being allowed to perform a procedure on live mice.

Examples: The TSE Phenomaster System allows the quantification of energy metabolism by measuring O_2 and CO_2 concentrations, food and drink intake while the animal is living in an IVC cage without any disturbance. For glucose and insulin tolerance testing a single incision will be made on the tail to take small sequential blood samples rather than sequential cutting for blood sampling from tail vein. We use ultrasensitive ELISA assays for hormone measurements to reduce the blood volume that has to be taken. Cardboard tubes are used for refined handling and body condition charts for humane endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will constantly consult the literature for experimental design, best practice, and humane endpoints for metabolic and diabetes research in animals. We also consult Simon Bate's book, 'The design and statistical analysis of animal experiments', for experimental design, statistical analysis, and sample size calculations.
Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment (PREPARE: guidelines for planning animal research and testing.
Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).
The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE 2.0 guidelines published by the NC3Rs.
The LASA giudlines: RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)
Jones HRP, Oates J, Trussel l BA (1999) An applied approach to assessment of severity. In: Humane End points in Animal Experiments for Biomedical Research (Hendriksen CFM, Morton DB, eds). London: Royal Society of Medicine Press, pp 40±7

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will perform literature searches, attend vendor's information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.
We will comply with the ARRIVE guidelines 2.0 (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.
My Lab group twitter follows the NC3Rs and lab members are subscribed to the NC3Rs newsletter - helping us keep up with advances in the 3Rs which will be discussed an implemented through our lab meetings.

Home Office

NON-TECHNICAL SUMMARY

12. Biocompatibility of medical devices and materials

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the aims mentioned in purpose (b)

Key words

Biocompatibility, irritation, systemic toxicity

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this programme of work is to evaluate some aspects of the safety and biocompatibility of novel materials and devices that will come into contact with body tissues before, during or after a surgical procedure

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

To assess the safety of materials or devices intended for human use to reduce or eliminate any adverse effects.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Over 5-years
Rabbit – 350
Rat – 400
Mouse - 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The nature of the skin irritation test will involve either topical or intra-dermal application; based on the previous *in-vitro* assessments, compounds and materials considered for testing will have very little harm and effect, and as such it is expected that a moderate severity banding is more than appropriate. Expected adverse effects are reddening of the skin at the test site and raising of the skin of approximately 1mm. If an animal scores a 3 at any single observation period; determined by the adverse effects set out previously, this will be brought to the attention of NVS/NACWO and PPL in order to receive supportive treatment or be humanely killed.
Animals will be killed at the end of the procedure.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Laboratory *(In vitro)* testing cannot fully replicate the in-body (*in-vivo)* physiological conditions required to test the safety of novel devices, therefore animal tests are necessary

Reduction

Explain how you will assure the use of minimum numbers of animals.

The number of animals required for each of the irritation protocols is either clearly defined in established methods detailed in international standards.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Animal suffering will be minimised by proactively refining the materials tested by:

(a) consultation with people with expertise in toxicology, animal welfare and statistics,

(b) Laboratory (in-vitro) tests to refine the biomaterials and hence, reduce the level of pain, distress or lasting harm experienced by the animals.

The species identified and the surgical techniques used are clearly defined in established methods detailed in international standards

Home Office

NON-TECHNICAL SUMMARY

13. Biology of Normal and Malignant Blood Cells

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Leukaemia, Microbiome, Infections

Animal types	Life stages
Mice	adult, embryo, neonate, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Acute leukaemia is the major type of cancer in children. Although treatment is now very successful with cure rates of around 90%, the treatment is traumatic and toxic.
Our project aims to model key components of the infection-based mechanism by which childhood leukaemia arises.
Over the years, we have generated a body of data indicating that the most common form of paediatric cancer – childhood acute lymphoblastic leukaemia (ALL) is triggered by an abnormal immune response to common infections (e.g. respiratory infections such as flu).
But this only happens in children who are susceptible by virtue of (i) have acquired, as a developmental accident, a leukaemia-initiating mutation in utero; and (ii) have, paradoxically, a deficit of microbial exposures in the first year of life. The latter, principally in the form of benign or beneficial microbes in the gut, are required to prime the new born immune system for proper networked function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

These modelling experiments with mice will endorse our longstanding infection-based model for the causation of childhood leukaemia (CL).
This would, in turn, encourage a search for a prophylactic intervention (microbiome-boosting) that would prevent childhood leukaemia.

What outputs do you think you will see at the end of this project?

The research we are undertaking has been many years in the making and has a foundation in the basic biology of leukaemia and in the evolution of the immune system.
As a necessary first step in this ambitious goal, we have established a mouse model of ALL in which development of leukaemia depends upon timing of exposure to common microbes. We will be seeking to establish that recognised gut bacterial species, if administered very early in life to 'clean' mice can protect against ALL. We will also be screening the gut microbiome (via stool collection) of newly diagnosed patients with ALL to see if their microbiomes are, as we anticipate, different (less diverse) than those of 'control' children.
We will publish our results in international journals and present our findings in conferences appropriate for our filed of research.
If our hypothesis is proved correct, this will suggest a potential preventative intervention – boosting of the gut microbiome in infants. This would require population-wide administration, orally we assume, with defined (and safe) bacterial species that prime the immature immune system.

Who or what will benefit from these outputs, and how?

Childhood acute lymphoblastic leukaemia (ALL) is a remarkable success story in oncology as this once fatal cancer now has a 90% cure rate. But, alas, this comes at a price. The treatment is both traumatic for very young patients and their families, non-specific and therefore toxic and damaging. The consequences include both illnesses concurrent with treatment (e.g., infectious complications of immunosuppression) and some longer-term health impacts. It follows that prevention, if it were possible, would be much preferred.
Our previous research has been to uncover the causal mechanism of the disease, substantiate the idea that abnormal immune responses to infection are critical triggers and to highlight the long term (5-10 years hence) prospect for intervention and prevention. Timelines are difficult to predict but we hope that within five years we should be in a position to know if microbiome boosting does indeed prevent ALL in our model system.
In anticipation that it will, we will begin to explore with colleagues what kind of bacterial formulations might be appropriate to trial in infants.
We note that risk factors for childhood ALL are very similar to those identified for childhood type 1 diabetes and allergies. All three of these immune disorders track, internationally, with affluence or development in societies;

the highest incidence rates for all three being in Scandinavia. This raises the exciting possibility of a standard ‘fix’ of prophylactic for all three.

How will you look to maximise the outputs of this work?

This project will produce large datasets, particularly for 16s rRNA sequencing and shotgun metagenomic sequence analysis, using both mouse and human faecal DNA samples. We anticipate that these data will be of significant interest to the broader scientific community and plan to make these datasets accessible at the time of publication. Prior to publication, the data will be stored in line with the data policies of both our institute and will be held on servers that are regularly backed up.

Our research findings will be disseminated via the usual scientific routes and we will also interact, via social media, with patient/parent support groups and interested parents (e.g. Mumsnet).

Species and numbers of animals expected to be used

- Mice: We plan to use 1,700 mice over the course of 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult immunodeficient mice to study the ability of leukaemic cells to reconstitute malignant haemopoiesis. It has been demonstrated that this strain of mice represents the best model to support the engraftment and expansion of leukaemic cells of human and murine origin.
We will also use wild type and transgenic mice carrying alterations in various genes that may impact normal/malignant haemopoiesis. These strains of mice will allow us to study how leukaemia develops in different conditions of exposure to infections, to study the role of the microbiome in this process and to test whether a preventative intervention may be effective.

Typically, what will be done to an animal used in your project?

Mice may be irradiated and transplanted with leukaemia cells of human or murine origin via intra-vein or intra-bone injection. Mice will be monitored and periodically blood samples from superficial tail vein will be taken to assess the engraftment and expansion of leukaemic cells. Mice will be culled when a sufficient level of engraftment is proved by laboratory test or as soon as they show any signs of distress. These mice will be monitored for up to 9 months post transplant.
Groups of transgenic mice will be transferred from the 'clean' facility to the 'dirty' one. Some mice will undergo faecal transplant before transfer in order to study a potential prevention mechanism.
Alternatively, some pups born in the 'clean' facility will be fostered by mothers from the 'dirty' facility to study how infections in early in life can boost the immune system and reduce the incidence of leukaemia. All these mice will be monitored for up to 30 months of age and blood samples from superficial tail vein will be periodically taken to assess development of leukaemia. Mice will be culled when the leukaemia onset is proved by laboratory test or as soon as they show any signs of distress. **What are the expected impacts and/or adverse effects for the animals during your project?**

Less then 1% of mice are expected to show signs of radiation sickness. These mice will be observed twice daily in the first few days after irradiation and prophylactic antibiotics may be administered.
No adverse effects are anticipated as a direct result of injections by intravenous route. Intra-bone injection may result in bone pain in the recovery period (48 hours). Analgesics will be administered to reduce the pain caused by injection into bone. Complications from anaesthesia at the doses and for the limited time proposed are very uncommon (<1%).
All our mice will be monitored for development of leukaemia. This includes periodically blood sampling from superficial tail veins. Little and transient pain is likely to affect mice. Blood sampling will allow us to determine the onset of the disease and prevent mice from suffering from typical symptoms of the disease.
Mice showing weight loss exceeding 20% or showing any signs of distress (e.g. dehydration, anorexia and unresponsiveness) will be culled.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of our experimental mice will suffer a moderate level of severity. Our mice will only be subjected to intravein or intrabone injection (one time) and multiple blood samplings. A percentage of mice might develop leukaemia and therefore show a higher lever of severity. We constantly monitor our mice for the onset and the disease and any signs of distress (such as weight loss, dehydration and fatigue).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There is, at present, no culture method that can identify and quantify cancer (or leukaemia) stem cell function or any non-animal model system that can recapitulate the development of full-blown leukaemia, in the context of a causal role of infections.

Which non-animal alternatives did you consider for use in this project?

90% of our research on childhood leukaemia has been conducted directly on clinical samples and/or in tissue culture.

Why were they not suitable?

There is no *in vitro* system that can mimic the process of leukaemia formation, driven by infection.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For statistical power analysis, we have used G*power software with the following assumption: α=0.05 (type I error rate) and β=0.2 (type II error rate, with statistical power of 1- β) and used our pilot data with respect to mean and standard deviation to estimate the effect size. This approach will be followed for all *in vivo* experiments to select for the correct mouse sample size.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To estimate correct mouse sample size, we liaised with a team of bioinformaticians with a good background in biostatistics. One person of the team is directly attached to this project and has calculated all the mouse sample sizes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For both ethical and financial reasons, we plan to use the minimum number of mice necessary. To perform the leukaemia stem cell project and model leukaemia in vivo with human and murine cells, we will use only three mice in each replicate group, the minimum acceptable for biological consistency.
For the studies involving transgenic mice, we will perform a very efficient breeding. We will use both wild type and heterozigous transgenic mice of both sexes, thus reducing the number of breedings needed to complete the project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Sustained leukaemia would lead to distress (and death) but we euthanase all mice early in leukaemia development as soon as there are any signs of distress.
No adverse effects are anticipated (or seen to date) via the initial irradiation of mice or injection of cells. Daily surveillance of the health status of mice and weekly assessment (via tail bleed) of the development of leukaemia ensures culling before the onset of any severe suffering.

Why can’t you use animals that are less sentient?

We use mice as we can generate and develop leukaemia that is similar to that found in children. Our studies cannot be undertaken in a less sentient species such as fish. To study development and prevention of

leukaemia, we need to monitor mice for a long period of time. This cannot be done in mice strictly in an immature life stage or terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be daily monitored for any signs of distress throughout the duration of the experiments. After carrying out procedures, we will increase the frequency of monitoring. Analgesics will be administered to reduce any bone pain post intrabone injection. Prophylactic antibiotic treatment may be administered after irradiation to reduce adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All our studies will be conducted in accordance with the NCRI Guidelines on the Welfare of Animals used for experimental neoplasia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep up to date with any new advances published. We will also keep up to date through our BSU staff. They hold regular meetings with scientists, regularly publish a newsletter where they foster the culture of care and upload on the intranet refresher courses about animal welfare, clinical signs and techniques.

Home Office

NON-TECHNICAL SUMMARY

14. Biology of the Pancreas: embryonic development, adult homeostasis and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words pancreas, diabetes, embryonic

development

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The pancreas is the site of virtually incurable diseases, such as diabetes and pancreatic cancer. An exhaustive understanding of the mechanisms regulating pancreatic cell identity will provide insights into pancreatic diseases and would be fundamental for the establishment of novel therapies of diabetes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The pancreas is a gland composed of different cellular compartments with distinct metabolic functions. Namely, the so-called acinar and duct cells produce and secrete digestive enzymes that promote nutrient absorption in the gut, while the pancreatic islet cells, also known as islets of Langerhans, produce the hormones (*e.g.* glucagon and insulin) that regulate the levels of sugar in the blood. The endocrine islets consist of mostly insulin-producing beta-cells (60% in humans) and glucagonproducing alpha-cells (30% in humans). The vital functions controlled by the pancreas are reflected in the severity and mortality associated with pancreatic diseases, such as diabetes and pancreatic cancer.

Diabetes is a group of metabolic diseases characterised by high levels of sugar in the blood (hyperglycaemia) and is still a leading cause of mortality and illness worldwide. Clinically diabetes is broadly classified into type 1 diabetes (T1D), which is caused by an autoimmune destruction of the pancreatic beta cells, and Type 2 diabetes (T2D), which is characterised by 1) progressive beta-cell failure in their ability to release enough insulin and keep blood glucose under control; 2) insulin resistance.

Currently, more than 400 million of people have diabetes in the world, the number is estimated to be > 3.5 million in the UK. The incidence of diabetes is increasing at an alarming rate and the current annual cost of diabetes to the NHS is already around £14 billion a year. By 2025, it is estimated that five million people will have diabetes in the UK. Adults with diabetes have a 50% higher risk of death from any cause than adults without diabetes, in addition to risk for myriad complications, such as cardiovascular diseases. However, this growing burden of diabetes has not been met with a comparable expansion in therapeutic options. Indeed, current treatments for diabetes focus on managing the symptoms of the disease rather than curing it. Finding a cure to diabetes represents therefore an important medical challenge with huge clinical and economical potentials.

Clinical transplantation of pancreatic islet cells provided proof-of-principle that reestablishment of an adequate beta-cell mass can restore normal levels of glucose in T1D patients. However, the profound scarcity and poor quality of donor organs restrict islet availability for study and transplantation. To overcome these limitations, significant efforts have been focused in the recent years on developing strategies for directing differentiation of human ESCs or iPSCs or for (re)programming of somatic cells (e.g. hepatocytes) into pancreatic progenitors and beta-like cells that can secrete insulin and are responsive to glucose to a certain extent. These advances have relied upon the understanding of the mechanisms and signalling pathways governing pancreas and islet development. To date, stem-cell derived beta-cells mostly resemble immature cells, which are naturally found in the neonatal pancreas, rather than adult mature pancreatic beta-cells. Stem-cell derived beta-cells display indeed inferior glucose-stimulated insulin secretion as compared to native pancreatic beta-cells. Efforts to provide the best road map for generating fully mature beta-cells remain an area of intense ongoing research activities.

While the challenge of curing T1D centres on the replacement of the destroyed insulin-producing beta cells, in the context of T2D the goal is to achieve preservation of the remaining beta-cell function to prevent the progression of the disease. Recent findings suggested that de-differentiation of mature insulin-producing beta-cells to a progenitor-like state and conversion into other endocrine cell types contribute to beta-cell failure in T2D. Therefore, deciphering the mechanisms that preserve the mature beta-cell state and hamper plasticity will be key towards a better comprehension of T2D pathogenesis. Moreover, fundamental beta-cell biology research will reveal important insights that can be harnessed for better treatment of insulin-dependent T2D patients, for instance for reversing or preventing beta-cell de-differentiation.

Finally, full comprehension of the mechanisms underpinning pancreatic cell differentiation will also be of paramount importance for pancreatic cancer, a devastating malignancy with an extremely poor prognosis and

unmet medical need. De-differentiation of pancreatic exocrine cells and aberrant activation of embryonic signalling pathways are often the initiation events in pancreatic cancer, making developmental regulators therapeutically attractive.
To study differentiation and function of pancreatic cells and use this knowledge to prevent and cure diseases, like diabetes, five important experimental tools are available. First, it is possible to culture cell lines established from mouse pancreatic endocrine tumours (*e.g.* insulinoma), which recapitulate some features of beta-cell differentiation and functions. Second, it is possible to differentiate mouse ESCs or human PSCs into pancreatic progenitors and beta-like cells using complex multistep protocols based on cytokines and soluble molecules, which recapitulate normal pancreatic embryonic development. Third, histological sections from normal embryonic or adult mouse as well as human pancreatic tissue can be examined and used to evaluate the significance of *in vitro* observations. Fourth, it is possible to make transgenic mice and knockout mice in which gene expression is altered either in pancreatic progenitor cells (for example, using the Pdx1 promoter) or in differentiating beta-cells (for example, using the Insulin promoter) or in cells of the surrounding pancreatic microenvironment, which are fundamental for pancreatic beta-cell differentiation (for example, using the Nkx3.2 promoter). Fifth, pancreatic cells that are generated *in vitro* either through differentiation of PSCs or reprogramming of other somatic cell types can be grafted into suitable recipient mice (for example diabetic mice) to evaluate their differentiation potentials. Observations based on the first three experimental approaches inform our decisions to carry out experiments with mice. We also access genomic and transcriptomics datasets, publicly available or from our laboratory (for example, gene mutations and SNPs in human patients), to generate hypotheses about gene networks or pathways that influence pancreatic cell differentiation.
My laboratory carries out experiments on cultured cells as much as possible. However, many biological processes are too complex for a complete recapitulation in a dish. The study of pancreas formation and diabetes involves a number of different cell types and organs making *in vitro* studies unreliable but also providing extreme challenges for the use of model organisms, such as *Xenopus* or zebrafish. For these reasons, it is essential to carry out some experiments on mice.

What outputs do you think you will see at the end of this project?

The work under this licence is expected to provide novel information about pancreas biology and the role of developmental pathways in diseases; this knowledge will be disseminated through publications and presentations at seminars and conferences. Our projects have attracted peer-reviewed project grant support and some of the work has been published demonstrating that the scientific community considers it an area worthy of investigation. Our genetic targets of enquiry have been selected for their direct relevance to human pancreatic diseases. Thus, this information will also generate proof of concept for clinical applications. Moreover, from the *in vivo* mouse model studies, we hope to identify mesenchymal signals and conditions that might improve current protocols for beta-cell generation *in vitro* (*e.g.* in terms of quantity or quality of cells available for future islet transplantation). Finally, one important output is to maximise the value of the mice that we study by sharing tissue with other researchers. We are expecting to generate and study transgenic mice and knockout mice for genes that are relevant to pancreas organ formation, beta-cell differentiation and human diabetes pathogenesis. However, the genes that we study in pancreatic tissues are often active in other embryonic or adult tissues, in particular in the brain. Therefore, we can share tissues from our mouse models with other researchers and mice that are sacrificed in this project licence can foster research on other disease relevant tissues.

Who or what will benefit from these outputs, and how?

Primarily, the data will be used by scientists working in my laboratory and will be made available to collaborators and later to the wider public through open-access publications and repositories. We have previously published in journals, such as *Nature Communications*, *Genes & Development*,
Development, and it is likely that the output from future studies will be placed in similar journals. That will enable users worldwide to access and further utilise the data generated in our licence. Staff working on the project will gain training in use of animals and as a result will have enhanced career opportunities. In the long run, the proposed studies will generate data of translational benefit to islet transplantation, as a therapy for T1D. My

group has links with the Diabetes Research groups and human Islet Transplantation Units in the UK, which will facilitate rapid translation of information from animal studies to changes into clinical practices.

How will you look to maximise the outputs of this work?

We have established collaborations with computational biologists and mathematicians to generate computational models based on experimental data that we generated from our mouse models. The models make predictions about *in vivo* experiments to test, which help us to reduce the number of mice to be used. We will disseminate new knowledge through presentations at conferences and conventional peer-reviewed publications. In addition, we share unpublished data via pre-print servers, such as BioRxiv, publicly available repositories (*e.g.* GEO) and protocol sharing websites (*e.g.* protocol exchanges; protocols.io). To maximise the output of our experiments, we intend also to publish work that yields negative results or is confirmatory via BioRxiv.

Species and numbers of animals expected to be used

- Mice: 22500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice to study the mechanisms underpinning pancreas organ development and functions. These processes can only be studied in whole organisms, because they involve a number of different cell types, making *in vitro* studies insufficient. Also, beta-cell function and blood glucose homeostasis involve complex tissue crosstalk among different tissues within the body, including the pancreas, liver, muscle and fat. The mouse is commonly used as a model system to mimic human diseases and to evaluate potential treatments. Indeed, the mouse is a genetic model system, anatomically and phylogenetically closer to humans than amphibians or fish, being therefore highly suited to study diabetes and to advance therapies toward the cure of diabetes. The objectives of the project are to study pancreatic organ formation at crucial embryonic stages and postnatally to study homeostasis and disease in adult tissues. In particular, between embryonic day (E) 14.5 and birth the different pancreatic cell types differentiate, including the insulin-producing cells, and the organ grows and acquires the well-defined final shape.

Typically, what will be done to an animal used in your project?

Mice may be subject to procedures, such as ear clipping for genotyping, and blood sampling to monitor glucose levels and metabolic parameters. Pregnant females will be treated with agents (*e.g.* Tamoxifen, Doxycyline) to induce transgene expression to knockout pancreatic genes or to label cells for lineage tracing experiments. To limit any adverse effects due to IP injections, we will inject pregnant female mouse using 1 ml syringe and 21G 5/8 needle, and inject between inner thigh and genitals to ensure no organs are punctured nor the amniotic sac and developing embryos physically damaged. Moreover, the number of IP injection in pregnant females will be limited to one and, typically, it will be performed before 12.5 days of gestation.
Similarly, adult mice will typically receive injections of agents, such as Tamoxifen, Doxycyline, labelling agents or AVV vectors for controlling gene expression. The mice may be subject to glucose challenges to further study the glucose metabolism parameters, insulin secretion and predisposition to diabetes. Most experimental observations are completed within 3 weeks to 3 months. However, some adult studies may last 6 to 12 months.

What are the expected impacts and/or adverse effects for the animals during your project?

The main aim of this project is to study pancreas formation and function(s) in a mouse model. No severe adverse effects are expected for the animals during our studies. The introduction of substances into pregnant mice is expected to induce only transient suffering. However, there is a risk (less than 1% in our experience) that the mouse will abort the embryos and the embryos will die.

Gene or mutations that are under investigation in our licence might eventually lead to pancreatic hypoplasia, alteration of pancreatic functions or diabetes. Animals with severe and overt diabetes might develop hyperglycaemia and have side effects, including weight loss and increased urine output. The measurement of body weight and observation of body condition (*e.g.* thin, normal, overweight) acts as a surrogate marker of appetite. The measurement of skin turgor and observation of cage bedding for urine output acts as a surrogate marker of thirst. Therefore, our trained animal staff will monitor these animals on a regular basis (twice daily) and specifically watch out for signs of distress, including changes in appetite, urine output, excessive thirst, dehydration, activity (*e.g.* lethargy or hyperactivity), weight loss, unkempt appearance, abnormal posture, and twitching or trembling. Mice that manifest these complications will be humanely killed by a Schedule 1 method and used for the experiments, which include blood collection at sacrifice and subsequent thorough analysis of the pancreas and other related tissues with histological and molecular biology methods. The expected level of severity in the above circumstances is moderate.
Other unrelated phenotypes, which might be due to spontaneous tumour development with aging or infection, indicative of a mouse that is in pain or experiencing stress (*e.g.* hunched posture, reduction in food and water consumption, a dishevelled coat, subdued behaviour and abnormal breathing) are expected to be rare and transient.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In protocol 1 the severity limit is 'mild' and it is expected that over 80% of mice have no phenotype at all.
In protocol 2-4 the severity limit is 'moderate' and it is expected that 70% of mice will experience this phenotype.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Primary pancreatic cells cannot be grown in culture, but immortalised *in vitro* insulinoma or tumour exocrine cell lines are available and pancreatic progenitors can be obtained from mouse ESCs and human pluripotent human cells (ESC and iPSC). These alternative models have been used to characterise regulatory intrinsic pancreatic factors. However, pancreas organ development relies on the continuous crosstalk between multiple cell types. These interactions cannot be adequately recreated in culture. Moreover, differentiated ES cultures have a limited lifespan of approximately 3-4 weeks. Therefore, our studies start *in vitro* using cells, but then they require mouse models to assess the complete formation of the pancreas *in vivo*. Likewise, pancreatic beta-cell function and blood glucose homeostasis involve complex cross-talks among different tissues within the body, including the pancreas, liver, muscle and fat. Thus, these processes can only be studied in animals, making *in vitro*

studies insufficient.

Which non-animal alternatives did you consider for use in this project?

Immortalised insulinoma or tumour exocrine cell lines are available and pancreatic progenitors and immature beta-cells can be obtained from mouse ESCs and human pluripotent human cells (ESC and iPSC). Histological sections of human pancreatic tissues are available for analysis. Data sets of gene expression and genomics as well as diabetes (T2D) genome-wide association studies (GWAS) are available; it is also possible to model using computational biology cell behaviour and developmental cell lineage decisions.

Why were they not suitable?

Even though large datasets analysis and mathematical modeling are very effective at hypothesis generation, biological validation requires mechanistic experiments that can only be carried out in cell culture or in mice. Cell culture cannot mimic the full complexity and extended time course of the interactions between different cell types that normally control pancreatic tissue development, homeostasis, or disease. Moreover, the properties of cells change in *in vitro* culture, for example they can lose their differentiated traits, and, therefore, they are not an adequate model for studying the biology of the pancreas or other endodermal-related organs, like the liver.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

My previous licences used a similar number of total mice. The estimated total number of mice in the new licence is based on the assumption that the number of animal experiments performed by my lab will remain the same as in the previous 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In all our studies we aim at reducing animal numbers to a minimum by using the NC3R's Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) web application and the ARRIVE guidelines. I obtained advice on statistical analysis from experts, who published books on the design of animal experiments, and gave classes during the PPL holder training course. Also, during the course of the project, to improve the design of animal experiments I can consult our in-house statisticians for advice, as I did in the past in my previous Institute.
Prior to performing an animal experiment, we perform statistical analysis to ensure that we use the minimum number of mice that will be informative. The unit of analysis will be one embryo or one mouse, according to the type of study. Significance will be determined by the unpaired t-test for biological effects with an assumed normal distribution or two-way ANOVA, and $P < 0.05$ will be considered a significant difference. We will usually analyse a minimum number of 8-15 embryos per time-point or 812 adult mice per experimental condition, based on prior experience that this is sufficient to obtain statistically robust data. However, the precise group sizes for individual experiments will depend on the specific question to be addressed and what is being measured. For example, for timed-mating experiments, we can follow the pregnancy by weighting the plugged females before

sacrificing them and avoid false pregnancy. If the animals have not gained weight, they are monitored for the duration of minimum a month after the plug and afterwards they can be used again for future timed-mating experiments. This is a simple and effective method for reducing animal use.
In my laboratory, when planning experiments involving a new application (for example AAV injection of a transgene), we begin with a pilot experiment before setting up the full experiment. Our use of viral vectors (AAV) to introduce genetic mutation helps us to reduce overall animal numbers as the animals carrying genetic mutations of interest would otherwise have to be produced using complex breeding schemes and intercrosses. In some experiments where AAVs are not suitable, a large number of animals have to be bred to obtain sufficient animals of the correct genotype. For example, we may need to activate a fluorescent reporter gene (mouse 1) by crossing it with a mouse expressing Cre
recombinase in a particular cell type (mouse 2) and a mouse in which we genetically knock-out a gene (mouse 3) or we might need to generate a compound mutant mouse (knockout for two genes). Our strategy in these cases is to use littermates that lack one or more of the transgenes as controls in the experiments. Littermate controls provide an extra level of control to our experiment and also reduce the need to set up extra breedings, lowering the overall animal numbers.
Comparison between groups or experimental situations are controlled by **(i)** using inbred animals, minimising genetic variability, and **(ii)** by analysing samples from each group within one evaluation session or test method. For example, sections and immunostainings of animals collected during multiple time points will be carried out in a single instance. This will ensure reproducibility and consistency of data across different groups. Objective analysis by digital imaging is ensured by blinding for group numbers and genotypes. Also, the independent assessment through an image analyst further ensures an unbiased analysis.
Biological variability in animal cohorts is minimised by housing all animals in a controlled environment that is monitored for light cycle, sound, temperature, and humidity. Littermate controls will be used wherever possible. Researchers are blind to the genotype of the animals being injected to prevent any bias.
Finally, we encourage labs that have an interest in other tissues to obtain necropsy samples from our mice. This allows other researchers to obtain preliminary data without having to generate their own mice. In order to reduce the number of mice, we keep stocks of frozen sperm and embryos so that if a line of mice is not required for several months we avoid unnecessary breeding.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whenever possible lines are maintained as homozygotes to increase the frequency of mice being born with the required genotype. This allows efficient breeding and is a measure to minimise the number of mice we use. To reduce the effects of normal biological variation, mice will be maintained on the same genetic background (C57/Bl6). We perform pilot studies prior to embarking on a new set of experiments. Computer simulation can be particularly informative on initial planning of experiments and for planning more targeted experiments. We encourage sharing of tissues, so that spare tissue from mice can be analysed to obviate the need for killing animals for tissue collection. We have regular meetings of mouse users within our Centre to ensure that lines of animals are not being maintained unnecessarily and can be shared with other users.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and

methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is ideal for our work as they are a well-established system to mimic human physiology and diseases. In particular, mice show similar glucose homeostatic mechanisms to humans, so data obtained are valuable for translation studies in humans. They have a relatively short gestation period and life span, their biological systems are well characterised in the literature, and their popularity in other research in the field will enable our data to be directly relevant and comparable for other researchers. Lower vertebrates, such as amphibians or fish, are excellent models to study developmental processes, but are relatively limited for understanding glucose metabolism and pancreatic diseases.
Mice are readily maintained in the laboratory and easily subjected to genetic modification. Years of research have refined conditions to provide an optimally enriched laboratory mouse environment and procedures to minimise stress and discomfort. Our mice are bred to a genetically uniform background allowing us to investigate the effects of specific genetic manipulation. Whenever possible, we use genetic mouse models to specifically target the genes of interest in the cells of interest (Cre-transgenic lines), reducing unwanted systemic effects, and under temporal control (TAM- or Dox-inducible transgenes), controlling the time window when mice display a phenotype. When a new sampling procedure is involved, training on dead animals is first carried out. When a new labelling agent or AAV is being tested, an initial experiment is carried out with a small number of mice using the conditions predicted from the literature to be most effective, to ensure that the injected substance does not result in

generalised adverse effects. The data from the first experiment then informs the design of subsequent experiments, which may involve larger numbers of mice. In the case of administration of agents, the table of maximum dosing volumes and frequencies that is included in each protocol will be used. In studying glucose homeostatic mechanisms, the animals suffering during the glucose or insulin tolerance tests is minimised by using blood glucose meters that require below 1 ul of blood, which can be achieved by pin prick to the tail, like a pin prick in humans. Also, when possible we will reduce the period of fasting prior to glucose tolerance tests.

Why can't you use animals that are less sentient?

The goal of our research is to understand mechanisms regulating pancreatic organ formation but also homeostasis and disease in adult pancreatic tissue, and therefore confining our analysis to embryos is not appropriate. Mice are the least sentient mammals that are suitable for the proposed experiments. Moreover, the mouse is the genetic model system, anatomically and phylogenetically closer to humans compared to amphibians or fish, being therefore highly suited to study pancreatic functions, diabetes and to advance therapies to cure diabetes. No surgical procedure is included in our study. Mild animal suffering in this study (*e.g.* due to injection of agents or blood collection) will be minimised by aseptic procedures, but terminal anaesthesia is not suitable to the type of procedures.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Throughout the period of the licence we will seek, and implement, ways to refine the procedures. All of the procedures included in the licence were in use in my previous licences in Germany. The most likely adverse events are not due to the procedures themselves, but might occur to genetic mutations or transgene expression in the mice or development of sporadic tumours. Strong communication is important between researchers and BSU staff to avoid animals going beyond their end points and to ensure that everyone involved is aware of what additional care is needed. In particular, the weights and overall condition of the mice is monitored at least twice a week and once any deterioration is seen the mice are monitored and weighed daily. During glucose metabolism studies (GTT or ITT) the mice being treated will be monitored very closely, in particular in the early stages, to ensure that any unexpected issues are caught rapidly. Also, the BSU staff will be informed and the cages display a notice.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow regular updates on the Home Office website guidance on animal testing and research. We will read the specialist literature, such as the UFAW (Universities Federation for Animal Welfare) journal. We will attend events organised by the local AWERB. We will also check the NC3Rs website on a regular basis (https://www.nc3rs.org.uk/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Members of my laboratory and I are in contact and receive regular updates from staff members of the BSU in a variety of formats. Home Office recommendations are forwarded to us and we receive invitations to workshops and update meetings. The Home Office Inspector is always very helpful in responding to queries face-to-face or via e-mail. Our NC3Rs Regional Programme Manager, who keep us regularly informed about the latest updates from NC3Rs.

Home Office

NON-TECHNICAL SUMMARY

15.Bone marrow adipose tissue and adiponectin as regulators of caloric restriction and ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Bone marrow adipocytes, Caloric restriction, Ageing, Metabolism, Sex differences

Animal types	Life stages
Mice	adult, juvenile, aged, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify the mechanisms underlying the health benefits of caloric restriction (reduced food intake without malnutrition) and the development of ageing-related diseases, including how these phenomena differ between males and females. Our focus is on the roles of bone marrow adipocytes (BMAds), the fat-storing cells in our bone marrow; and adiponectin, a BMAd-derived hormone that may have beneficial effects on immunological function and cardiovascular and metabolic health.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Scientists first noticed the existence of BMAds over a century ago. Having fat in our bones might strike you as unusual, but it is not: BMAds make up to 70% of bone marrow volume in healthy adults, suggesting a role for them in normal human physiology. BMAds further accumulate with ageing and in conditions of altered skeletal or metabolic health. For example, BMAd numbers increase during osteoporosis, suggesting that they might promote bone fragility. Increases in BMAds also occur with ageing and in obesity, suggesting that they might influence the progression of age- and/or obesity-related diseases. Perhaps most bizarrely, BMAd formation increases during states of caloric restriction (CR), a health-promoting dietary intervention in which food intake is decreased but without causing malnutrition. This property of BMAds is in stark contrast to adipose tissue elsewhere in the body, called white adipose tissue (WAT), which is broken down during CR to supply energy. CR has numerous health benefits, including decreased risk of cancer, diabetes and cardiovascular disease. These observations suggest that, like WAT adipocytes, BMAds might directly impact metabolic health. However, unlike WAT, little is known about the biological functions of BMAds.

Previous research from my lab has begun to elucidate the functions of BMAds. In particular, CR is associated with increased circulating levels of adiponectin, a hormone implicated with beneficial cardiovascular and metabolic effects. I discovered that BMAds are a key source of adiponectin during CR. This suggests that adiponectin and BMAds might contribute to the health benefits of CR. It also raises the possibility that BMAds contribute to increases in adiponectin in other contexts. For example, ageing is also associated with BMAd accumulation and increased circulating adiponectin; however, how BMAds and adiponectin influence the pathophysiological effects of ageing remains poorly understood. Finally, my lab's research has identified striking sex differences in the effects of CR and ageing, but the basis and extent of these remain to be firmly established.

The work to be pursued under this project license is important because it will establish the role of BMAds and adiponectin in the sex-specific effects of CR and ageing. These include effects on immunological function; the formation and maintenance of bone tissue; and our metabolic and cardiovascular health. This knowledge is relevant not only to fundamental understanding of key biological processes, but also to diseases that are placing a major burden on the health of our society. Pursuing this work may therefore help to identify new approaches for the prevention and treatment of these diseases.

What outputs do you think you will see at the end of this project?

This research will generate new knowledge of the fundamental biology of bone marrow adipose tissue (BMAT) and adiponectin, including their metabolic and endocrine functions; whether they contribute to the cardio-metabolic, skeletal and/or and immunological effects of caloric restriction and ageing; and the extent and basis

of sex differences in the effects of ageing and caloric restriction. These advances may help to design improved strategies to benefit human health, including the diagnosis, prevention and treatment of diverse diseases.

This new knowledge will be communicated in scientific publications and, where relevant, in the general media. In the longer-term it may also yield products relevant to the use of BMAT or adiponectin as therapeutic targets and/or biomarkers for treatment efficacy and/or disease risk.

Who or what will benefit from these outputs, and how?

A primary benefit of this new knowledge will be for scientists with interests in metabolic regulation, endocrinology, caloric restriction, gerontology, cardiovascular biology, adipose tissue and bone development, bone remodelling, immunology, biomedical imaging, machine learning and population-level studies.

A secondary benefit is the translational potential of this work. To complement our studies in animal models, we are pursuing three related lines of clinical research. One study involves the isolation and characterisation of BMAT from human patients, including those undergoing surgery for hip replacement, knee replacement, or ankle fractures. A second group of studies involves the use PET-CT and PET-MRI imaging to non-invasively assess the metabolic functions of BMAT in humans. Finally, we are using machine learning to identify BMAT in up to 100,000 participants from the UK Biobank study, which will allow genomic approaches to dissect BMAT formation and function. We are also utilising such population-level approaches to assess the functions of adiponectin, and sex differences in health and disease. The combination of this clinical research with the mechanistic insights generated through our animal studies may, in the longer-term, facilitate the development of new drugs that target BMAT and/or adiponectin to benefit immune function, cardio-metabolic and skeletal health.

As one example, our research will reveal if BMAT contributes to glucose clearance in conditions of CR and whether this is altered in states of obesity, diabetes and ageing. If so, then BMAT might represent a therapeutic target against diabetes. Similarly, our infection studies in both wild-type mice and mice genetically modified to express no adiponectin will reveal new knowledge about this widely studied hormone, including how it influences the impact of age, sex, and obesity/diabetes on immune function. This knowledge is directly relevant to our understanding of risk factors for COVID-19 and other infectious diseases.

Improved knowledge of BMAT function could also benefit current diagnostic practices. For example, BMAT is emerging as an important clinical indicator for increased fracture risk, and therefore could be used as a biomarker to identify high-risk individuals. Our research will reveal if BMAT also exerts systemic metabolic effects, in which case BMAT might be associated with altered cardiometabolic health. Such knowledge would better inform clinicians and public health policymakers in using BMAT as a clinical biomarker.

Finally, our research may establish new methods for BMAT analysis that will benefit research and potentially allow development of new clinical approaches.

In summary, the research described in this license will reveal new fundamental knowledge of BMAT and adiponectin, including their therapeutic and pathophysiological relevance, and will develop new methods with potential to benefit basic research and clinical practice. Such knowledge might benefit diverse clinical settings and therefore has widespread translational potential.

How will you look to maximise the outputs of this work?

We will maximise our research outputs in several ways. Firstly, all of our data, protocols and study designs, including the results of unsuccessful approaches, will be made publicly available. This will include publishing in open-access journals and depositing information in open-access repositories such as protocols.io and the NCBI GEO platform. Secondly, we collaborate widely with researchers from across the diverse fields relevant to our research, including metabolism and endocrinology, cardiology, bone biology, immunology, biomedical imaging, machine learning, and genomics. These collaborations allow us to maximise the insights gained from our research and to share methods and resources, thereby enhancing research impact. Finally, to facilitate translation and innovation we have established close working relationships with our university's innovation team, who provide expertise in facilitating the commercialisation and translation of research.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use various strains of common laboratory mice, because these are well-characterised, reliable models of human health and disease.
These species also allow genetic modifications and other interventions that are extremely useful for identifying the basis for biological processes and disease progression.

We typically study sexually mature adult animals (0-12 months of age) and for some studies will study aged animals (12-24 months of age); the latter are used to investigate ageing-associated changes linked to increased risk of chronic diseases such as diabetes, heart disease, and osteoporosis.

Typically, what will be done to an animal used in your project?

Our typical interventions include caloric restriction (CR) and ageing. Substances, such as hormones or drugs, may be administered to animals by injection or using devices implanted subcutaneously.

Gonadectomy (removal of the ovaries or testes) may be done to test the basis for any sex differences in cardiometabolic, skeletal or immunological functions.

Metabolic function may be tested using imaging studies; tolerance tests and/or injectable tracers to assess glucose and fat metabolism; and other methods to determine insulin responsiveness.
Cardiovascular function may be tested by measuring blood pressure; using ultrasound to analyse heart function; and through surgeries (done under terminal anaesthesia) that mimic heart attacks. Skeletal function is tested using cell labelling to measure rates of bone formation, and by analysing the concentrations of factors in the blood that indicate bone formation and turnover. Immunological functions are tested by sampling blood for analysis of white blood cells.

What are the expected impacts and/or adverse effects for the animals during your project?

CR causes decreased body weight and minor bone loss, but not to a pathological extent. Ageing is associated with increased incidence of spontaneous tumours and can feature other comorbidities. Thus, aged animals are monitored weekly for clinical signs of illness and removed from studies before undue suffering occurs.

Very little mortality is associated with device implantation, while mortality rates from gonadectomy are low (<1%). A minority of animals (<5%) will die during surgeries that mimic heart attacks; however, they will be under general anaesthesia, preventing any pain or suffering. Tests of metabolic, cardiovascular or skeletal function generally do not cause adverse effects. In all studies, we carefully monitor animals to ensure that moderate severity levels are not exceeded. Animals are humanely euthanised at the end of each study, once we have gathered the necessary information.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately half of the mice will be used for breeding purposes and are expected to experience mild severity. The remaining mice will be used to investigate experimental objectives and are expected to experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Caloric restriction induces interconnected physiological effects on diverse tissues, including the brain (e.g. appetite), the skeleton (e.g. BMAT expansion), adipose tissue (e.g. decreased lipid storage), and muscle (e.g. increased fat oxidation). Ageing also causes numerous systemic metabolic effects, while sex differences typically relate to complex multi-organ actions of sex hormones. Studying such effects is not possible *in vitro*; hence, there is no way to replace the insights gleaned through animal studies.

In addition to studies in live animals, we extensively analyse animal tissues taken post-mortem and human tissues from clinical studies. These approaches support and complement our investigations in live animals.

Which non-animal alternatives did you consider for use in this project?

In vitro cell culture using cell lines such as 3T3-L1 preadipocytes and ST2 mesenchymal stromal cells can serve as useful models to investigate the formation and function of cells involved in fat storage (adipocytes) and bone formation (osteoblasts). Therefore, we considered if these non-animal models could be useful to address our

research aims, including how CR and/or ageing regulate fat and bone formation and the function of osteoblasts and bone marrow adipocytes.

Why were they not suitable?

Using cell culture systems, it is not possible to replicate the diverse pathophysiological effects of CR, ageing, or sex differences. Moreover, we and others have found that available cultured cell lines do not faithfully recapitulate the properties of adipocytes and osteoblasts in vivo. Therefore, these alternatives are not suitable for robustly and reliably addressing the aims of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Over this 5-year project we expect to use up to 4000 mice, 60% of which will be for breeding programmes. We will use as few mice as possible to answer our questions, aiming to maximise the amount of information obtained per animal to help realise the potential benefits of our research.

The numbers of mice required for breeding genetically altered strains have been estimated based on refined breeding strategies in which we have extensive experience. The numbers required for our experimental protocols are estimated based on both the numbers of experimental groups/variables within each study (e.g. male vs female, control vs experimental diet, young vs old, control vs experimental substance/agent, etc...), and the number of animals needed within each group. The latter has been estimated based on the results of previous studies (from our lab and/or others) that have used similar model systems to investigate the effects of variables of interest. The effect sizes from these previous studies have been used to estimate the minimum number of animals needed to draw robust and reliable conclusions from our experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The estimates above incorporate power calculations using G*Power software and, where necessary, consultation with statisticians. To further reduce the overall number of animals required we:

- Use inbred mice to reduce inter-animal variability.
- Where possible, increase statistical power by using a multi-factorial design that incorporates several different experimental variables. Such variables may include sex, diet, genetic modification, surgical intervention, control vs experimental substance/agent (etc...). Including multiple variables within a single study provides more power to detect effects of each individual variable and the interactions between them, thereby decreasing the numbers required per group. In addition, such multi-factorial designs prevent the need for separate studies that each assess the effects of a single variable, and which would each require their own dedicated control groups. By doing so, multi-factorial designs reduce the numbers of separate control groups and thereby reduce overall animal numbers.

- Maximise the use of non-invasive techniques (e.g. non-invasive imaging, tail cuff blood pressure measurement) and other methods that allow repeated measurements within a single animal. This increases statistical power and reduces the total number of animals required.

- Use other advanced techniques that allow reliable results to be obtained using fewer animals (for example, the use of dynamic PET/CT rather than static PET/CT analysis).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For breeding of experimental animal lines we use the most refined and efficient breeding strategies. We always take into account the ages at which males and females have the greatest fecundity. For genetically altered strains that require more-complex breeding strategies we have developed breeding strategies that maximise efficiency while minimising potential adverse effects.

For experimental protocols we perform pilot studies to identify the parameters that minimise adverse effects while producing the most robust, reproducible experimental readouts. This enhances the effect size of variables of interest, allowing fewer animals to be used to obtain reliable results.

We embrace open science principles and collaborate extensively within our University and beyond. Regular meetings within our research group and with other researchers ensure that maximal data is obtained from animal studies. We make datasets and methods publicly available (i.e. via public repositories) and, wherever possible, we encourage other scientists to analyse some of our postmortem animal tissues. These open, collaborative approaches provide valuable insights into other fields (e.g. cancer, haematology, evolution/ecology, reproductive health) and reduce the need for additional animals to be used by others.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mice on a particular in-bred genetic background called ‘C57BL/6’ because this has been used extensively to refine the experimental procedures of interest, including surgeries, skeletal and metabolic analyses. The prior optimisation of these procedures in C57BL/6 mice makes these mice the ideal model for pursuing our research while causing the minimum stress and suffering to the animals. In addition, the C57BL/6 background offers a range of genetic modifications (e.g. lack of the hormone adiponectin; effects on sex hormones) that are the most refined models possible for addressing our research objectives.

For caloric restriction (CR), animals are fed a micronutrient-enriched diet to avoid malnutrition. Previously, CR has required mice to be singly housed; however, we are now exploring the use of cage dividers during food administration, to allow mice to undergo CR whilst being group housed. Ageing studies are done in

animals below two years of age to ensure a low incidence of age-related comorbidity while still allowing development of experimentally and clinically relevant age-related changes.

We progressively develop and refine our methods. For example, our metabolic analyses begin with exploratory methods (e.g. insulin tolerance tests) to assess if experimental interventions have major effects on broad outcomes (e.g. “insulin sensitivity”). Only in the presence of a clear effect are more in-depth methods used, such as using infusions of labelled nutrients (e.g. glucose) and tracking their fate in a living animal. Such in-depth methods allow us to better determine the mechanisms underlying major effects. For such methods, the use of any invasive (e.g. surgical) techniques is discussed with colleagues performing similar work locally and across the country. We will tailor monitoring systems to each model and apply strict humane endpoints to minimise suffering.

Why can’t you use animals that are less sentient?

Immature life stages cannot be used for two main reasons. Firstly, a key aim of our research is to determine the basis and extent of sex differences in the effects of caloric restriction, obesity and ageing.

Such sex differences typically depend on animals first reaching sexual maturity. Secondly, our research into ageing necessarily requires the use of aged animals.

We are unable to use less sentient species because we seek to reveal new knowledge of diverse pathophysiological processes relevant to human health. These processes include metabolic and cardiac function, bone biology and immunological responses, and whether these differ between males and females. The need to assess bone biology necessarily precludes the use of invertebrates. The need to assess sex differences would greatly complicate the use of lower invertebrates, e.g. zebrafish, because their sexual characteristics (e.g. hormones, method of sex determination) are very different to those of mammals. Finally, the pathophysiological processes that we study are often influenced by interconnected whole-body effects, e.g. mediated by hormones and interactions between organs and tissues. Studies of mammalian species are therefore required if we are to gain insights that are closely relevant to human health.

We do use adult animals that are terminally anaesthetised for some procedures, including surgical models of heart attacks, and in tracer studies that allow us to analyse carbohydrate and fat metabolism in living animals. This minimises the suffering experienced by these animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Throughout our studies we strive to minimise suffering. We closely monitor animals for adverse effects (e.g. comorbidities associated with ageing, CR, surgeries, or other experimental interventions). In some experiments the combination of procedures and conditions may exacerbate adverse effects on animal welfare. For example, gonadectomised mice might display an enhanced adverse responses during CR, such as weight loss or hypoglycaemia. In such cases we increase the frequency of animal monitoring and, should adverse effects develop beyond defined limits, steps are taken to address these. These monitoring and treatment strategies minimise welfare costs for the animals.

For other procedures, associated stresses can be minimised by training the animal. For example, placing mice in restraint tubes is required for measurement of body composition or blood pressure, but these restraints can increase stress to the mice. In such cases the animals are habituated to these conditions, which minimises the stress response. For surgical procedures, appropriate anaesthesia, analgesia, postoperative care and aseptic techniques will be used. Surgeons are thoroughly trained and rigorously assessed prior to performing surgery on a live animal. Substances will be administered at non-toxic doses and through the least invasive routes, e.g. in

food/water. If injection is necessary, needles will be used only once. For some metabolic analyses we use new low-stress procedures that minimise suffering while maximising the amount of information obtained per animal, e.g. non-invasive imaging for fat mass determination, or indirect calorimetry to assess energy homeostasis. Finally, we will continue to implement refinements in animal handling, such as use of non-aversive mouse handling methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the refinement resources on the NC3Rs website to identify guidance for continued refinement of our experiments, including animal handling (https://www.nc3rs.org.uk/handling-and-restraint), use of anaesthesia (https://www.nc3rs.org.uk/anaesthesia), and implementation of humane endpoints (https://www.nc3rs.org.uk/humane-endpoints). Other publications will be consulted for guidance on more-specific procedures, e.g. experiments to assess metabolic function (https://pubmed.ncbi.nlm.nih.gov/20713647/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive the monthly NC3Rs newsletter. In addition to this, my university organises a frequent seminar series focussed on the 3Rs, with seminars typically held fortnightly or monthly. My lab members and I will frequently attend these seminars and consult with animal care staff, including Named Veterinary Surgeons and Named Animal Care and Welfare Officers, to identify strategies to implement any advances in our project.

NON-TECHNICAL SUMMARY

16. Brain Mechanisms of Cognition & Behaviour

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Brain, Behaviour, Cognition, Rat model

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We will study brain mechanisms of cognitive functions (such as memory, attention and behavioural flexibility) and other behavioural functions (including sensorimotor functions, such as locomotor activity, and motivational functions) and how aberrant brain function causes clinically relevant impairments in such cognitive and behavioural functions. We will focus on the 'hippocampus', a brain region underneath our temples, the 'prefrontal cortex', a region at the front of the brain, and 'subcortical' regions, regions that lie deep in the brain, and on the role that inhibitory control of these regions by the brain chemical GABA plays in the function of these brain

regions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Generally, there is a strong public interest in understanding brain-behaviour relations in health and in disease. Behavioural and cognitive impairments due to brain disorders are a major cause of functional disability and economic burden in the UK and worldwide, but development of efficient treatments has stalled, largely due to an insufficient mechanistic understanding of brain-behaviour relations. This project will address aspects of these public and clinical needs.

More specifically, aberrant function of the brain regions studied in this project has been implicated in important psychological problems, including in age-related loss of cognitive functions, such as memory and attention, in schizophrenia and in Tourette's (a disorder characterised by 'tics' - involuntary movements and sounds that the patient cannot control). Moreover, impairments in the inhibitory control of neuron firing in these brain regions by the brain chemical GABA has emerged as a key feature of these disorders. Therefore, it is important to understand better how inhibitory control of neuron firing by GABA contributes to how the brain produces behavioural and cognitive processes.

What outputs do you think you will see at the end of this project?

The research project will produce new information to improve our understanding of the brain mechanisms of normal cognition and behaviour, as well as of the pathophysiological mechanisms relevant to neuropsychiatric diseases, including age-related cognitive decline, schizophrenia, and Tourette's syndrome.

To disseminate our findings to other academic, clinical and industry researchers across the world who focus on brain-behaviour relations in health and disease, we will publish our findings in high-quality peer-reviewed research papers in high impact academic journals. In addition, we will disseminate our findings at national and international scientific meetings and at seminars.

Our findings will also inform our teaching of undergraduate and postgraduate students and will be communicated to the general public as appropriate (via our webpages and press releases, Brain Awareness Week events, Summer Schools for school students, Pint of Science events, articles in popular science journals, etc.).

Who or what will benefit from these outputs, and how?

Outcomes of this research will immediately improve understanding of the brain mechanisms of normal cognition and behaviour, as well as of the pathophysiological mechanisms relevant to neuropsychiatric diseases, including age-related cognitive decline, schizophrenia, and Tourette's syndrome. This addresses the strong public interest in understanding brain-behaviour relations in health and disease.

Cognitive and behavioural dysfunctions due to brain disorders are a leading cause for functional disability and a major socio-economic burden in the UK and worldwide, but development of efficient treatments has stalled. A mechanistic understanding of brain-behaviour relations and of the pathophysiology of these disorders is likely the best hope for better treatments in the long-term. Some of our in vivo research is in collaboration with drug discovery industry partners who are involved in applied research with the aim to discover new medicines that improve cognitive impairments. These industry partners and their drug discovery research programme will immediately benefit from the outcomes of our research, which will help them in their prioritisation of promising neural mechanisms that could be targeted by new pharmacological treatments.

How will you look to maximise the outputs of this work?

We aim to publish comprehensive, high-quality peer-reviewed papers, which we make available for open access.
Throughout the project, we will present preliminary findings in form of poster presentations and talks at international conferences and through other invited talks. In addition, once papers are completed for submission to peer-reviewed journals, we will place them on a pre-print server (bioRxiv). This will ensure that our findings are disseminated as swiftly as possible. It has the added benefit that the progress of our project can benefit from early feedback by peers.
We also aim to broaden the benefits of our research by including our research findings in our teaching to undegraduate and postgraduate students and by disseminating it to the general public via our webpages and press releases, Brain Awareness Week events, Summer Schools for school students, Pint of Science events, articles in popular science journals, etc.

To maximise the impact of our research on the discovery of new pharmacological treatments, we collaborate with colleagues from the neuroscience drug discovery industry.
We also closely integrate our in vivo research in rats with non-invasive studies in human participants, including patients, that uses similar behavioural and non-invasive imaging methods. This will help to maximise the translation of our findings to humans.

Species and numbers of animals expected to be used

- Rats: 1,000 rats

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use young adult rats, because their brains are similarly organised as in humans, and a wide range of behavioural tests is available to study the cognitive and behavioural functions of interests. In addition, the welfare demands of rats can be well satisfied in captivity.
The brains of rats are large enough to manipulate and analyse specific brain regions with high selectivity, and behavioural tests are well-established in this species, because it has been used for research for a long time.

Typically, what will be done to an animal used in your project?

To examine the brain mechanisms of cognitive and behavioural processes, rats will undergo behavioural testing while specific neural mechanisms are being manipulated. These manipulations can be brain site-specific or systemic. Brain site-specfic manipulations require that the rats undergo surgery under full anaesthesia, so that we can manipulate a specific brain region or implant cannulae into the brain region of interest, so we can later manipulate the brain region by infusion of small quantities of neuroactive compounds, which modulate neural activity. Systemic manipulation of neural activity will involve the systemic administration of a neuroactive compound. The behavioural testing procedures often rely on the rats' spontaneous behaviour. For example, we use the rats' spontaneous exploration of an environment or object to measure their lococomotor activity or their 'interest' in an object. The latter allows us to measure the rats' memory of this object, as rats are more

'interested' in novel objects (i.e., the more they explore the object during a test, the less they remember it from a previous training session). In other procedures, we require rats to attend to and remember certain stimuli and procedures in order to receive food reward or to find a hidden platform that offers escape from a pool of water (note that rats are very good swimmers!).
Complementing our behavioural studies of the effects of specific manipulations of brain function, we also use direct electrophysiological recordings of neural activity, by insertion of electrodes into specific brain regions, or the non-invasive measurement of brain function by magnetic resonance imaging methods (similar to those that are used in clinical studies to measure brain function in human participants). These procedures will be performed under anaesthesia and tell us how a brain manipulation specifically affects the activity of neurons and the pattern of such activity within different brain regions.
At the end of the studies, all rats will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

The welfare demands of rats can be well satisfied in captivity. The welfare of our animals is important for the success of our studies, which would be confounded by undue discomfort and stress of the animals.
Our experiments require surgical procedures to manipulate selected brain sites and monitor their function. These procedures are performed under full anaesthesia, complemented by appropriate analgesia, and typically do not cause lasting discomfort. In fact, following a few days of recovery, rats are ready to take part in our behavioural tests that require attention and inquisitiveness.
Some of the behavioural procedures we use to assess cognitive functions require mild to moderate aversive motivation, by requiring escape from water by swimming to an easily accessible platform. Others rely on the motivation to ‘work’ for food and require that the animals are maintained with restricted access to food. The discomfort caused by these procedures is mild to moderate, and probably less severe than that experienced by wild rodents due to predators and other natural stressors. By examining how manipulations of neural activity in specific brain sites change the animals’ performance measures on our behavioural tests, we can find out how these brain sites contribute to the behaviours under study.
The impact of the manipulations of brain activity would typically result in specific impairments in selected cognitive and behavioural processes. These impairments would often not be visible to the naked eye, but their detection and measurement would require dedicated and sensitive behavioural assays. As the manipulations of brain activity are temporary, the behavioural and cognitive impairments are temporary, too.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that virtually all rats used in this project will expect temporary moderate severity, due to the surgical procedures, the manipulations of brain function, the behavioural testing procedures or a combination thereof.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The detailed mechanistic understanding of causal brain-behaviour relations requires the combination of behavioural testing with invasive methods to manipulate and analyse function of brain sites with high specificity. For ethical reasons, this is impossible in human participants, and animal experiments are necessary.
Therefore, no alternatives can fully replace the in vivo animal experiments to achieve our aim and objectives.

Which non-animal alternatives did you consider for use in this project?

Although no alternatives are available to fully replace our animal experiments, our experiments in rats are informed by and closely integrated with complementary non-animal approaches. Non-invasive brain imaging studies in humans reveal important brain-behaviour correlations, although they cannot reveal the causal roles of specific brain processes in a behavioural phenomenon. We collaborate closely with colleagues studying related topics in human participants, using non-invasive brain imaging. For example, based on our behavioural tests in rats, we have developed similar behavioural tests for human participants. Combining these with non-invasive imaging in human participants, we can reveal neural correlates of the cognitive and behavioural processes of interest, complementing our invasive studies in rats. Even though these studies cannot replace the proposed animal experiments, a close integration of studies in humans and in animal models will help to maximize the benefit of animal experiments. Moreover, our clinically motivated animal experiments are strongly informed and, in some instances, are directly based on clinical non-invasive imaging studies in humans. For example, our rat studies involving non-invasive brain imaging methods in rats are aimed at revealing the causes for changes in brain imaging measures that have been observed in patients of neuropsychiatric disorders, including schizophrenia, age-related cognitive decline and Tourette's Syndrome.
In vitro studies in brain slices can reveal important basic neurophysiological processes, but in vitro results are difficult to link directly to behavioural studies. Moreover, neuronal interactions within extended structures, such as the hippocampus, and between brain structures are difficult, if not impossible, to study using brain slices in vitro, as the brain "slicing" destroys the relevant neuronal connections.
Using in silico computational methods to model the neurochemical and neural circuit mechanisms of cognition is possible to some extent, but these models depend on the type of data generated by experiments as proposed in this project. We have begun collaborative work with neurocomputational scientists to integrate our data into neurocomputational models. Even though such models cannot replace the proposed animal experiments, such models help to maximize the conceptual benefit of our experiments and they will enable us to devise more accurate and specific hypothesis.

Why were they not suitable?

Please see section above for why potential non-animal alternatives are not suitable to fully replace our animal experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animal numbers required for individual experiments have been estimated to be as small as possible, while still enabling us to reveal reliably the effects of interest.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We plan each experiment carefully (using the NC3R's Experimental Design Assistant, if appropriate) and use state-of-the-art methods to minimise variability and to obtain robust, sensitive and reliable measures with the minimal number of animals. Experimental procedures will be standardised as far as possible to avoid unnecessary variance.
Where possible, within-subjects designs will be used, so that each animal serves as its own control in order to reduce variance and the number of animals. However, some experiments require between subjects factors, e.g. when the measure under study changes due to repeated testing. To increase the probability of revealing real effects of our manipulations, rather than spurious effects caused by confounding variables, the influence of confounding extraneous factors will be minimised by random allocation, counterbalancing and/or matching, and blinding as appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As indicated under Replacement, our animal experiments are closely integrated with non-invasive brain imaging studies in human participants and with neurocomputational modelling work.
Our in vivo experiments are complemented by ex vivo measurements, e.g. of how the manipulations we use affect certain neural markers.
If we run larger studies, which are completed using several batches of rats, we will stop the study for 'futility' if the results obtained with the first batches of rats indicate that we will not be able to detect the predicted effect (this will be done using statistically sound criteria).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Our experiments are conducted in rats, because their brains are similarly organised as in humans and a wide range of behavioural tests is available to study the cognitive functions of interests. In addition, the welfare demands of rats can be well satisfied in captivity.
The brains of rats are large enough to manipulate and analyse specific brain regions with high selectivity and behavioural tests are well-established in this species, because it has been used for research for a long time.
Our main experimental tool to manipulate brain function is the temporary pharmacological manipulation of specific brain sites in awake rats by local microinfusion of neuroactive drugs via pre-implanted cannulae. A main focus is on manipulating regional inhibitory signalling between neurons by infusing drugs that block the actions of the main inhibitory neurotransmitter GABA. The regional infusion of such drugs mimics aspects of regional GABA dysfunction associated with neuropsychiatric disorders, including schizophrenia, age-related cognitive decline and Tourette's. We have long-standing experience with the intra-cerebral micro infusion method and perform this to the highest standards, using fine-gauge cannulae and small infusion volumes to minimise non-specific neuronal damage and mechanical effect of the infusions and to limit the regional spread of the drug. This approach enables us to study specifically the role of GABA-mediated inhibition within specific brain sites. Furthermore, the reversibility of pharmacological manipulation enables us to study brain substrates of behavioural processes with fine temporal resolution (e.g., we can test if a brain region contributes to learning or retrieval of information by selectively switching it off during one of the two stages); reversibility (due to ‘wearing off’ of the drug effect within typically a few hours) also enables within-subjects studies (helping to reduce the required number of animals), which are not possible with permanent lesions. To complement drug microinfusion

studies and examine directly the functions of inhibitory neurons that release GABA, we will use new pharmacogenetic DREADD (Designer Receptors Exclusively Activated by Designer Drugs) technology. In addition to the advantages of drug micro infusion approaches indicated above, pharmacogenetic DREADD technology offers us the opportunity to directly manipulate a specific type of neurons in a specific brain region. Using this approach in transgenic rat lines expressing Cre-recombinase in GABAergic marker genes, this approach enables us to study directly the functions of GABA-releasing inhibitory interneurons in specific brain regions. This is important, because regional malfunction of these neurons has been implicated in many neuropsychiatric disorders, including schizophrenia and Tourette's.
Animal welfare is vital for the success of our studies: behavioural tests require the animals' inquisitiveness and free exploration; insertion of infusion cannulae into pre-implanted guides (as necessary for our studies involving pharmacological manipulation of specific brain sites in behaving rats) requires tame and comfortable animals; undue stress would interfere with most of our measures. Surgical procedures are conducted under aseptic conditions and under appropriate general anaesthesia, complemented by appropriate peri-operative analgesia and care. Appropriate recovery from surgery will be allowed before any behavioural testing. We minimise undue stress of the experimental animals by carefully habituating them to the required handling before any procedure. If we require purely physiological measures, without behavioural measures, experiments will be conducted under anaesthesia, thereby minimising suffering. Within our animal facilities, high welfare standards are maintained, and, if appropriate, we seek advice from qualified staff or the vet to minimise any suffering.

Why can't you use animals that are less sentient?

The study of the clinically relevant brain mechanisms and behavioural and cognitive functions of interest require a mammalian species and mature animals.
If we take purely physiological measures of neural activity, without the requirement of behavioural measures or of repeated measures, we perform the experiments under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All rats used in this project are monitored regularly and carefully, especially following surgical procedures or experimental manipulations that have an increased potential for adverse effects. If the rats show any signs of adverse effects, we will seek the advice of the named persons or vet and remedial action will be taken promptly. Our protocols have clear and well-defined humane endpoints to reduce animal suffering.

Before the start of any procedure, all rats are habituated to the facilities and to the experimenter, by regular handling, so as to minimise any stress and discomfort of rats in relation to handling required for the completion of our procedures.
To minimise pain in relation to surgical procedures, general anaesthesia is complemented by local anaesthesia and appropriate analgesic regimes, based on consultation with the vet.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidelines published by NC3R, including the ARRIVE guidelines
(https://www.nc3rs.org.uk/arrive-guidelines
), as well as guidance published by the Laboratory Animal Science Association (LASA)
(https://www.lasa.co.uk/current_publications/).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular NC3Rs e mails, which keep us updated about advances related to the 3Rs.
We also receive regular updates and latest animal welfare guidance through our Named Competency and Training Officer (NCTO).

NON-TECHNICAL SUMMARY

17.BRCA1-associated pathways in cancer development

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, therapy, cancer development, Hereditary, PARP inhibition

Animal types	Life stages
Mice	adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate distinct BRCA1 pathways and functions in tumour development and identify new treatment strategies for familial breast and ovarian cancer and for other cancers in which the BRCA-pathway is disrupted.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inheritance of a change in known cancer-preventing gene, BRCA1, PALB2 or BRCA2, can cause breast or ovarian cancer. There have been more than 2500 changes of 'unknown clinical significance' found in patients with family history of cancers in the BRCA1 gene alone. These changes may, or may not, give an increased risk of cancer. A recent test-tube experiment that made many thousands of changes to the BRCA1 gene and predicted that ~4000 changes may cause cancer (Nature 2018). At the moment genetic counsellors are unable to tell patients with a change of unknown clinical significance of their likely risk of disease, and thus cannot advise appropriate management. The reason we cannot tell people of the danger these genetic changes pose is that the precise function of BRCA1 and its associated genes in stopping cancer development is poorly understood.

Most breast cancer patients are treated successfully. In ~20% of patients, their cancer comes back. Breast and ovarian cancers arising as a result of inheritance of defective genes are often sensitive to treatments that targeting the DNA repair deficiency that occurs when the BRCA gene is changed. In particular, these treatments include agents called PARP inhibitors. Cancers that occur without inherited changes in these genes may also nevertheless have defects in the BRCA-DNA repair pathway and so are also candidates for this treatment. These cancers include lymphoma, prostate, endometrial, brain and gastric cancers.

Sadly we know from the investigations of ovarian cancers treated with PARP inhibitors that all eventually continue to grow despite the presence of the drug, so there is a need to identify new treatments. We need to better understand the molecular function of the genes involved in ongoing cancer growth to identify new vulnerabilities that could be targeted to help patients.

We aim to breed animals with different changes in the mouse BRCA1 gene. These changes are designed at specific locations to disrupt particular functions, but not others. By examining the animals we will be able to find out whether these particular functions prevent tumour development. We aim to cross these with other animals with changes in genes that we know alter the way BRCA1 works. For example, one of these is very important only when certain functions of BRCA1 is missing, remarkably its removal allows embryo survival and suppresses cancer development, while in cancers its reduction is associated with therapy resistance.

What outputs do you think you will see at the end of this project?

The principal outputs from this project will be in the form of new information that will be disseminated to the pharmaceutical and academic community via high impact publication and presentations at conferences.

We expect to characterise new models of BRCA1 disruption that may inform mechanisms of cancer development. We believe that this will help to better understand the tumour development process and functions of the BRCA1 gene within it. Given our active collaborations, our results could lead to new treatment strategies and phase I clinical trials for cancer treatments.

Who or what will benefit from these outputs, and how?

The work will add to the knowledge of which BRCA1-mediated pathways are, and are not, relevant to tumour development -accelerating the classification of genetic variants that are currently of unknown clinical risk.

It will accelerate the analysis of which agents are, and are not, effective in treating BRCA1-mediated cancers (output). In the short term, the outputs will accelerate scientific progress towards a greater understanding of BRCA-mediated cancers (output expected during or slightly after the project).
Both the agents used to test effectiveness, and the agents based on targets to be inhibited are available to us and so our evidence may thus accelerate trials and/or identify the patient group that the agents may be effective in (output of the current project expected to be released some 5-20 years after the project depending on the agents used, and whether they are new or already developed.
In the longer term, it is hoped that the work will impact the patients themselves if agents/targets we investigative prove to improve tumour regression (longer-term).

How will you look to maximise the outputs of this work?

To maximise the outputs we are collaborating with different groups internal and external to the establishment that will lend their expertise and knowledge to our work. We will publish our work in peer-reviewed journals and present at conferences to disseminate new knowledge including reporting of unsuccessful approaches. We will also share best practice of new techniques and protocols we have developed and validated with collaborators.

Species and numbers of animals expected to be used

- Mice: 15000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice to enable a genetic approach to understand how cancer develops and thus identify novel targets for therapeutic intervention. Mice are the species of choice because there are a large number of widely available genetically modified strains that means that the function of most genes of interest can be studied. Moreover, they are able to grow tumours as engraftments enabling drug testing and in vitro genetic manipulation before implantation. This enables us to mechanistically interrogate tumour growth, and hence identify new ways in which to drug target. We are predominantly using mouse strains that are bearing mutations either found in breast cancer patients or designed to interrogate a particular molecular pathway.
A second reason we have chosen to use mice is that the majority of cancer models we will be using have been extensively characterised previously and develop tumours with a similar aetiology and molecular profile as that observed in human disease. Tumour growth rate is predictable, thus fewer mice are required to be used for each experiment. Some of our studies will involve the generation of novel genetically modified animals, however during this process, all animals will be closely monitored for signs of distress and handled in the appropriate manner.
Also, we need to isolate and immortalise primary cells for further studies. In this case, embryos are isolated from E13.5 enabling the generation and culturing of mouse embryonic fibroblasts. This provides us with a source of genetically altered cells in which we can conduct in vitro experiments in order to better understand molecular mechanisms.

Typically, what will be done to an animal used in your project?

Most of our animals will be set up in breeding pairs enabling the generation of mice with specific mutations. Generation of those strains enables us to investigate tumour development and progression during ageing of animals. Mice used for breeding will undergo a maximum 6 breeding cycles.
Some of the dams will be culled at day 13.5 of pregnancy in order to isolate primary mouse embryonic

fibroblasts.
Some of the dams will have nipple injection of viral particles to induce development of tumour growth in mammary glands.
Animals will have injected or implanted tumour cells or pieces. The tumours could take up to 12 weeks to form. We will closely monitor this process by: 1) caliper measurements, 2) feeling the abdominal area or 3) in some cases live imaging where cells are tagged with fluorescent protein and imaged using IVIS, which involve IP injection of luciferin and general anaesthesia. In some cases we will need to implant tumour material in immune compromised animals to allow tumour growth.
To determine the role of the DNA damage response in our cancer cells, mice will undergo whole body irradiation and culled within 24 hrs.
To be able to switch on inducible genetic elements in cells that have been engrafted into mice, we may feed animals doxycycline food.
An important part of this project is the test of small molecule inhibitors to target proteins, either alone or in combination with known therapies. The route of administration may vary depending on the agent used. Animals may undergo multiple rounds of IP, IV or SC injections, or by oral gavage. To monitor any adverse effects in mice we will test blood samples for anaemia and leukopenia. In some cases, mice will undergo “drug holidays” and aged to observe if tumours are growing back.
For many of our experiments, 1-3 hrs before culling, mice will be IP injected with BrdU enabling proliferation rates of tumour to be determined in vitro.
Mice will be humanely killed at the end of experiments. Afterwards, we will analyse their tumours and organs in order better understand tumour development and how the drugs used worked.

What are the expected impacts and/or adverse effects for the animals during your project?

Many of the mice we are using have mutations which genetically predisposes them to generate tumours. Some of the animals will be engrafted with mouse cells that will form tumours. The main expected adverse effects will be related to this. Potentially, this could include weight loss (maximum of 20%), a reduction in BC score of <2, reduced activity, failure to respond to gentle stimulation, lethargic, abdominal distension, jaundice, piloerection, intermittent hunched posture, diarrhoea, or intermittent laboured respiration. Most of those symptoms usually appear at the late stage of tumour development.
When mice present with these symptoms the animal will be humanely killed immediately, so they will not experience them for long.
It is possible that delivery of chemotherapeutic drugs will cause adverse effects. As the drugs we will use are well reported in the literature, we will be able to pay close attention to the development of any signs of distress. For example, anaemia and leukopenia are common side effects of chemotherapy, and we will be able to monitor the extent of this by tail vein blood analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of our animals used for breeding carry a mutation which predisposes them to develop tumours. These animals will only be used for a limited period at a young age to minimise the possibility of tumour growth and will be killed immediately a tumour is apparent. 100% of animals may experience mild severity due to sampling for genotyping.
When ageing the animals with different mutations some (80%) may develop tumours. Animals that do not develop tumours will be classified as mild (as they have undergone at least one procedure), animals that do develop tumours will be classified as moderate.
In our implanted tumour experiments, control mice are expected to generate tumours as we need to compare

them to mice receiving shRNA or genetic material we hope will restrict tumour growth. Although all mice will undergo injection with the aim of developing tumours, genetic manipulation may slow growth rates and hence reduce severity experienced. We predict that 80% of mice will experience moderate severity.
Similarly, we are expecting that some small molecule inhibitors or their combinations will slow down or prevent tumour growth, unfortunately, it is unlikely that this will happen in all animals, plus a control group are needed with receive sham or vehicle, rather than the active compound. All animals that will be implanted with tumour pieces will be classified as moderate as this is a surgical procedure. Animals injected with cells will be classified as mild. Taken together 90% of animals will experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The majority of our work has used non-animal alternatives. Using mouse and human cell lines we have defined separation of function mutations that delineate specific molecular roles of BRCA1, and its binding partner BARD1. Similarly our findings of novel support pathways for BRCA1 mutants has arisen from non-animal methods.
In a partial replacement we will use cells derived from embryos, reducing the need for molecular and pathway analysis in the animals.
However, these means do not give an understanding of whether the genetic alterations (and subsequently altered molecular pathways) lead to growth of tumours or whether possible treatment approaches are likely to have in vivo treatment efficacy.
Very few, if any, in vitro cell culture based models are able to recapitulate the complex interplay between cancer cells and the tumour microenvironment. Indeed, studies using murine models of cancer that enable the modelling of disease within a complex multicellular living organism have been fundamental in enabling a better understanding of the processes that lead to malignancy that could not have been achieved otherwise. As a direct consequence of this, new drug targets and insights into the molecular mechanism of disease have come to light.
We need to use cancer tissue and cells in a live organism to evaluate the effectiveness of targeting a specific molecular targets on cancer development of real patient tumours.
Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

Which non-animal alternatives did you consider for use in this project?

The majority of our work has used mouse and human cell lines where we have defined the separation of function mutations and identified of novel support pathways for BRCA1 mutants, while in a partial replacement we will use cells derived from embryos, rather than animals themselves.
In vitro data obtained from cell culture approaches will always guide in vivo studies, and we always conduct cell culture based experiments to justify the need to use animals. These systems include culturing cells in a

monolayer as a homogeneous population on plastic, and the more sophisticated 3D culturing of either cells lines grown in matrigel (as acinar) or mouse/human derived tissue as organoids. However, these models are not suitable to investigate the tumour development and how treatments affect it as mentioned in the above and below section.

Why were they not suitable?

There are significant limitations of basic culture conditions using cells grown in isolation as a monolayer on a piece of plastic as this is not an accurate representation of what occurs within a patient. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment. Technologies are being developed to address this gap, including the development of 3D cultures (acinar cell line cultures and organoid mouse/human derived tissue). However, none of these model systems are yet able to phenocopy the integration and interplay between the numerous cell types that constitute the tumour and its microenvironment, or the fact that tumourigenesis occurs in and is influenced by biological systems (such as the immune system).
Moreover, genetic manipulation of organoid cultures is still technically challenging. Modelling cancer in mice is thus still required to fully understand disease progression and identify novel therapeutic avenues.
The development of 3-D tissue culture of tumour cells bearing the specific genetic changes we require risks losing the precious patient material, as many of the tumour and non-tumour microenvironment cells do not survive. Nevertheless, this is an avenue we are eager to continue to investigate. The advantage of in vivo propagation is it may allow us to increase the tumour material to test alternative means of 3D culture and organoid development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For breeding, we have estimates of animal numbers based on our previous experience and number of strains which we will breed during the term of this license.
We have based the numbers of animals we will use for each experiment through consultation of the literature, in which experiments done in the past have assessed spontaneous tumour development and examined genetic changes that give a similar effect to those we are examining. These allow us to work out how many animals per group are likely to be needed to detect a difference, for example in tumour growth. Our estimates also take into account how many different strains and strain combinations we intend to examine.
For treatment approaches our numbers are based on how many animals we will need to detect an effect, for example of a drug, of a 25% reduction in tumour growth. These numbers similarly take into account how many methods we intend to study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will use the EDA in conjunction with a local statistician to assist with experimental design to reduce animal numbers, methods to reduce subjective bias, and appropriate statistical analysis without compromising the scientific objectives. When possible, experiments will involve a factorial design that will maximise the information

obtained from a minimal number of animals. For example, non-invasive imaging and quantification techniques of transplantations will enable multiple measurements on the same animal over a period of time. In such cases, ANOVA will be utilised for statistical analysis.
When conducting engraftment experiments, we routinely inject two contralateral flanks of the mouse, thereby reducing the number of animals being used by a half.
Our approach of modelling breast cancer by induction with oncogene injections will substantially reduce the number of animals used in experiments as most of those animals will develop tumours and the need for lengthy breeding is reduced.
Where possible, we will use live imaging to track tumour development longitudinally. Not only does this mean fewer animals are needed overall as there is no need to cull at each time point, but it also reduces variation and so improves the quality of the data produced.
Two flank sites or two intraductal injections will be used only when control and experimental material can be introduced into a single mouse. This approach reduces the number of mice used.
Strains not immediately required for the scientific study will be cryopreserved as embryos.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to estimate variability and perform power calculations to calculate sample sizes.
Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.
We always strive to generate the most effective breeding strategies to ensure that we obtain mice of the desired genotype with minimal animal wastage. If we are unable to estimate an effect size from our in vitro data, the literature, or our collaborators, we will conduct small pilot experiments.

All tissue surplus to requirement will be deposited into SEARCHBreast (https://searchbreast.org), a resource to facilitate sharing of archived material derived from in vivo breast cancer models.
In vivo imaging of engrafts will be conducted to enable us to monitor tumour progression in living animals throughout the experiment and will therefore reduce animal numbers by performing longitudinal measurements in fewer animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the species of choice for a genetic approach to the analysis of biological phenomena. In particular, the wide availability of genetically modified mouse strains and mouse ES cells means that the function of most genes of interest can be studied in the tissue of choice.
We have mouse models which carry mutations found previously in patients with breast cancer that will develop tumours with similar aetiology and molecular profile as that observed in human disease. Hence, we will be aware of potential adverse effects and monitor for them appropriately. In line with this, we will use tailored welfare sheets that have been developed based on our experience with other strains. The phenotype of any novel genetically modified strain that we generate will be closely monitored for signs of distress and handled in the appropriate manner and a tailored welfare sheet developed.

We plan significant refinement by using intraductal delivery of viral particles containing oncogene. This procedure has recently been used in many laboratories and requires fewer animals than traditional our models. By using this procedure we are considering Reduction and Refinement aspects, thereby enhancing the welfare experience of mice used during our experiments.
To decrease tumour events in our breeding colonies we will keep young animals for further breeding.
In vivo imaging of engrafts will be conducted through the use of non-invasive techniques that will enable us to monitor tumour progression in living animals throughout the experiment and will therefore reduce animal numbers and achieve better humane endpoints. Here, the tumour volume as determined by non-invasive caliper measurements or bioluminescence imaging will be plotted against time. This design offers the advantage of determining significant differences between tumourigenic growth potential of cell lines before the limited tumour volume is reached. We will use immune compromised mice in order to achieve engraftment. These models are characterised in pilot studies to identify any unexpected adverse effects.
For testing a new treatment strategies, we will perform pilot studies to determine dose range and develop score sheets and robust human endpoints.

Why can't you use animals that are less sentient?

We need to study tumour development in adult mice as this is what most closely resembles what occurs in humans. We have chosen to use mice over other less sentient species such as Danio Rerio (zebra fish) and drosophila melanogaster (the fruit fly) as mice and humans share 97.5% of their coding DNA sequences. In comparison, the drosophila genome is only 60% homologous to that of humans and only
75% of the genes responsible for human diseases have homologs in flies. Mice are also more appropriate for studying complex biological systems found in humans as they possess immune, endocrine and nervous system. Consequently, like humans, mice naturally develop diseases, including cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Through advice of colleagues performing similar work we are aware of refined treatment doses and route of administration for four of our most commonly used anti-cancer drugs so that we know the maximum tolerated dose, the minimum effective dose, and sub-optimal doses. This minimises the possibility of adverse effects from chemotherapy.
Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.
When conducting a surgical procedure, we ensure that analgesia is administered 30 min before the start of the procedure. Mice are allowed to recover from the surgery by being housed in a warm cage and observed by a member of the team until the animal has fully recovered and is mobile. Mice are checked again for wellbeing and wound closure 4hrs later. We have found that by placing the wound towards the bottom third of the spine with a combination of suturing and glue, mice are less likely to bite and cause reopening.
Once mice start to develop tumours, they are monitored at least twice a week, and more so if tumour growth develops rapidly. Tumours that developed in the mammary gland are carefully monitored for signs of ulceration, and hard housing replaced by cardboard housing and additional bedding if this occurs.
We are fortunate to have excellent colleagues both within our local research community and our animal facility, who have extensive, relevant animal procedure experience from whom we can learn refined techniques from. Our team will undergo extensive training on dead animals and require to be authorised as competent by the NTCO before being allowed to perform a procedure on live mice.
Examples of refinement;
Repeated injections (therapeutics) will be done on opposite sides or at different areas from previous injection so as to not aggravate any visible bruising.

In order to reduce the possibility of ulceration where external tumours are present, hard cage environmental enrichment (e.g. plastic houses) will be replaced with additional nesting material and cardboard houses. If animals are showing early signs of ill health then long spouts will be supplied on drinking bottles. Animals comfort and ability to move and reach food/water will be monitored daily.
Intraductal injections into the 4th mammary gland avoid the 1st gland as tumour growth may impede movement.
Use of fractionated irradiation scheme and antibiotics in the drinking water will significantly reduced adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines for the welfare and use of animals in cancer research. Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.
RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

Jones HRP, Oates J, Trussel l BA (1999) An applied approach to assessment of severity. In: Humane End points in Animal Experiments for Biomedical Research (Hendriksen CFM, Morton DB, eds). London: Royal Society of Medicine Press, pp 40±7.
We aim to publish in journals that support the ARRIVE guidelines and conduct our experiments with advice from the PREPARE publication (PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).
Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.
We will use SyRF the free online platform for researchers to perform a systematic review and metaanalysis of animal studies. https://www.nc3rs.org.uk/camarades-nc3rs-systematic-review-facility-syrf.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research. ARRIVE has now been endorsed by more than 400 journals including the Nature group, PLoS, and Cell, as well as funders, universities, and learned societies.
I also monitor the NC3Rs twitter account, so will be made aware of any notification via social media.
Any new advancements will be made clear to members of my team through our weekly lab meetings.
Literature searches, attendance at vendor’s information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.

NON-TECHNICAL SUMMARY

18. Cancer Vaccine Development Using Immunotherapy by Natural Anti-Carbohydrate Antibodies

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to provide in vivo proof-of-concept of the tumour vaccine approach by demonstrating efficacy in mice where circulating antibodies have been raised.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Around 1 in 2 people in England develop cancer in their life-time, with cancer now causing around 1 in 4 deaths. This picture is similar throughout the 'developed' world. There is thus a clear need to develop new therapeutic strategies for cancer, to continue the progress seen in the past 20 or so years due to the movement towards targeted therapies, with improved survival rates seen for most common solid cancers.

There is a growing interest in immunotherapy as a treatment for cancer, and there are several strategies which have been adopted for this which have successfully progressed to the clinic, e.g. Rituximab for NHL and Atezolizumab for bladder cancer. Despite the progress, however, clinical studies have raised two fundamental challenges. 1) The majority of patients still do not respond to the molecular blockade at the heart of the therapy. 2) The mechanism of action of the therapy has consequently been found to lead to a set of undesired immune- and autoimmune-related adverse events, which observation indicates a broad-range of side-effects mainly occurring at barrier tissues (e.g. the skin, gut and lung). Therefore improved clinical practices are urgently needed to overcome the limitations of tumour heterogeneity and inaccuracy for immunotherapy.

A company we are collaborating with focuses on an alternative novel approach to overcome these limitations and supplement immunotherapy using a highly effective carbohydrate-to-protein ligation probe based on two criteria:

1) It selectively, yet homogenously, labels a person's own tumour cells with immunogenic carbohydrate moieties, thus providing a tumour and person-specific treatment opportunity.

2) It exploits the presence of circulating natural antibodies. These antibodies often recognize carbohydrate determinants, such as blood group antigens, so deploying them in an ex vivo ligation approach offers a safe and effective opportunity for intervention. The resulting immune recognition of autologous TAAs allows for the development of long-lasting personalized vaccines that may limit remission.

What has not yet been done is in vivo proof-of-concept studies, and these form the basis of this licence.

What outputs do you think you will see at the end of this project?

The therapeutic strategy which forms the basis of this licence has the potential to overcome the current challenges with 'conventional' immunotherapy, and the in vivo proof-of-concept studies carried out under this licence will validate the potential of this approach, and allow further progress towards the clinic through late-stage preclinical and clinical trials.

Who or what will benefit from these outputs, and how?

Ultimately the hope is that the therapeutic approach being investigated here will translate to the clinic and benefit cancer patients. This will not be until beyond the timeframe of this project, with perhaps another 5-10 years of preclinical and clinical development required to realise this aim.

How will you look to maximise the outputs of this work?

As the work is being carried out on behalf of a biotech company, then dissemination of any positive or negative information will be their decision.
Where we have any information that we can use that is non-confidential, then we will use this on our website and associated material in order to promote the work as a potential service going forward.

Species and numbers of animals expected to be used

- Mice: 1600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the most frequently used mammalian species for cancer immunotherapy studies. This is beneficial when carrying out such studies due to the depth of knowledge available plus standard protocols, methods and reagents which have all been optimised for use in this species. In addition it is important to use a mammalian model, since this closer models for the components of the mammalian immune system seen in the clinical situation, which would not be the case if a different Class is used.
Adult animals are used since these will have a fully developed immune system.
Typically, what will be done to an animal used in your project?

Each protocol covers different facets of the project, with some of the experimental steps similar across the project.

In protocol 1, once a suitable candidate immunogenic carbohydrate has been identified through extensive preliminary in vitro work, then the initial work in vivo will be to demonstrate that it is possible to introduce this antigen (which is normally not present in mice) to immunocompetent mice and generate antibodies to it. This will involve injection of the antigen to generate antibodies, and blood sampling to check for antibody titre. Typical duration will be ~2-3 months.
In protocol 2, tumour cells will be inoculated s.c., and the primary tumour grown to a volume of approximately 300mm3 as measured by callipers. The animals will be killed and the tumour will then be excised and vaccine prepared by isolating the tumour cells ex vivo and labelling with the modified antigen. Typical duration will be ~2 months.
In protocol 3, following confirmation of generation of circulating antibodies, primary tumour development will be monitored after s.c. inoculation of tumour cells. After measurable xenograft growth is evident, a tumour vaccine either comprising inactivated and homogenised in vitro cultured or in vivo-derived (P02) tumour cells labelled with the modified antigen will i.v. be administered. Calliper measurements will be utilised to assess tumour volume. To further confirm efficacy is down to the immunotherapy, systemic effector T cell responses will also be

assessed, by isolating T cells from harvested spleens, and evaluating expression of markers such as cytokines. Typical duration will be ~3-4 months.
In protocol 4, further complexity is added compared to P03, by monitoring efficacy in a model of tumour dissemination. The in vitro or in vivo derived vaccine will be administered to mice, followed by i.v. inoculation of tumour cells, and monitoring of the effects of the presence of vaccine on generation of lung tumour deposits. The number of lung deposits will be assessed by both counting of surface deposits in fixed excised intact lungs, and by histological evaluation, and where a fluorescence or luciferase tag has been engineered into the cells then tumour burden can also be monitored noninvasively. To further confirm efficacy is down to the immunotherapy, systemic effector T cell responses will also be assessed. Typical duration will be ~3-4 months.
In protocol 5, the potential of this therapeutic strategy to enhance the efficacy of ICI therapies will be investigated. Here following confirmation of generation of circulating antibodies, and administration of vaccine, after i.v. or s.c. tumour inoculation, then an appropriate ICI therapy will be administered, e.g. anti-CTLA-4 immunotherapy. As above, generation of lung tumour deposits for i.v. inoculation, or s.c. inoculation of the tumour cells and monitoring the effects on primary tumour growth will be carried out, and to further confirm efficacy is down to the immunotherapy, systemic effector T cell responses will also be assessed. Typical duration will be ~3-5 months.

What are the expected impacts and/or adverse effects for the animals during your project?

For protocols 1, 3, 4 and 5, Freund's Complete Adjuvant can be an inducer of an intense local inflammatory response at the site of injection. We envisage an incidence of <1% for this occurring. We might expect this effect to last for no more than a few weeks.

For protocols 2, 3 and 5, potential harms would be the tumour becoming sore, inflamed, infected or ulcerated, or approaching a maximum combined volume per animal of 1200mm3. Any showing signs which would suggest they are likely to exceed moderate severity are to be killed by a Schedule 1 method. It would be expected that <1% of animals would experience these symptoms for no more than 72 hours.
For protocols 3, 4 and 5, one might see inflammation at the sight of injection of luciferin. There may also be a systemic reaction to administration of the anaesthetic. It is predicted that both these events will occur with a <0.1% frequency. We might expect the inflammation to last for no more than 72 hours, with the anaesthesia effect a matter of hours.
For protocols 4 and 5, tumour burden in the lungs may have an impact on lung function as evidenced by abnormal breathing and panting. From previous experience, <1% of inoculated mice experience these symptoms and would be sacrificed if this persisted for 48 hours.
In addition to the specific harms detailed above, in general, animals are checked twice daily by competent animal care staff who will notify the PIL holder and/or NACWO of any indication of pain, suffering or distress including but not limited to abnormalities in behaviour and/or appearance, such as poor coat condition, piloerection, unusual posture (hunching), discharge or lack of grooming to eyes, ears, nose, ano-genital region, facial grimace, obvious signs of injury, abnormal movement, reduced activity, reluctance to socialise, reduced alertness, vocalisation, indications of reduced eating or drinking. An informed assessment of the level of severity will be made based on the above observations, the known phenotype, and the procedures undertaken and appropriate treatments/ actions such as antibiotics, analgesics, or euthanasia will be considered (taking NVS advice where needed).
In cases where unexpected side effects are observed which are expected to exceed the moderate severity limit, the animal will be humanely killed by a competent person. Indications that a moderate severity limit is likely to be exceeded include but are not limited to, significant (easily detectable by a competent person) or lasting (more than a few hours following procedures, or 48 hours in stock mice) changes as listed above.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is expected that the majority of animals (~99%) will experience no more than mild severity, with ~1% experiencing moderate severities of the types described in the section above on expected impacts/adverse effects.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are 2 key reasons why it is necessary to use animals in order to evaluate the efficacy of the immunotherapy strategy under investigation here.
Firstly, there is the multi-faceted immune response which is stimulated by the presence of the vaccine. Whilst in vitro it might be possible to assess one or a few components of the immune system response, what is not accounted for is the complex interplay between the various components which can be generated in different locations in the body in response. Therefore an intact immune system is required to follow all these.

Secondly, as has been seen with the lack of success with ICI-based therapy, issues have arisen with off-target immune and autoimmune effects occurring in a range of tissues and organs, and therefore a whole body approach is required to validate the desired therapeutic effects. The off-target effects would manifest at the gross level in the deleterious effects we would be monitoring for throughout the procedures.
As mentioned above, extensive preliminary in vitro investigations will take place to ensure every chance of success with the selected target antigen in vivo.

Which non-animal alternatives did you consider for use in this project?

For efficacy, none, for the reasons given above **Why**

were they not suitable?

See above

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on estimate of number of antigens / vaccines that will be evaluated over the course of the project, with the numbers of animals for each particular study calculated by power calculations where necessary. For each protocol this breaks down as follows over the course of the project: P01 ~20 tests; P02 ~50 tests; P03 ~15-20 tests; P04 ~10-15 tests, and P05 ~ 5 tests.
In order to determine the minimum numbers of animals required to demonstrate a statistically significant control of tumour compared to controls, the B16 lung deposit- and the subcutaneous melanoma models have been used as these will be the most commonly used models in these studies.
To determine the expected range of metastatic nodule numbers in the lung and melanoma xenograft growth in the B16.F0/F10 models, fifty scientific publications have been carefully examined for each, and we have carried out statistical power analyses based on this data.

These calculations indicate that for an effect of of the minimal desired reduction in tumour development, the investigators need to work with a minimal sample size of n = 9-12 in both models. Therefore, group sizes of 10 animals are proposed for all work on P03-P05, which also take into account an experimental dropout rate of at least 10 %.

If we work with other tumour models, then a similar exercise will take place to determine the minimally significant group size required.
Animals will be randomly assigned to experimental groups at random within a cage. Due to the aggressive and territorial nature of some strains of mice which could be used, we will avoid mixing cages to form the groups.
For sample analysis where feasible, samples will be blinded.
We will also consider using the Experimental Design Assistant for planning experiments available through the NC3Rs web-site, and refer to the ARRIVE Guidelines (Animal Research: Reporting In Vivo Experiments) on reporting animal experiments to ensure relevant endpoints when designing individual experiments to further aid in minimising animal use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Discussion with scientists at the company we are working with and reference to the literature
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The use of pilot studies as mentioned elsewhere.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and

methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the most frequently used mammalian species for cancer immunotherapy studies. This is beneficial when carrying out such studies due to the depth of knowledge available plus standard protocols, methods and reagents which have all been optimised for use in this species. In addition, it is important to use a mammalian model, since this closer models for the components of the mammalian immune system seen in the clinical situation, which would not be the case if a different Class is used.
If the cells lines that are being used have been engineered to express a fluorescent tag, e.g. Green Fluorescent Protein, or luciferase, then this gives the capability to perform non-invasive optical imaging (fluorescence or bioluminescence) and allows us to monitor internal tumour burden throughout the ongoing experiment. This minimises the risk of developing an unexpectedly high tumour burden, as we can follow tumour growth 'live'.
Animal suffering will be minimised by adhering to the UK National Cancer Research Institute Guidelines for the Welfare of Animals. Specifically, we will always use aseptic technique and will commit to the LASA Guidelines as set out in 'Guiding Principles for Preparing for and Undertaking Aseptic Surgery' (2nd edition, April 2017).
Analgesics and anaesthesia will be used where required, and we will take advice relating to care and welfare via the AWERB and other appropriate sources.

Why can't you use animals that are less sentient?

It is important to use a mammalian model, since this closer models for the components of the mammalian immune system seen in the clinical situation, which would not be the case if a different Class is used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Analgesics and anaesthesia will be used where required, and we will take advice relating to care and welfare via the AWERB and other appropriate sources.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animal suffering will be minimised by adhering to the UK National Cancer Research Institute Guidelines for the Welfare of Animals (ref). Specifically, we will always use aseptic technique and will commit to the LASA Guidelines as set out in 'Guiding Principles for Preparing for and Undertaking Aseptic Surgery' (2nd edition, April 2017).
For blood sampling we will follow guidelines as set out in the 'Handbook of Laboratory Animal Management and Welfare, Third Edition' Editor(s): S Wolfensohn & M Lloyd (2003) & use as a a guideline for clotting time, Emeis et al. (2007), J Thromb Haemost, 5: 670-679.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through scanning most recent literature, referring to the NC3Rs website and through information passed on by the local NIO.

Home Office

NON-TECHNICAL SUMMARY

19. Cell plasticity in the normal and diseased brain

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

brain cancer, stem cells, neurological disease, pathophysiology, epithelial-mesenchymal transition

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our research is focused on understanding biological mechanisms of cell plasticity in the central nervous system. The main goal is to identify regulators of cell plasticity that are relevant for the development and progression of neurological insults, such as traumatic injury, neurodegeneration and brain cancer.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cell plasticity is an important process in tissue maintenance, tissue repair and the response to injury, as well as in the development and progression of diseases. Cell plasticity allows certain cells to adapt to a changing environment and to dramatically alter their gene expression and phenotypes. Alterations in cell plasticity occur during normal development and tissue homeostasis, e.g. in specification of cell lineage, but also accompany various neurological insults. Many of these neurological insults cannot be treated appropriately, resulting in a major burden on healthcare systems and significantly impacting the lives of patients and carers (e.g. traumatic brain injury, neurodegeneration such as Alzheimer's disease, Parkinson's disease and Huntington's disease, and brain cancers).
Our research focus is to understand the cellular and molecular biology of cell plasticity in the CNS, and how this contributes to normal brain function as well as to neurological insults. In many neurological diseases, changes in cell plasticity either directly or indirectly affect the progression of the disease and/or the response from healthy cells. A better understanding of how molecular regulators of cell plasticity act in the normal brain and how their functions are altered by disease processes is essential to develop new and improved therapeutic options for these devastating diseases.

What outputs do you think you will see at the end of this project?

This project will generate new information in the biology of EMT-AMs and how these molecules regulate cell plasticity and lineage selection in health and neurological diseases. We expect to increase understanding of fundamental biological processes that are broadly applicable to stem cells and their differentiation. This will reveal targetable vulnerabilities that can be leveraged to develop new treatments for neurological diseases that are currently incurable. For instance, our work will evaluate the contributions of reactive astrocytes to traumatic injury, and neurodegenerative diseases (e.g. Huntington's disease, Alzheimer's disease) and how modulating this reactivity impacts on disease progression. We will further probe how cell plasticity contributes to brain cancer progression and how blocking this can be used for treating brain tumours. Finally, increased understanding of how EMT-AMs regulate brain cell plasticity may also be beneficial for regenerative medicine approaches, e.g. in areas of stem cell transplantation.

Who or what will benefit from these outputs, and how?

In the short-term, outputs such as new information and experimental models will benefit the neuroscience, stem cell biology and cancer research communities. The clinical benefits of this work are likely to be long term; our principal hope is that by investigating regulation of cell plasticity, we may identify new targetable vulnerabilities in neurological diseases (injury, neurodegeneration and brain cancer) that can be exploited for the development of new therapies. It is noteworthy that during our work under the previous PPL, we successfully identified a new, targetable pathway that may be exploited to treat the brain cancer, glioblastoma.
The project also contributes to the refinement of existing animal models of brain cancer to better mimic the

clinical setting. This will improve the relevance of experimental findings and thus further increase the likelihood that new therapeutic strategies will successfully be applied to humans.
Given the ubiquitous expression patterns of EMT-AMs, the putative therapeutic targets identified here may also be relevant to other tumour types, and therefore may have impact on a broader range of clinical settings, including other cancer types.
Additional long-term clinical benefits may arise from evaluating regulators of cell plasticity for regenerative medicine approaches. Great effort in this field is dedicated to the guided differentiation of specific cell types for transplantation. Our work may help to design protocols for guiding differentiation into specific cell types.

How will you look to maximise the outputs of this work?

All knowledge generated in this project will be disseminated through peer-reviewed publications and presentations at national/international conferences/scientific meetings. Impact will be maximised through press releases accompanying publications and distribution on social media to alert interested stakeholders. Data will be shared via open access journals and repositories. We will continue to actively engage with the general public via events within the University/local communities and via national charities. Other progress and successes in key milestones will be released via University research pages, newsletters and social media.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use genetically altered mouse models of EMT-AMs and CNS cancer and primarily juvenile and adult life stages (including aged animals; e.g., > 26 weeks old). Mouse models recapitulate human disease accurately at the genetic, tissue and clinical level. Our research goals are to investigate functions of EMT-AMs in the development and progression of CNS cancer and neurological diseases. By using genetically altered mouse lines and Cre-lox technology, we will determine genetic predisposition in specific target tissues and unravel whether/how exogenous risk factors such as inflammation contribute to disease. All mouse lines used in this project will also express a reporter (e.g., fluorescent protein), which will allow us to monitor and assess the fate of mutant cells in tissues over time.

Typically, what will be done to an animal used in your project?

Typically, we induce conditional gene expression/deletion in juvenile/adult mice (e.g., 4-8 week old) using inducible-Cre recombinases and under the control of a CNS-specific promoter, e.g., tamoxifen induced GLAST CreERT2. Expression of Cre recombinase also induces expression of a fluorescent protein (e.g., tdTomato) from the ROSA26 locus. Induced animals are aged to a defined end point (e.g., 4 or 8 weeks post induction) before being killed by a Schedule I method or transcardial perfusion.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect that expression of oncogenes such as KrasG12D combined with loss of tumour suppressors (e.g.

Tp53, Pten) in the CNS will lead to the development of tumours over time. In these cases, adult animals may experience the adverse effects of malignant tumours such as weight loss, hunching, inappetence, lack of grooming. Since we are interested in tumour development and progression, we will not routinely use tumour burden as an end point and experiments will be stopped before the appearance of clinical signs in many cases. Neurological diseases, such as neurodegeneration and brain injury, will impact animal health. Animal models of neurodegenerative diseases, or animal models with brain injury, may experience adverse effects from progressive loss of neurological functions, which manifest by weight loss, hunching, lack of grooming, and potential motor symptoms (e.g. increased or decreased motility). These symptoms occur in later stages of neurological disease. Clearly defined criteria for monitoring animal health ensure that animals will not experience symptoms longer than necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect tumour development to have a moderate severity. Only animals that carry site-specific Cre recombinases and a combination of conditional alleles will develop tumours. CNS tumorigenesis requires the combination of multiple alleles (e.g. loss of Tp53 and Pten, and expression of mutant KRas G12D). Based on current experimental design, approximately 25% of cohorts may experience a moderate severity (e.g., GLAST-CreERT2/+; KrasG12D/+, Tp53 f/f, Pten f/f animals).
Animals exhibiting symptoms of neurodegenerative diseases are expected to have a moderate severity. Based on experimental design, approximately 25% of cohorts may experience a moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Several aspects of neurological diseases, such as brain cancers, neurodegeneration or brain injury, cannot be feasibly studied outside of the living organism. Development and progression of neurological diseases are critically influenced by interactions between different brain cell types. Yet, there are currently no in vitro or animal-free simulations that allow us to study the complex and multifaceted interactions of all of the interconnected cell types at play within the living organism.
There are most certainly, reductionist, cell-culture models of specific aspects of neurological diseases within the literature; however, none of these systems can faithfully recapitulate all aspects of neurological disease. Essentially because these in vitro systems are intentionally simplified, they do not allow for the degree of complex cellular interconnectivity required for the proposed studies.

Which non-animal alternatives did you consider for use in this project?

Ex vivo explant models offer non-animal alternatives for some aspects of this work but are limited.

Why were they not suitable?

Current ex vivo CNS explant models do not robustly recapitulate healthy normal tissue, principally because CNS tissue is complex, composed of multiple cell types that are exquisitely sensitive to manipulation outside the organism. Essentially, growing neurons or glial cells derived from later than early postnatal stages is impossible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were estimated based on previous experience and then validated using the NC3Rs Experimental Design Assistant and Power Calculations. For these calculations, effect size (m1-m2) and variance (S.D.) were calculated using current data, or from data reported in the literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We calculated minimum group sizes to obtain statistically significant data from our planned studies. All calculations were made using the NC3Rs Experimental Design Assistant and with data from our own research or from published literature to estimate variability and effect size. This allows us to reduce the overall number of animals used for experiments.
Wherever possible, experiments are designed to avoid redundancy by addressing multiple questions (e.g. tissue from animals used for behavioural studies will also be used to analyse histology).
Wherever possible, experiments are designed so that one cohort of control animals can be used for multiple cohorts of experimental animals to avoid redundancy.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All aspects of this work will be supported by experiments involving cells isolated from brain tissues and tumours and maintained in culture in the laboratory. This will reduce the number of animals required. However, animals are required to study tumour biology because it involves a complex interaction between multiple tissue types and the immune system, therefore analysis of tumour behaviour or neurological diseases ultimately requires intervention in the context of the whole organism. Determining overall cohort sizes is based on previous experience with these models and validated using power analyses. The use of non-invasive imaging techniques, while part of the research and development of new diagnostic tools in their own right, will further reduce animal numbers. Where appropriate, homozygous parents will be bred to reduce numbers of excess offspring of incorrect genotypes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use genetically altered mouse models and site-specific Cre-lox technology that allows temporal and inducible gene modification in CNS tissue. Mouse strains will also express reporters of Cre that will allow tracing of recombined cells in tissues over time. All genetically altered lines will carry conditional alleles; therefore, only mice that carry site-specific recombinase and the conditional allele will develop tumours. These models are well characterised during work undertaken under the previous PPL and by our collaborators; experimental time points and timelines of the development of predictable phenotypes is known. We will only use genetically altered animals appropriate to our objectives (i.e., targeting of specific transgenes in a tissue-dependent manner) to ensure that the work carried out is accurate. In vivo imaging approaches (where appropriate) provide non-invasive methods to monitor disease progression in the same animal over time.
Tissue transplantation assays provide approaches where we can uncouple cell intrinsic from cell extrinsic factors in vivo; test putative cancer stem cells and monitor tumour progression in short-term assays without the need for primary tumour formation.

Why can’t you use animals that are less sentient?

Mice are considered the most suitable experimental animal model for neurological diseases, including brain cancer, neurodegeneration and brain injury, for the following reasons:
There is a large body of knowledge on the physiology, histology and molecular biology of the mouse CNS; there are a wide range of existing genetically modified lines, a number of which are directly relevant and amenable to our studies; the relatively short life-cycle and high fecundity of mice is advantageous for genetic studies; and mice are generally regarded as being of lower sentience compared to other mammals such as the primates.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements will include frequent monitoring of induced, post-operative or anaesthetised animals. Exogenous substances/agents will be administered at the minimum dose, as determined using NC3Rs guidelines for best practice and dosing regimens and following consultation with our collaborators. All procedures will be carried out by trained and experienced staff with the support of experienced animal facility staff/NACWOs/NVS (e.g., application of anaesthesia, analgesics, surgical techniques).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have extensive experience in all procedures from work during the previous PPL. All procedures will follow LASA guidelines and we will make sure to implement any updated recommendations on best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Engage with NC3Rs representatives on a regular basis via local workshops/meetings, newsletters and social media.

NON-TECHNICAL SUMMARY

20. Central Nervous System (CNS) Safety and Efficacy in Rodents

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Mental illness, Central Nervous System, Mood disorders

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile
Rats	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to support the assessment of a test agents for potential adverse effects on behaviour or their ability to modify impaired mood, sensation, thinking and behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Mental illness is a growing problem, with 1 in 4 people experiencing mental health issues each year, with an associated economic and social burden.

- Depression is a leading cause of disability worldwide, often occurring in conjunction with other mental health issues and associated with suicide and heart disease.
- Anxiety affects a significant number of people, and over recent years has been seen to be increasing among young people.
- Psychosis and schizophrenia are also on the increase, with the latter being increasingly connected to cannabis consumption at an early age.
- Autism Spectrum Disorders (ASD) is increasing. ASD is complex and is associated with varying levels of disability, including those related to social interaction, repetitive behaviours, frustration, aggression, anxiety, sensory sensitivity and motor coordination. In addition,
  ASD commonly co-occurs with other diagnoses including developmental, psychiatric and neurologic conditions.

Such conditions can be hugely debilitating for the individuals and challenging for care givers and family.
Although a number of treatments are available for such conditions they are often associated with varying degrees of side-effects. For example, anti-psychotics may cause weight gain, suicidal feelings/behaviour, seizures, sedation, neuromuscular effects, emotional effects and heart problems. As such, new medications are required which have improved or equal efficacy with lower associated side-effects.
For the treatment of Schizophrenia, medications have primarily targeted the positive symptoms (e.g. hallucination, delusions, disorganization speech and behaviour), however, more recently, there has been an increase in drugs being developed to treat the negative symptoms of this condition (e.g. lack of emotion/hedonia, low energy, low motivation and impairment of social interactions).
Data from this project will be used to improve human health by 1) supporting the development of new medicines for these and other related disorders, 2) assessing novel drugs for their potential to produce unwanted behavioural/CNS side-effects and 3) support the requirements of regulatory submissions.

What outputs do you think you will see at the end of this project?

Reports and data which will be submitted to support the regulatory filing of new drugs.
The refinement of models and associated publications sharing such data and best practices.

Who or what will benefit from these outputs, and how?

The primary benefit of work carried out under this licence will be to allow regulatory authorities (who are totally independent from the commercial interests behind every marketing application) to come to informed decisions, based upon data generated in these studies, regarding the risks and/or benefits when humans are exposed to medicinal products.
Achievement of the objectives of this Licence will enable medicinal products to progress into clinical testing and onwards to marketing authorisation and ultimately improving the health and welfare of humans. Without these pre-clinical studies, progression of new medicines to early human studies and on to patients/marketing could not occur.
There is also a major benefit when using early drug selection type experiments, as the most promising compounds for further development will be selected and then fully tested so that they can reach the market sooner and as such benefit the health and welfare of humans.
The use of the experiments described in this licence may indicate major safety concerns or lack of effectiveness with the substance under evaluation at an early stage thus precluding requirement for additional experiments after these screening studies. This can greatly reduce the number of animals required in a programme of work. In addition, scientific knowledge gained in one programme of work will often be applied to future experiments in order to reduce animal numbers and/or reduce pain and stress to those animals used in the subsequent work, or to target investigations to a particular organ or tissue during toxicity testing or clinical trials.

Sponsors will benefit from work undertaken within this project licence, by obtaining data which allows them to make decisions on the development of the drugs and to support regulatory filings.

How will you look to maximise the outputs of this work?

Where confidentiality permits, data, study design and best practice will be openly shared at conferences, workshops, webinars, blogs and publications.

Species and numbers of animals expected to be used

- Mice: 3500
- Rats: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Animals used during the course of this licence will be rodents. There is wide knowledge of the behavioural response of rats and mice in response to a wide range of substances and a wealth of background literature. The innate curiosity and anxiety of these species has established them as species of choice for assessing conditions involving emotional state.
Although the majority of studies will use adult animals, on occasion, neonatal or pregnant animals exposed to valproic acid (a medication for the treatment for various types of seizures) may be required for modelling autism disorders. In addition, on rare occasions, juvenile animals may be used when age-sensitive effects are of concern.

Typically, what will be done to an animal used in your project?

The majority of animals within this project will administered test agents as a single administration or daily administration for up to 4 weeks. At various time-points animals will be observed for physiological or behavioural changes (e.g. body temperature, anxiety, exploration, social interaction, learning and memory, reaction to a stimulus). Blood samples may be taken on occasion so that test agent exposure levels or biomarkers of disease can be determined and related to the human situation.
These assessments may be conducted in normal animals, animals genetically susceptible to emotion state disorders, or animals which have various emotional states induced chemically. Animals assigned to protocols which require them to learn to lever press in order to obtain a positive reward (e.g. sugar pellet) have an extended duration or several months which is largely determined by how quickly the animals learn the task.
In all cases, upon completion of testing the animals are humanely killed.
The endpoints will be carefully selected based on the purpose of the study and by considering the effect that each test may have on the outcome of another test or on multiple testing. In general, each observation (test) is of short duration (e.g. 15 minutes). Examples of study designs based on therapeutic purpose are as follows;

- **Positive symptoms of Schizophrenia could be assessed in amphetamine pre-treated animals**
  Locomotor activity
- Visual observation for stereotype behaviour
- Pre-pulse inhibition
  (acoustic startle)

Negative symptoms of Schizophrenia could be assessed in MK-801 pre-treated animals

- Novel object recognition
  Social interaction
- Morris water maze
  Anxiety
- Social interaction
  Holeboard activity
- Light/dark box
  Staircase test
- The above could also be applied to Autism Spectrum Disorder in genetically susceptible animal or animals previously exposure to valproic acid.
- **OCD**
- Marble burying
  Pre-pulse inhibition
- The above could be applied to Autism Spectrum Disorder in genetically susceptible animals or animals previously exposure to valproic acid.

In all cases, a single intravenous administration of a non-labelled tracer may be administered (e.g. 15 to 60

minutes before the animal is killed) for receptor occupancy purposes.

What are the expected impacts and/or adverse effects for the animals during your project?

Humane endpoints (documented within the licence) will be applied to animals used under the protocols specified in this licence.
Although these studies are typically conducted at the early stage of drug development and often for lead optimization purposes, preliminary toxicology and or pharmacokinetic studies are anticipated to have been performed and as such the dose levels can be carefully selected in order to avoid undue toxicity. The majority of the protocols within this licence are behaviourally based and as such adverse effects are not desirable.
These assessments may be conducted in normal animals, animals genetically susceptible to emotion state disorders, or animals which have various emotional states induced chemically. In the majority of cases, the resultant effects will not be obvious, with animals appearing normal. However, under certain conditions, such as a test which requires the animal to remember a task, to interact with another animal, respond to a novel environment or response to an auditory stimulus, the genetic or chemically-induced phenotype may be revealed. Such effects are also anticipated for positive controls used within this project licence.
If overt effects are seen, then these are anticipated to be transient and will typically be stimulant- or sedative-like.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity limit specified (moderate) is considered to be the minimum commensurate with achieving study objectives. For the majority of studies conducted under this licence, the severity limit is moderate due to the procedures required to achieve the protocol objectives. Repeat dosing and multiple subthreshold and mild procedures are primarily responsible for the moderate severity imposed. In the majority of cases animals will not experience more than mild signs as a result of administration of the test agents. Marked effects anticipated are primarily those related to the known pharmacology of drugs e.g. sedation or stimulation.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As a service provider we do not own the test materials under evaluation, therefore, in silico screening tools for candidate selection are not appropriate, however, available literature is searched prior to commencing any in vivo procedures. Prior to conducting in vivo studies, sponsors are requested to provide information relating to their test material candidate, together with details of other work performed, relevant regulatory requirements and a justification for conducting in vivo investigations.
Due to the studies within this project requiring the assessment of behavioural and learned responses, the use of animals is essential.

Which non-animal alternatives did you consider for use in this project?

Although there are presently no non-animal models for behavioural responses, in vitro information e.g receptor binding/functional assays and chemical structural analysis will typically form part of the over profiling of candidate drugs.

Why were they not suitable?

Non-animal studies are not sufficient to fully evaluate behavioural responses and learned behaviours.
To fully assess the pharmacodynamic effects (effects of a drug on the body) of a new drug testing in animals is necessary. Only in a fully operational circulating system can the drug's distribution, metabolism, excretion which may alter or intensify the efficacy or adverse effects of the new medicine be fully understood.
For these reasons animal models remain essential in the development and safety assessment of new medicines.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The total estimated numbers of animals to be used have been determined based on previous projects over the past 10 years, anticipated future requirement, and in review of future services being developed and offered globally for regulatory non-clinical studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Studies will be designed under this licence such that the minimum number of animals will be used in order to obtain the maximum information, whilst the scientific objectives of each study are met, in accordance with regulatory requirements and agreed standard practices.
Data generated from pivotal studies will be statistically analysed, with comparisons drawn between control and treated groups, and reported in a format consistent with the ARRIVE guidelines published by the NC3Rs.

Where possible, studies will be designed in such a way that individual animals will be assessed for behaviour in a battery of tests as opposed to separate groups of animals for each test.
For studies within this project which are primarily designed for efficacy or investigative purposes, side effects may be detected which if considered unacceptable for the therapeutic area for which the drug is intended may lead to the cessation of its development early on. Having the opportunity to terminate the development of a drug as early as possible in the development process reduces the unnecessary use of animals.

Where possible, multiple behavioural assessments will be conducted in order to minimise the number of animals used and the need for separate standalone studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our organisation has a wealth of experience and knowledge regarding regulatory requirements and the industry standards used, hence we are in an ideal situation to influence study designs when discussing requirements with our Sponsors and will always consider ways of reducing animal requirements. We also have available professionally trained statisticians to help design studies.
Study protocols are reviewed by the AWERB against known guidelines and the Company's ethical compliance policies. For regulatory studies, guidelines require the appropriate number of groups to clearly demonstrate the presence or absence of effects of the substance; core study designs are based on international guidelines where these exist. If not, use is made of literature and scientific principles of experimental design. Where appropriate, use is made of removing or limiting control groups and challenging the need for the use of both sexes. Additional justification will be requested from the study sponsor and reviewed by the PLH/AWERB for studies requiring a greater number of animals in order to better characterise the variability of a scientific endpoint.
Statistical input is sought, where appropriate, to strengthen the overall scientific quality and relevance of studies, with power-sample size calculations performed for specific studies if necessary to determine group size. Where group sizes allow, data are analysed statistically. However, due to the behavioural nature of studies within this project licence test agent effects are made by examination of data from each animal, rather than or in addition to simply assessing group mean values and statistical parameters.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animals used during the course of this licence will be rodents. The models within this licence are behavior based and as such animals are required to be in a good state of health in order to perform tasks associated with some protocols.
In general, tests are conducted as follows;

- Tests which involve placing animals within a novel environment (e.g. maze or arena) and observing their natural behaviour within these environments for a relatively short period of time (e.g. 10 minutes).

- Tests which involve a 'task' such as shredding nesting material, burying marbles, pressing a lever, walking along a beam or rotating drum.

- Tests which require learning and memory recall, such as negotiating a maze for a positive reward e.g. radial arm maze, novel object recognition.

- Tests which require a reflex response to an external stimulus e.g. computerised auditory startle, pupil response to light, or response to an approaching object.

In all cases, the potential to cause stress or distress is minimal and short-lived. The assessments performed are not based on pain or fear, nor do they induce, or require a behavioural despair component.
Animal welfare costs are minimised by the careful selection of dose levels to reduce the likelihood of unexpected toxicity, and the application of rigorous and comprehensive humane endpoints. Individual studies will be designed to cause the least possible suffering by frequent review of practices, provision of highly skilled technical staff and veterinary support, purpose built facilities and a clear focus on animal welfare.

Why can't you use animals that are less sentient?

Rodents are the animals with the lowest neurophysiological sensitivity that allows you to meet the aims of the studies. Scientific opinion, including that of the regulatory agencies, indicates the use of rodents within these study types are appropriate, and to use a non-rodent species should only be done if there is strong scientific justification to do so.
The tests within this licence are strongly behaviourally based and as such require the use of conscious animals .
Adult, juvenile or neonates may be used within the project licence.
Neonates will only be used for the purpose of inducing an autism spectrum disorder for which they will receive a single administration of valproic acid.

Juvenile animals may be required if certain aspects of behaviour or treatment are thought to be age sensitive e.g. exposure to cannabinoids may have greater effects in children and adolescents compare to adults.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?
The severity limits specified are considered to be the minimum commensurate with achieving study objectives. Studies conducted under this licence are within the moderate severity category and it is expected that the majority of animals will have an actual severity that is the low end of moderate or mild. The actual severity is anticipated to be largely determined by procedural effects (such as repeat administration) rather than clinical signs resulting from administration of novel test agents.
All procedures are kept to the minimum commensurate with the study objective. Best practice guidelines for all animal care and use are followed.
It may be necessary to take serial blood samples from the study animals to monitor plasma levels of the test compound. The tail vein and jugular vein are accessible in rats and will provide adequate blood samples. Blood sampling from mice may be required on rare occasions. Where blood samples are required we will take them using the sampling site, volume, and frequency that has least welfare impact on the animals. Where possible samples will be taken under non-recovery anaesthesia. Microsampling (using very small volumes of blood, which causes less distress to an animal) will be utilized where methodology is available to do so.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Technical, scientific and regulatory developments will be monitored throughout the duration of this licence. Opportunities to introduce refinements will be evaluated by the Project Licence Holder and Animal Welfare Ethical Review Body to ensure the regulatory and scientific objectives of individual studies can be met whilst achieving the intended benefit. If required, validation studies will be conducted under this licence to ensure these objectives can be met.
Prior to the start of a particular programme or study, the client will be requested to provide information regarding known or potential effects/drug interactions that could be confounded by routine veterinary treatments or standard husbandry practices. Any such interactions are rare but with pre-planning, alternative treatments may be available (e.g. opioid vs NSAID analgesia, different bedding types etc).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information issued by regulating authorities, the Home Office, cross company consortiums, in-house projects and scientific associations (e.g. the NC3Rs) will be reviewed and adopted as appropriate in

accordance with best practice.

Home Office

NON-TECHNICAL SUMMARY

21. Central Nervous System Determinants of the Transition from Acute to Chronic Pain

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Pain, Nociception, Central Nervous System, Fear

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage. Acute (normal) pain is a necessary sensory function that signals actual or potential damage, such as the heat of a fire. It is short lasting and is essential for survival, as it drives simple protective measures such as removing the hand from the fire. However, many people suffer from continuous, (chronic), painful conditions such as arthritis or back pain. In addition to the suffering incurred by the individual concerned, the knock on effects of suffering chronic pain often has detrimental effect on family, friends and society as a whole through loss of workforce and the cost of healthcare. For the majority of sufferers, the available drugs fail to provide

effective relief and often have unwanted side effects. Current treatments are largely ineffective and so new lines of research are needed to identify novel targets for the development of treatments.
Whilst the cause of pain (e.g. injury) is invariably remote from the brain, its perception is always at the level of consciousness within the brain itself. For most people pain stops after recovery from injury. However, in a significant proportion of individuals chronic pain persists beyond the period of tissue repair and can last for months or years. Why some individuals, and not others, are susceptible to this form of chronic pain is unknown. One mechanism of chronic pain might be due to the inability of the brain to forget a pain signal following injury, similar to the inability to forget a fearful memory in anxiety disorders (such as post traumatic stress). Testing an individuals ability to forget (extinguish) a fear memory might therefore predict how vulnerable they are to developing chronic pain.
The question that will be addressed in this project is how the original injury sets up changes in the brain that lead to a continued perception of pain at the level of consciousness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Current medicines for the treatment of chronic pain are at best only partly effective and often have unwanted side effects. The outlined work aims to advance understanding of the mechanisms underlying the experience of pain, at the level of the brain, and thereby identify new strategies for the relief of pain. The results from these studies will provide important information relating to the way the brain regulates pain perception and why some individuals are more susceptible than others to chronic pain. In so doing we aim to identify new mechanisms that can be used to bring about the more effective relief of continuous pain for the benefit of people and animals.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The study will be carried out in rats because, like humans, they show variability in their susceptibility to chronic pain. Therefore, the information gained in rats will be directly relevant to development of pain-relieving strategies for humans and other animals. We will use an experimental design that minimises animal numbers while ensuring we achieve our scientific objectives. The study is expected to use 280 rats over five years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

In order to investigate the susceptibility to chronic pain it will be necessary to evoke a pain state resulting from nerve injury that models human disease or injury. This will be achieved using techniques that the sensory experiences of animals brief escapable mechanical and thermal stimuli will be applied to the skin. In order to facilitate drug delivery or to record activity within the brain animals will undergo a small surgical procedure under general anaesthesia. Some animals will be maintained under terminal anaesthesia to minimise harm. In other animals, following surgery they will be given analgesics and are expected to recover uneventfully and return to normal behaviour with 24 hours. All animals will be humanely culled within 8 weeks at the end of the studies.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The neural circuits responsible for the perception of pain are located within the brain. The integrated neuronal circuitry involved cannot be adequately modelled by computer or using isolated cells cultures. Consequently, it is not possible to undertake these studies without using animals.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Affective and tests of nociception in animals are designed to assess emotional and physical behavioural responses to painful stimuli which is inevitably associated with distress and discomfort to the animal. Therefore, it is imperative to reduce the numbers of animals and use the minimum number possible to minimise pain and suffering.
In order to do this, for each of the proposed experiments, power calculations, based on data from published studies, will be used to determine the numbers of animals needed. Batches of animals will be tested and an assessment of the results will be carried out before experiments are continued, to ensure the minimum number of animals are used to make statistically significant conclusions.
Whenever possible experimenters will be blinded to treatment allocations and animals will be randomly assigned to study groups to ensure any findings are robust by minimising bias, meaning fewer animals should be needed for replication of results.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

A lot is already known about the functioning of the rat brain in relation to pain. Rats have been used extensively for similar studies in many laboratories worldwide because their brains share much in common with that of human and they response to pain is well characterised.
The behavioural responses to pain using outbred strains of rat have been shown to provide a good model for replicating the variation of human susceptibility to chronic pain. This choice of model, although more variable, should provide a better method to investigate our research questions and make results more robust and reliable. Results gained from experiments under this licence may provide further refinement for experimental rat models relating to chronic pain, and any such findings will be published and made available to the wider scientific community.
The models of pain induction and assessment selected for this work have been extensively validated and are least severe needed to undertake the study. In all cases the period of sensitisation will be kept to minimum required to obtain therapeutically meaningful results, while ensuring that observations made over time yield the maximum data from the minimum number of animals. Any refinement in methodology relating to pain induction and assessment that minimises suffering and distress, whilst maintaining meaningful results, will be made available to the wider scientific community.

Home Office

NON-TECHNICAL SUMMARY

22. Cerebrovascular health and function in ageing and Alzheimer’s disease

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Alzheimer's disease, Cerebrovasculature

Animal types	Life stages
Mice	adult, juvenile, embryo, neonate, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how risk factors for the development of Alzheimer's disease impact on the structure of the cerebrovasculature, how this affects clearance of solutes and fluids from the brain and the impact on brain function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Alzheimer's disease (AD) affects more than 850,000 people in Britain and 35 million people worldwide. The annual cost of dementia is estimated at more than £30 billion/year in the UK alone. Current treatments for AD help to stabilise memory loss for a short period of time, but do not stop or reverse the disease. Risk factor for AD include old age, genetic factors and metabolic disease like obesity and diabetes. Women are also more likely to be affected than men. However, it is still not understood how these factors increase the risk of developing AD.

One of the hallmarks of AD is the build-up of beta-amyloid (Ab) in the brain. As it accumulates, Ab becomes toxic and kills brain cells, leading to dementia. In healthy individuals, Ab is cleared from the brain before it has a chance to accumulate. Blood vessels in the brain play a critical role in this process. They also help to form the blood-brain barrier, which is a physical barrier between the blood and the cells of the brain. This allows the brain to strictly regulate what gets into and out of the brain. Damage to blood vessels can slow down the removal of Ab from the brain and lead to its accumulation both in the brain and blood vessels themselves. This results in less blood flow to the brain and leakage of damaging components from the blood into the brain which contributes to the death of brain cells. Therefore, we believe that factors that increase the risk of developing AD do so in part by damaging the blood vessels of the brain, leading to increased amounts of Ab and decreased cognitive performance.

Results from this project will provide new information about how damage to blood vessels in the brain contributes the risk of developing AD and help to identify new ways in which AD may be prevented or treated.

What outputs do you think you will see at the end of this project?

This project will generate data from behavioural analyses and quantitative and qualitative observations represented in tables, graphs, databases and microscopy images. These data will be used to generate public lectures, posters and publications in scientific journals.

Who or what will benefit from these outputs, and how?

The findings from this project will give a better understanding of how factors such as age, diet and genotype affect the efficiency of Ab clearance from the brain. This will provide new information for the scientific and medical community as a whole and will highlight a new direction for effective treatments for AD to be developed. As such, these groups are likely to be the immediate beneficiaries of the results generated from the project. In the longer term, potential beneficiaries include health professionals who work with AD patients (e.g. gerontologist, psychologists), the commercial private sector (e.g. drug companies that develop AD-targeted

therapeutics), the general public and AD patients themselves.
How will you look to maximise the outputs of this work?

This data will be used by our group, our collaborators and other academic and clinical colleagues to whom the information will be disseminated at conferences and through publications. In addition, we will use our existing relationship with AD charities (e.g. Alzheimer's Research UK) to give public talks about our work within local communities.
Species and numbers of animals expected to be used

- Mice: 5700
- Rats: 1400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents are model organisms for choice as the least sentient mammal that can be reasonably used for these studies. There is a considerable body of data on the neurobiology of the rodent that is directly relevant to the functioning and pathology of the human brain. Further, genetically altered mice and rats replicate many aspects of human AD, including age-related pathology in the brain and cognitive impairment. Identification of factors that influence protein aggregation and solute clearance in animal models can be used to develop new therapies to treat human AD patients.
Typically, what will be done to an animal used in your project?

To understand how blood vessels contribute to clearance of solutes from the brain, animals will receive an injection of Ab or related proteins into the brains under anaesthesia. Some of these animals will have had a previous surgery to kill specific groups of brain cells that are known to die early in AD. A subset of animals will be treated with drugs or biological compounds that influence vessel function before or during the intracranial injection. Another group of animals will be treated with drugs that are designed to prevent the aggregation of Ab or other AD-related proteins to see if this treatment improves brain clearance pathways. The animals will be killed shortly afterwards with an overdose of anaesthesia and the pattern of distribution of Ab within the brain and blood vessels will be analysed. These experiments will be carried out in young, adult and aged wildtype animals and using GA animals that express mutations that mimic AD pathology or have abnormal blood vessels. To determine how modifiable risk factors for AD, such as obesity and diabetes affect vascular and cognitive function, wildtype and GA mice and rats will be fed either a normal or modified diet. This diet will be administered to male and/or females animals before, during and after pregnancy and/or lactation. A subset of foetal and neonatal offspring will be killed to determine the effects of parental diet on early brain and vascular development. At weaning, offspring with be fed either the same or opposite diet to that of the parents. A subset of animals will be used to assess fluid and solute movement in the brain using tracer injections as described above. Offspring will undergo behavioural analyses to test the effect of risk factors on behavioural parameters that are affected in AD. In some cases, the same animal will be tested at different times during its lifespan to determine how behaviour changes with age. A subset of animals will be treated with drugs that target metabolic disease or will be given a running wheel for voluntary exercise before or during the behavioural tests. At the end of the experiment, animals will be killed with an overdose of anaesthesia and their brains will be analysed to determine the effect of diet and dietary interventions on brain and vessel structure. These experiments will be carried out in foetal, neonatal, young, adult and aged wildtype and GA animals to assess changes across the lifespan.

What are the expected impacts and/or adverse effects for the animals during your project?

For experiments requiring surgery, there is a low risk that animals may develop hypothermia during surgery and post-operatively. During the post-operative period (e.g. ~1 week), there is a low risk that animals may experience pain or infection. Feeding a modified diet high in fat or low in protein will likely result in sustained weight gain or loss. High fat-fed animals may also develop obesity-related health issues. For experiments using behavioural tests, there is a low risk that animals will be stressed by the novel environment during behavioural tasks (~60-90 mins) and of fighting injuries of male mice when they are re-homed together after testing. Some GA models may develop behavioural abnormalities (e.g. hyperactivity).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

None of the procedures in this project will exceed a moderate severity. Most animals (~90%) used in breeding protocols will be transferred to an experimental protocol before the onset of a phenotype. A minority of breeders (~10%) that are kept up to 12 months may experience moderate severity as a consequence of a progressive phenotype. All animals on experimental protocols will experience a moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complex nature of the mammalian brain and blood vessels makes it difficult to study movement of fluid and solutes into and out of the brain using animal-free mechanisms. Rodents are model organisms for choice as the least sentient mammal that can be reasonably used for these studies because there is a lot of information about the brain and behaviour of rodents that is directly relevant to humans. Further, genetically altered mice and rats replicate many aspects of human AD, including pathological and behavioural changes which can be used to develop new treatments.

Which non-animal alternatives did you consider for use in this project?

Tissue culture models of the blood-brain barrier and computer models of fluid movement within the brain.

Why were they not suitable?

Where possible, we will use tissue culture and computer models to test basic functions of cerebral blood vessels and to model the dynamics of fluid movement under normal and diseased conditions. However, neither of these models fully replicate the complexity of the cerebrovasculature or the properties of fluid exchange between the brain and blood. In addition, complex behavioural and cognitive functions that mimic human behaviour cannot be fully assessed in non-mammalian systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may

include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers have been calculated using power calculations that are based on effect sizes generated either from preliminary or previous experiments or as an estimate where no pre-existing data exists. Each outcome has been assessed individually and the animal numbers in each study group represents the minimum required to detect statistical significance of 5% between the experimental groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, calculations have been made based on data collected from preliminary or previous experiments (generated either by our group or in the published literature) to ensure that effect sizes are accurate. The NC3Rs Experimental Design Assistant is also used when formulating experimental design. We have also consulted with statisticians to ensure that power calculations and statistical tests used for data analysis are appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For heterozygous GA strains, breeding protocols will be used to minimise the number of offspring without the target gene and wildtype littermates will be used as controls where possible. For experiments where animals are aged, all major organs will be collected from the animals at the end of the experiment and banked either for future use or shared with colleagues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use wildtype and GA mice and rats. Protocols for rodent husbandry and health management are well established and there are many rodent-based resources that can be consulted for standard operating procedures. In addition, the size of these animals also makes it ideal for physiological manipulations. Rodents have high reproductive capacity and a relatively short generation time that facilitates multigenerational studies and studies on the consequences of ageing.

Why can’t you use animals that are less sentient?

Where appropriate, foetal animals will be used to assess the effects of risk factors on brain and vascular structure. Similarly, acute intracerebral injections and tissue collection will be carried out in terminally anaesthetised animals. Recovery surgeries and ageing protocols will only be used where there is a need to study time-dependent effects or to evaluate a phenotype across the lifespan.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For procedures that require surgery, levels of anaesthesia will be maintained at sufficient depth for the animal to feel no pain. Aseptic techniques and sterile instruments will be used to help prevent postoperative infection. The animals' body temperature will be maintained throughout surgery and during recovery. Animals will be administered analgesic pre- and post-operatively and given additional doses if they show signs of pain or discomfort. Animals will be monitored during recovery until they regain consciousness and daily for the first post-operative week for signs of illness (e.g. loss of body weight, dehydration, poor grooming, social isolation) or infection.

For procedures that require dietary manipulation, including food restriction, animals will be weighed daily until a stable weight is achieved and then a minimum of 5 days/week to ensure that body weight is maintained at target weight. Animals will be given additional food immediately if they approach their target weight and dominant animals will be separated where animals are housed together.

During behavioural tests, animals will be closely monitored and removed immediately if they show signs of illness or distress. Animals will be handled appropriately throughout the procedures and where possible habituated to the novel environment of the behavioural task. Animals will be monitored daily for fighting injuries or signs of illness and distress following re-housing in groups.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Consultation with PREPARE and ARRIVE guidelines and use of NC3Rs and related resource hubs, including published literature.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Experimental design will be done in consultation with published literature as well as PREPARE and ARRIVE guidelines. NC3Rs and related resource hubs will be routinely checked for current standard operating protocols and advice will be sought from the NVS before undertaking new procedures.

Home Office

NON-TECHNICAL SUMMARY

23. Characterizing the function of a gene family involved in stress sensing in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

heart, skeletal muscle, cyclic nucleotides, regeneration, disease

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile

Retrospective assessment
The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits
Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

A gene family involved in stress sensing is important for preserving the structure and function of the heart and skeletal muscle. We are characterizing zebrafishes carrying altered (mutant) forms of these genes to define their role in health and disease.
A retrospective assessment of these aims will be due by 02 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A gene family involved in stress sensing encode proteins that bind a signalling molecule produced in cells in response to hormonal (for example adrenaline) stimulation. It is vital for the heart, as it regulates the speed and force of contraction and is also required in skeletal muscle to preserve its structure and function. Patients suffering from cardiac and/or skeletal muscle disease have been identified to carry mutations in one of the three members of this gene family. Introducing these mutations in zebrafish and studying the resulting heart and skeletal muscle defects will help to characterize the activities of these proteins and to define their function in health and disease. Recently, we began to explore the function of this family of proteins in cardiac and skeletal muscle regeneration. Defining the reasons for impaired heart and muscle regeneration in zebrafish mutants will lead to a deeper understanding of the roles of these proteins and possibly may lead to a novel class of drugs, which might be able to improve healing after an infarct.

What outputs do you think you will see at the end of this project?

- This work is expected to provide new information about the role of these stress-sensing genes in cardiac and skeletal muscle regeneration and will help to elucidate the mechanisms of how they are controlling pathways that regulate the response of muscle cells to stress.
- The primary expected benefit is the publication of new scientific knowledge about how these stress sensors control cardiac and skeletal muscle regeneration.
- New information will also be obtained about the mechanisms how mutations in these genes are causing heart and skeletal muscle disease.
- The results of this work will be presented at scientific meetings and subsequently in publications in peer-reviewed journals to ensure wide dissemination to the appropriate audience.
- Research may in longer term also result in novel therapeutic products as these stress sensing proteins represent a unique molecular target, which is involved in many vital functions of the heart and skeletal muscle.

Who or what will benefit from these outputs, and how?

The scientific research community will benefit from this work. Primary recipients are the research communities working on cyclic nucleotide signalling, which includes approximately 500 researchers worldwide. Another research community that will be interested are researchers that work on cardiac regeneration in zebrafish with an estimated number of about 100 researchers worldwide. Our work will also be of interest to the wider heart and skeletal muscle research communities, which are estimated to be approximately 10,000 and 2,000 researchers, respectively. In the short term we will provide novel insight into the mechanisms of how these proteins are mediating stress signalling in the heart. In the longer term, the research may yield novel pathways, which could be exploited for the development of novel drugs.
The work on cardiac regeneration in zebrafish may help to develop novel therapies to alter the fate of myocardial infarction, which currently is a highly detrimental disease-causing heart failure and death. Understanding how these genes are involved in heart and muscle regeneration in the short term will lead to novel information about the cellular pathways involved in this process. It is uncertain whether this novel knowledge will indeed have an impact on clinical practise and alter the outcome of myocardial infarction. It may have a 20% chance that the new knowledge generated might be of benefit in the clinics in the longer term.

How will you look to maximise the outputs of this work?

The results of this work will be presented at scientific meetings, will be published in peer-reviewed journals to ensure wide dissemination to the appropriate audience. We also regularly writing review articles to further foster dissemination to the various research communities that are interested in our work. These information routes will encourage further collaborations and potentially lead to translational opportunities.

Species and numbers of animals expected to be used

- Zebra fish: 8,100 adults

Predicted harms
Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The gene family involved in stress sensing consists of three genes, which are present in all vertebrates including zebrafish. The high conservation grade allows to model mutations in zebrafish, which have been discovered in patients. The adult zebrafish has the ability to fully regenerate the heart after injury. In mammals this ability is also present at birth but is lost one week after birth. Overall zebrafish and mammals display very similar processes in response to heart injury. However, while the zebrafish is able to heal its heart, the mammalian heart will substitute cardiac muscle with scar tissue.
The scar tissue will not participate in pumping blood, which in the long run might cause heart failure. The adult zebrafish may serve as a model to unravel mechanisms involved in cardiac regeneration that lie dormant in the adult mammalian heart but potentially could be reactivated. Studying heart regeneration in adult zebrafish lacking one member of the gene family involved in stress sensing therefore may help to identify novel pathways that are involved in this process, which when activated help to recover the human heart from myocardial infarction. We are also interested in skeletal muscle regeneration and membrane healing. Skeletal muscle unlike the heart maintains the ability to regenerate as muscle contains a specialised cell population, the so-called satellite cells that are able to reconstitute muscle after injury. Skeletal muscle injury is commonly present after sport or walking downhill for example. Restoration of muscle structure is impaired in animals lacking these stress

sensing genes and we are interested to identify the reason for this failure. Knowledge gained in this way may help to understand the function of these proteins in muscle regeneration and this knowledge might help to treat patients carrying mutations in one of these genes. Patients carrying point mutations in these genes also develop an irregular heartbeat as do zebrafishes carrying mutations found in patients. Characterising the underlying reasons for irregular heartbeat remains challenging but it is hoped that the study of adult zebrafish hearts in this context will help to elucidate the underlying pathology. For this purpose, fishes will be subjected to electrocardiography in order to assess the presence of an irregular heartbeat. Since these genes are involved in stress-signalling, the heart abnormalities will become fully apparent only after stress induction. This is accomplished by injecting substances which trigger a faster heartbeat and it is in this situation that the mutant heart is expected to show its abnormal response to stress.

Typically, what will be done to an animal used in your project?

Adult zebrafishes are anaesthetised and placed ventral side up on a damp sponge. A small incision is made through the chest to access the heart. A small part of the ventricular wall is freeze-injured by applying a cryoprobe precooled in liquid nitrogen. Fishes are returned to water and after overnight recovery from surgery the fishes are taken back to the aquarium facility. At 1-365 days after injury, euthanasia is performed by an overdose of anaesthetics.
For skeletal muscle injury, the tail musculature of the anesthetized fish will either be injected with a small volume of a toxin, cryoinjured with a cold probe, or wounded by a needle. These treatments are causing skeletal muscle injury. The healing response will be studied usually in the next four weeks and not longer than 6 months after surgery. Animals will be euthanised at the end of the experiment.
These proteins are important regulators in stress signalling, which in the heart lead among other responses in a faster heart rate. In case these stress-sensing genes are not functioning properly the response to stress is causing an abnormal heart beating. We want to elucidate the underlying cellular and molecular causes of this abnormal stress response. Mutants will be subjected to electrocardiography (ECG) analysis at baseline and after injecting substances, which trigger a molecular stress response. Under these circumstances, the mutant heart will display an abnormal heart beating pattern, which will help us to define the underlying molecular mechanisms. ECG analysis is a non-invasive method. After anaesthesia the animals will be placed ventral side up on a damp sponge and the ECG electrodes will be lowered on the body surface of the fish in order to pick up the electrical signals. Substances will be injected into the abdominal cavity at the appropriate volume and dose and subsequently returned to continue ECG analysis. The procedure will be repeated up to five times in order to study changes in clinical phenotype as a function of age of the animal. Animals will be euthanised at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that do not recover from cryoinjury normally die in the first 24 hr after surgery. Usually, the mortality of the procedure is around 10%. Successfully operated animals do not display signs of discomfort and are swimming and feeding normally. The animals will be studied usually up to 90 days after injury and in some cases up to one year after surgery.

Animals subjected to muscle injury will show no mortality and only some minor discomfort due to the muscle injury, which however will improve as regeneration will take place. The animals will be studied usually up to 4 weeks after injury and in some cases up to six months after surgery.
Animals subjected to ECG analysis are expected not to show any mortality and the procedures will only transiently cause an abnormal heart beating, which will return to nearly normal heart beating at the end of the procedure.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- Heart lesioning is a severe procedure and 10% are expected to experience this severity level while 90% will have a moderate outcome.
- Muscle lesioning is a moderate procedure and 100% of the animals are experiencing this severity level.
- ECG phenotyping is a mild procedure and 100% of the animals are expected to show this severity level.

What will happen to animals at the end of this project?

- Killed
- Kept alive

A retrospective assessment of these predicted harms will be due by 02 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our aim is to model heart and muscle disease found in patients carrying mutations in genes involved in stress sensing. These diseases are complex and are only partially modelled using cell culture models. Moreover, we want to study heart and muscle regeneration. Also in this case, cell cultures only can model certain aspects of the wounding response Regeneration of heart and skeletal muscle involves many different cell types. These processes therefore too complex to be investigated in cell culture. While the work in animals will be complemented with experiments in cultured cells, a complete substitution of animal work is currently not possible.

Which non-animal alternatives did you consider for use in this project?

We also work with primary cultured cardiac myocytes, frog oocytes and other cell lines. Some of our work involves preparations of the whole heart or part of it, which are maintained in a viable and functional condition outside of the body for several hours, which also helps to limit the number animals used for our research.

Why were they not suitable?

Work in isolated cardiac muscle cells, frog oocytes or cell lines are suitable for certain aspects of our research. However, these cell models do not show the full spectrum of responses that we see in the intact animal and therefore are not sufficient to fully substitute the work in animals.

A retrospective assessment of replacement will be due by 02 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animal numbers are estimated based on the demand of the previous license.
Protocol 1 Obtaining Zebrafish Gametes (mild procedure): We estimate the need for approximately 100 adult fishes for five years.
Protocol 2 Generation of Founders (F0 Generation) (mild procedure): We estimate the need for approximately 500 adult fishes per 5 years. The production of transgenic animals is a routine procedure. However, depending on the genetic manipulation several attempts might be needed before the right genetic alteration is observed. For the generation of single mutations sometimes only 1% or less of the injected oocytes contain the correct genetic alteration.
Protocol 3 Breeding and Maintenance of Genetically Altered Zebrafish (mild procedure): The number of fishes required for the maintenance of the various lines (breeding as well as the crossings to generate homozygous animals or crossing in any reporter gene or transgenes) will amount to 5,000 adult fishes for five years.
Protocol 4 Heart Lesioning (severe procedure): We estimate a total of 1,500 adult fishes for five years to allow for a detailed analysis of the regeneration defect in the mutants. For some of the examinations, the small size of the fish heart will require the use of several animals per time point to obtain sufficient amount of tissue.

Protocol 5 Skeletal Muscle Lesioning (moderate procedure): We estimate a total of 500 adult fishes for five years

Protocol 6 Phenotyping (ECG) mild procedure: We estimate a total of 500 adult fishes for five years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase, we will utilize online tools such as the NC3R Experimental Design Assistant in order to reduce the number of animals used in this project. We minimise live animal use by capturing as much ex vivo and in vitro data as possible from each animal. A large part of the experimental work in my group is carried out ex vivo. The PREPARE guidelines will be utilised to optimally plan a new set of experiments and to avoid any duplication of efforts. The ARRIVE guidelines will be followed and in particular the ARRIVAL Essential 10 in order to standardise the reporting of animal research and improve the reproducibility of the research outcome.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continuously trying to optimise the breeding and genotyping of the animals. We will also do pilot studies if a new experimental protocol will be implemented. In order to estimate the required numbers of animals to find significant differences between experimental and control group. If possible, tissue will be used for different experiments
A retrospective assessment of reduction will be due by 02 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement
Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Zebrafish is an established model for biomedical research and the genetics and working protocols are very well developed. We breed the least number of animals for line maintenance and for the various experimental protocols. Injury triggers heart regeneration in zebrafish and the molecular response is very similar to those observed in higher vertebrates including the human heart. Cryoinjury is a less invasive procedure than surgical resection, which is causing bleeding and therefore may cause a higher mortality. Importantly, cryoinjury triggers transient scar formation and therefore models the situation after myocardial infarction in the human heart quite well.

Why can’t you use animals that are less sentient?

For the purpose of studying gene function, most of the scientific research we are planning requires the use of adult stages. This is for example true to model heart and muscle disease in patients or to study the role of these genes in cardiac regeneration. While regeneration could in principle be also studied in the immature larval stages, at this developmental stage many of the cell types present in the adult heart are not yet present. Observations made at this stage will therefore not be directly applicable to the adult heart. Similarly, patients develop muscle and heart disease in response to mutations only as young adults at the earliest, some of the mutations trigger a late onset of the disease and only appear when patients are in their forties or even older. Therefore, it is mandatory to study the role of these genes in the adult zebrafish.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have noted and incorporated a number of refinements to each protocol since we started to use zebrafishes more than 15 years ago. We continue to monitor animals closely, and with NVS constantly assess possible improvements in post-operative care, pain management, and animal environments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the latest guidance of publications by the zebrafish community such as: Aleström P, D'Angelo L, Midtlyng PJ, et al. Zebrafish: Housing and husbandry recommendations. Lab Anim. 2019;23677219869037. doi:10.1177/0023677219869037. We follow PREPARE guidelines, plan and conduct studies according to the ARRIVE guidelines and use NC3R guidelines to ensure our animal experiments are as robust and reproducible as possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are regularly attending scientific meetings and talk to colleagues using the zebrafish model. We read the monthly updates from the NC3Rs on their events and publications and their e-Learning resources all of which detail advances in 3Rs technologies and best practice and provide information how to put these in place.
A retrospective assessment of refinement will be due by 02 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

24. Circadian regulation of pulmonary immunity

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Lung, Circadian, Inflammation, Immunity

Animal types	Life stages
Mice	juvenile, adult, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how the circadian clock interacts with the immune system to regulate how the lung responds when faced with a challenge via a biological agent that causes disease or illness.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Pulmonary diseases such as asthma and chronic obstructive pulmonary disease (COPD) affect 1 in 5 people in the UK, and prior to the outbreak of COVID-19 in 2020, lung diseases were responsible for more than 700,000 hospital admissions in the UK each year (data from the British Lung Foundation). The symptoms of chronic pulmonary inflammatory diseases, often show daily variation in their occurrence, worsening during the night. Similarly, biomarkers used in the clinics to assess disease severity fluctuate over the course of the 24h day. The circadian clock is a timing mechanism which synchronises animal physiology to the 24h environment created by the earth rotating on its axis. This biological timer regulates numerous aspects of physiology, including sleep wake cycles, feeding and metabolism, hormone secretion and the immune system. Disruption of the circadian clock is associated with increased prevalence of inflammatory diseases, including pulmonary disorders.

The circadian clock plays a critical role in regulating the normal working of the immune system and ensuring appropriate inflammatory responses are mounted when the system is challenged. This work investigates mechanistic links between the biological timing and immune systems to understand the involvement of the clock in regulating pulmonary physiology. An ultimate goal of these studies is to reveal novel therapeutic targets or improve existing therapeutic regimes to treat pulmonary disease through the use of biological timing (chronotherapy).

What outputs do you think you will see at the end of this project?

A major output from this project will be an advance in our knowledge regarding circadian control of immune responses within the pulmonary system. More specifically, information generated from these studies will contribute to our understanding of how the circadian timing system affects the development and progression of human pulmonary diseases such as chronic obstructive pulmonary disease (COPD), asthma and pulmonary fibrosis. This information will further our understanding of how circadian disruption (a consequence of rotating shift-work) may impact on lung function in both health and disease. Additionally it is predicted that data generated by studies outlined here will have a positive impact on the diagnosis and treatment of human pulmonary disease. An example here is the implementation of chronotherapy (for example timing therapeutic interventions with the peak of disease symptoms) to treat asthma.

In order to maximise these positive benefits, it is essential that information obtained from studies outlined here is disseminated effectively. This will be achieved through: publication in academic journals (reaching basic scientists and clinicians); presentation of data at seminars and conferences (targeted at clinicians and basic scientists); and through public engagement events.

A secondary benefit of this programme of work is the advancement of research methods. This may be in the form of refining or enhancing current methods or through the development of new transgenic mouse lines. Furthermore, the data generated from this project will be made available to other researchers in the scientific community at the earliest appropriate time therefore informing further scientific discovery within our research community.

Who or what will benefit from these outputs, and how?

Healthcare sector: Outputs from this research will be of benefit to the healthcare sector. There is a growing

understanding of the importance of considering circadian time in the diagnosis and treatment of pulmonary disease. This work will further develop our knowledge of how the circadian timing system interacts with processes underlying human pulmonary conditions. It is hoped that these studies will promote further incorporation of "clock logic" into clinical practice in the long-term. That may be through standardising the time of day at which a patient's blood or sputum is sampled for a disease biomarker, or through recommending the best time of day at which to take medication.
Scientific community: This programme of work will generate new research tools and advance research methods which will be shared with the scientific community (through publications and seminars) in order to benefit scientific discovery worldwide longer term. Although the focus of this project is pulmonary disease, pathologies and processes underlying these diseases are applicable more broadly in the field of immunology. Thus data generated in this project will advance our basic understanding of clock control of immunity and will be of benefit to the wider research community. Data will be disseminated at the earliest opportunity benefitting the scientific community as soon as possible.
General public: The importance of the circadian clock and good sleep hygiene for maintenance of health is becoming widely recognised by the general public. Information obtained through this project will be of interest to the general public, including people engaging in shift-work and patients suffering with pulmonary disease. It is becoming more and more evident the disruption of the circadian clock has negative consequences on health. Whilst sometimes circadian disruption cannot be avoided (e.g. shift workers), for some individuals small lifestyle changes may have a positive impact on health. In order to engage the general public we will continue to reach out via public engagement events run by the University and charities.

How will you look to maximise the outputs of this work?

Outputs from this work will be published in highly visible journals targeting a multi-disciplinary audience. The research group has an excellent track record of publishing data in high impact journals read by basic scientists and clinicians. Furthermore, through the use of social media (Twitter) and the establishment press office, we will publicise these publications as widely as possible in order to engage with the general public. In the past, this has led to opportunities to present our research on the radio, television and news websites. We appreciate that it is important to disseminate negative findings to minimise replication of experiments across research institutes. In addition to publication of articles, on going work will be presented at international and national meetings aimed at circadian biologists, immunologists and respiratory clinicians.
To maximise the benefit of our research we will continue to engage with the general public and relevant patient groups through organised events. These activities are important for maintaining public interest in our research and also further developing trust in UK research.

Species and numbers of animals expected to be used

- Mice: 24 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These studies will utilise juvenile and adult mice, which may be genetically modified. Mice are the most appropriate species for these studies as the systems which we are studying here (the body clock and immune

system) are well reproduced between mice and humans.

Typically, what will be done to an animal used in your project?

Animals may be monitored non-invasively for behaviour under normal or altered environmental conditions (typically for periods lasting 2-6 weeks). These environmental manipulations include changes in the light/dark cycle, changes to the composition of the diet, or changes in timing of food availability. More rarely, animals may undergo physiological monitoring using implanted telemetry devices (requiring a brief surgical procedure) or imaging facilities (under recovery anaesthesia). Rarely repeated imaging may be utilised (up to 8 times in one day). Changes to rhythmic biological signals (such as glucocorticoid hormones, melatonin hormones or microbial metabolites) may be instigated through implantation of hormone pellets under the skin (brief surgical procedure) or through application of antibiotics.
Approximately one third of the animals utilised in this project will undergo a procedure to induce pulmonary inflammation. To instigate pulmonary inflammation one of four approaches will be utilised, each modelling a different human chronic inflammatory disorder. (1) Inflammatory mediators (e.g. lipopolysaccharide - a component of the bacterial cell wall) may be applied acutely (20 minutes) via an aerosol to directly target the lung. (2) Allergic inflammation may be induced via application of a reagent that the animal has previously been sensitised to, such as house dust mite. (3) Fibrosis of the lungs may be induced through brief local application of reagents that cause local lung injury (bleomycin) resulting in tissue remodelling in the longer term (2-4 weeks). In rare instances animals which have developed fibrosis will receive a second inflammatory insult of aerosolised lipopolysaccharide (a bacterial product). (4) Animals may undergo a surgical procedure (under terminal anaesthesia) where the lungs are mechanically ventilated for a period of time. Prior to, or during these four procedures the immune system may be manipulated, this includes the application of reagents to target specific pathways (e.g. through the use of antibodies). On rare occasions the immune system may be manipulated further through irradiation to deplete host haematopoietic cells before replacement with donor cells. Additionally, reagents may be administered which target the clock or the immune system to establish their effects on inflammatory processes.
Animals utilised in these models of lung inflammation may be assessed using *in vivo* imaging, collection of small volume blood samples and/or assessment of respiratory mechanics (under terminal anaesthesia).
In addition to these procedures, mice will be used in this project for breeding, and for provision of cells and tissues for *ex vivo* studies.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may experience mild adverse effects such as temporary stress or brief pain and discomfort. Temporary stress may be induced by a brief period of restraint (e.g. in order to administer an injection) or alterations in their housing environment (e.g. single housing or alteration of the light cycle). Mice may experience a brief period of pain and discomfort in response to dosing (e.g. injection or intra-nasal dosing) or blood sampling, or following surgical intervention to implant a telemetry device or hormone pellet. In these instances the stress and discomfort will be transient.
Weight loss may occur after manipulation of the diet (either through altered timing of food availability or altered composition). Weight loss will be transient and will either reverse and return to the starting level as the animal fully adjusts to a new regime (e.g. food available only during the daytime) or may stabilise below the starting level if the total amount of food available is reduced. Furthermore, administration of antibiotics in the drinking water and irradiation protocols may results in transient weight loss.
Acute models of pulmonary inflammation are associated with transient discomfort and stress due to application of inflammatory reagents and may result in brief periods of mild respiratory distress. The chronic models of pulmonary inflammation (allergic inflammation and fibrosis) may also be associated with longer periods of mild respiratory distress (hours), transient weight loss and occasionally loss of condition.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The studies outlined in this project will result in a cumulative impact to the animals that are subthreshold to mild (approximately 60 percent) or moderate (approximately 40 percent) severity rating.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In the context of organ-level inflammation, it is currently not yet possible to replicate the complex multicell environment underpinning disease. Thus, *in vitro* cellular models and *in silico* models have limited application as a replacement for studies of pulmonary inflammation. In order to study complex interactions between the circadian timing system and immune responses occurring in the lung, mouse models are the most appropriate approach.

Which non-animal alternatives did you consider for use in this project?

In vitro approaches include the use of single-type cell lines or co-culture systems (where two or more relevant cell types are studied together). We utilise these methods to inform the direction of animal studies. *In vitro* assays can be used to test how genetic or pharmacological interventions alter the function of the cell intrinsic clock and/or regulation of inflammatory processes. For example, *in vitro* assays using cell lines or primary cells allow us to first test a diverse range of potential therapeutic interventions and identify a small number of candidate molecules with the most potential for subsequent use *in vivo*. However these approaches cannot replicate the complex environment of the lung and cannot replace the use of animals.

Why were they not suitable?

We have successfully utilised cell lines (such as Human Bronchial Epithelial Cells) to examine circadian control of inflammatory responses. Furthermore, on going projects in the laboratory involve exploring the potential of various cell lines in monoculture or co-culture to help address our research questions. However, it is critical that any cell lines utilised are circadian rhythmic. Our experience here however, is that cultured cell lines are often non-rhythmic, in contrast to the situation *in vivo* where they may be rhythmic. This may be an artefact of multiple passages of cell lines, or due to the absence of other signals (hormones or cytokines) that these cells would normally be exposed to *in vivo*. Thus their use is somewhat limited. Furthermore, *in vitro* assays cannot adequately model the complete array of inflammatory responses or address how systemic timing signals may modify these responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been

taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our grouping has extensive experience with the methodologies and approaches outlined here and of running projects of a similar scope. Consequently, estimates of animal numbers are based firstly on previous experience with the models to be utilised and the types of data generated, and secondly with careful consideration of the experimental design.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Throughout the duration of this licence, we will carefully consider the design of each experiment. As the project develops, and we build up further data sets, we will utilise this information to further refine the experimental design. When considering the design of experiments underpinning this project we have consulted with statisticians to gain specialist advice on the types of experiments that will be undertaken and the nature of the datasets that will be collected. We will continue to do this as the work develops. We will be utilising purpose written software (such as the NC3Rs Experimental Design Assistant) to further support experimental planning and randomisation and blinding.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Throughout this project we will continue to strive to optimise animal use wherever possible. This starts with efficient breeding of transgenic mouse lines, achieved through close monitoring of colonies which is facilitated by the use of specialist colony management software and effective communication between our laboratories and technical staff managing the colonies. We aim to minimise numbers of animals bred whilst still achieving adequately powered, age and sex-matched groups of experimental animals. When individual projects have been completed and data is being prepared for publication, breeding of relevant mouse strains will be minimised until a suitable time to preserve the colony by freezing down gametes.
Pilot studies are utilised to optimise experimental conditions when we are developing new approaches. Where it is appropriate we utilise technologies that permit longitudinal assessments in the same animal. Furthermore, we always look to maximise the amount of data that we can gather from a single sample using the latest technologies to their full capacity (for example using mass cytometry to assess expression of numerous proteins in one individual cell).
At the end of each experiment we carefully consider which tissues to collect with future studies in mind. By building a well archived tissue bank we are able to utilise existing samples in the laboratory to test new protocols or reagents (e.g. new antibodies) without the need to utilise further animals. We also make our banked tissue available to our collaborators.
Through providing our collaborators and the wider scientific community with access to data generated through our studies (through depositing large datasets in online data repositories) we aim to maximise the scientific knowledge than can be obtained from our animal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A substantial proportion of the methods that we will use in the project are non-invasive and involve environmental manipulations to study effects on circadian physiology and/or immunity. This includes manipulation of the lighting, meal composition or meal timing. These processes themselves are unlikely to cause suffering or distress. On occasion these manipulations may require animals to be single housed, to minimise potential distress in this situation, where possible we will supply mice with environmental enrichment (e.g. plastic tubes, plastic igloos, wooden logs or nestlets). Some animals may be subject to a brief surgical procedure to implant a telemetry device or hormone pellet. We have significantly refined our approach to glucocorticoid hormone replacement by establishing in previous studies that it is not necessary to surgically remove the adrenal glands (the major source of these hormones) prior to pellet implantation. This has reduced requirements for surgical intervention and improved recovery times.
Where we seek to administer reagents to experimental animals we utilise the most refined route of administration possible. For example, we routinely administer antibiotics in the drinking water rather than through oral gavage. Furthermore we always seek to minimise the numbers of doses of a treatment in order to achieve our objective, this may involve pilot studies to identify an optimal dosing regime.
This project involves the use of models of pulmonary inflammation. We chose to use the most refined models available to address our experimental objectives. For example in order to establish a local acute inflammation within the lung, we utilise aerosolised administration of lipopolysaccharide (a component of the bacterial cell wall) rather than dosing with bacteria itself (e.g. Streptococcus pneumoniae, which induces a more profound inflammation which can rapidly spread to the periphery). Other models we utilise include administration of a chemical to the lungs which causes local tissue damage and scaring, which has been optimised in terms of dosing route, dosage and time post administration in order to induce a robust and consistent response whilst causing the least harm and suffering to experimental animals. Models of allergic inflammation utilised in this licence are relatively mild with the period of lung inflammation an animal experiences being minimised as much as possible whilst not compromising experimental aims. Further, assessment of respiratory mechanics in these models is performed utilising *in vivo* approaches which generates the most robust and reliable data and is performed under terminal anaesthesia.

Why can't you use animals that are less sentient?

We cannot replace these studies in mice with studies in another species (such as insects or fish) to achieve our objectives, as they lack the complex immune and circadian systems seen in higher order species. Whilst we are able to carry out some of our studies in terminally anesthetised animals (for example lung ventilation studies) this is not appropriate for the majority of our pulmonary inflammatory models as they take a prolonged period of time to initiate disease and/or we require longer term assessment of disease progression.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely seek to minimise stress and discomfort to animals during our work and achieve this by ensuring all researchers utilise appropriate animal handling techniques (e.g. tube handling to remove animals from their cage) and by using environmental enrichment wherever possible, especially in instances where it is necessary to singly house an animal.
Occasionally animals may undergo a brief surgical procedure (e.g. to implant a telemetry device or hormone pellet). After surgery, animals are closely monitored and post-operative care provided (pain management with analgesics and provision of extra fluids). Analgesics may be provided in the form of a palatable gel to encourage voluntary ingestion.
Animals which develop allergic pulmonary inflammation or pulmonary fibrosis are monitored regularly, including monitoring weight loss and general condition. Where transient weight loss is expected as a consequence of this condition, soft food (wet mash) will be provided on the cage floor as well as environmental enrichment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure that our experiments are conducted in the most refined ways we continually assess our experimental design and re-assess approaches if the opportunity arises. We stay informed about best practice guidelines by referring to information provided by Laboratory Animal Science Association (LASA) and NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group stays informed about recent advances in 3R approaches by staying up to date with NC3Rs recommendations and developments. This information from the NC3Rs is obtained through interaction with their website, local seminars, contact with their staff and through social media (Twitter). We also discuss further refinement opportunities with our NVS and NACWO and through interaction with colleagues at conferences, workshops and seminars.

NON-TECHNICAL SUMMARY

25. Complement in chronic kidney diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

proteinuria, kidney failure, complement, fibrosis

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The finding of protein in the urine (proteinuria) identifies a group of patients at risk of kidney failure. These patients are most likely to develop progressive kidney disease and to need dialysis, but there have been no new treatments for over 20 years. Leakage of protein into the urine in kidney diseases causes damage to cells lining the kidney tubes ultimately resulting in scarring and loss of normal kidney function. Proteinuria is damages the kidney by activating in the kidney an element of the patients' own immune system - known as the complement system. Targeting the complement system is therefore an attractive option to treat kidney disease. There are

several new genetic models in mice and complement inhibiting agents that could be used to explore this potential therapeutic avenue.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project is therefore of direct relevance to human disease. Currently there have been no significant advances in treatments for chronic kidney disease for 20 years. Increased knowledge of the underlying mechanisms of kidney diseases has shown how proteinuria is of key importance, and new understanding of the pathological pathways activated in the kidney under these circumstances has provided new opportunities. Complement has been shown to be of key importance in kidney diseases. At the same time new modifiers of the complement pathways have become available as potential therapies. Therefore resting these potential therapies in these models is timely and likely to be very beneficial. A positive outcome will lead to direct evidence to support the design of new clinical trials in patients with proteinuria and kidney disease. These findings may be very generalisable to patients with a wide range of kidney diseases and will reduce the numbers requiring dialysis or transplantation. Furthermore new markers of disease and response to treatment will be identified.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The project will use mice – either normal wild type mice or mice genetically manipulated to modify their complement system.
The project may require up to 1750 animals.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Animals may be subjected to the removal of one kidney or the obstruction of a ureter at surgery, and other less invasive procedures. These are of moderate or lower severity. Repeated injections of ip saline or BSA solutions have been reported to cause pulmonary oedema. This is mitigated by minimising the volumes injected, and the protocols are based on the literature and our own previous experience. Trauma from repeated injections is minimised by varying injection sites. Adriamycin can be associated with systemic toxicity and death in mice if given at too high doses. This will be avoided by minimising doses administered according to previous experience and the published literature. Previous experience shows us that these procedures are generally well tolerated since we have previously performed similar studies have refined the techniques.
Animals will receive analgesia and close monitoring for distress. Humane endpoints will be determined according to daily observations recorded and scored using score charts (see embedded). These observations will focus on parameters based on body weight, coat condition, body functions, and behaviour, with each parameter assigned a pre-determined severity score. It is anticipated that the great majority of animals will not meet these endpoints and will reach the planned end of the experimental protocols.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The objective is to study mechanisms by which complement participates in progression of kidney diseases. While cell culture models have allowed valuable progress to be made, these are imperfect to model of the behaviour of whole kidneys which comprise multiple different cell types. Many kidney cells in culture also lose many of their specialised functions and do not properly resemble the same cells in a whole kidney. In view of this complexity, non-animal techniques, such as mathematical modelling, are unable to reproduce the necessary complexity.
For studies of inflammation, interactions between kidney cells and infiltrating cells, such as white blood cells, that occur during inflammation cannot be modelled without knowing the cell populations involved, which can only be determined in animal models.

Reduction

Explain how you will assure the use of minimum numbers of animals.

To minimise animal numbers we draw heavily on our experience with these models and the numbers in groups needed to obtain significant results. Power calculations have also been used derived from the published scientific literature.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Mice will be used for these studies to allow us to exploit the local availability of genetically altered mouse strains which will enable us to test more effectively the underlying mechanisms of complement involvement in kidney disease.
The study proposes to use the most refined versions of proteinuria or ureteric obstruction currently available in mice. Unnecessary animal suffering will be further minimised by drawing on our previous experience with these experiments and by refining our techniques where necessary using pilot studies with small numbers per experimental group.
Mice are the most relevant species to use and have previously been used successfully to generate rodent models of renal disease relevant to human disease.

NON-TECHNICAL SUMMARY

26.Consequences and complications associated with diabetes

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Diabetes, Hypoglycaemia, Hyperglycaemia, Complications

Animal types	Life stages
Mice	juvenile, adult, neonate, pregnant, embryo
Rats	juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

This project will investigate the impact of diabetes, and in particular how fluctuations in blood sugar levels (glycaemic variability; GV) affect organ systems such as the brain and heart. By examining the effects of glucose dysregulation on organ function and/or integrity we hope to identify the underlying mechanisms that may lead to diabetes-associated complications.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The incidence of diabetes is increasing exponentially and with the age of the population rising the incidence of diabetes-associated complications will be a huge financial and societal burden. Improving our understanding of the mechanisms underlying these complications may improve our treatment strategies and minimise the long-term consequences.

What outputs do you think you will see at the end of this project?

The immediate outputs of this project will be scientific publications in high quality, peer-reviewed, high impact journals appropriate to the field of research, communication to relevant national & international scientific conferences and press releases disseminating the research findings.

Who or what will benefit from these outputs, and how?

The findings of this research will, in the short term, improve our understanding of factors that may contribute to complications associated with diabetes. For example, if we identify that oxidative stress plays a pivotal role in the development of the cognitive dysfunction associated with diabetes, we will look at measures to reduce this such as antioxidant supplementation. These findings will be disseminated to the wider community through interaction with our clinical collaborators, publication in peer-reviewed journals and presentation at local, National and International meetings. In the long term, the findings of these studies will be translated into the clinic. By working closely with our clinical colleagues, we hope to ensure that our animal models recapitulate the human condition as much as possible.

How will you look to maximise the outputs of this work?

The output of this work will be published in peer-reviewed journals and presented at National and International conferences. We will continue to work in close collaboration with clinicians and with other collaborators within the scientific field. A paper is in preparation to describe in detail the mouse model of Type 1 diabetes that we have developed and techniques that we have optimised (e.g blood sampling from the tail vein without restraint) to disseminate this knowledge to the wider scientific community. The publication of negative data is crucial to minimise unnecessary experiments being performed and this will take place via platforms such as BMC Research Notes.

Species and numbers of animals expected to be used

- Mice: 1500
- Rats: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult rodents (mouse and rat) in this project as they are widely used in this field of research and share a similar physiological and behavioural response to hypoglycaemia as do humans i.e. polydipsia and polyuria at the onset of diabetes. The use of transgenic models enables us to examine the impact of individual genes on diabetes progression or response to hypoglycaemia. The complications associated with diabetes usually occur over a period of several years in humans and therefore we will study adult rodents in this project.

Typically, what will be done to an animal used in your project?

The animals (rat and mouse) used in this project will be made diabetic by the injection of a compound that preferentially destroys the insulin-secreting cells of the pancreas (beta-cells). We will then give the animals insulin replacement therapy to maintain health, in a very similar manner to insulin therapy given to individuals with Type 1 diabetes or long-duration type 2 diabetes. To mimic the hypoglycaemic episodes experienced by those on insulin therapy the animals will be given insulin injections and blood glucose allowed to fall to the hypoglycaemic range (<3.0mml/l). We know that this will lead to a suppression of the normal counterregulatory response to hypoglycaemia. We will then assess the impact that diabetes and/or hypoglycaemia have on aspects of cardiovascular function (Objective 2), cognition (Option 3), mechanisms that may be able to restore the ability to respond to hypoglycaemia (Objective 4) or how ischaemic preconditioning may alter the cardiovascular system in diabetes. These experiments will typically last 2-3 months, and animals will undergo no more than 8 procedures.

What are the expected impacts and/or adverse effects for the animals during your project?

We anticipate transient pain following injection of STZ however, this is minimised by using Hanks Balanced Salt Solution (HBSS) rather than citric acid that is normally used. The animals may be lethargic following STZ administration, but this is transient with normal movement and eating behaviour returning within an hour. Weight loss may occur in the week following T1D induction and confirmation of hyperglycaemia, but this is restored following implantation of the insulin pellet and better glycaemic control. Insulin-induced hypoglycaemia may cause transient discomfort at the site of injection and care will be taken to alternate the site of injection. The animals will typically become slow and lethargic during hypoglycaemia, initially, they may display foraging behaviour as glucose drops. Animals will typically become hypoglycaemic within 30 mins of insulin injection and will be monitored closely to minimise the chance of severe hypoglycaemia. If glucose continues to fall food will be provided and if the animal is unable to stand on all 4 paws dextrose will be administered to restore euglycaemia. This procedure will last no more than 2 hours (max 1 hour at hypoglycaemia). All animals undergoing surgical procedures will be given appropriate analgesia to minimise pain. Weight loss is likely to occur in the first 2 days following surgery, but soft food will be given to minimise weight loss. Guidance will be sought from the NVS and NACWO should any animal display signs of abnormal behaviour or any unexpected change in physical appearance.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Adverse effects depend on the studies being performed and mainly relate to surgery or the development of diabetes (approximately 60% of our studies), very much as we see in humans. Diabetes, as in human subjects is monitored by checking blood sugar levels and treated with insulin when needed. Surgical procedures such as

the insertion of a catheter into an artery or vein are of moderate severity and performed under general anaesthesia, this will account for <20% of animals on this licence. Pain killers are used routinely, and antibiotics as required. When animals have completed all the *in vivo* studies they are humanely euthanized.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Diabetes is a complex disease characterised by elevated blood sugar (glucose) levels and alterations in insulin production (Type 1 diabetes) or sensitivity (Type 2 diabetes). Although we can model some aspects of the condition *in vitro* for example the exposure of cultured neurons to high levels of glucose, this does fully replicate the interaction between different cell types (neurons, astrocytes, glial cells) or tissues that have a fundamental role in the development of many of the co-morbidities associated with diabetes. Replicating the complex and variable conditions that occur in a disease state such as diabetes is extremely difficult and limits the applicability of these models to disease.

Which non-animal alternatives did you consider for use in this project?

Where possible we perform studies in cell systems first to ensure that a candidate gene or pathway is important to the things we want to study. Subsequently, highly specialised techniques have been developed for measuring the animal's response to challenges such as low or high glucose and this means we can compare much smaller groups of animals. Techniques have been developed that allow us to study the animal while awake so we can conduct repeated tests on the same animal rather than using lots of groups.

Why were they not suitable?

Replicating the complex and variable conditions that occur in a disease state such as diabetes *in vitro* is extremely difficult due to the complex interaction between cell types and organ systems (pancreas, brain, liver, muscle, adipose tissue) and this limits the applicability of these models to disease.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals required for this project has been calculated based on previous experience using these models We have also estimated the number of pollutants and complex mixtures available for our research and the experiments required to understand their toxicity mechanisms.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design will be in line with ARRIVE guidelines and will follow NC3R guidance using the Experimental Design Assistant. Studies will be kept as simple as practically possible to maximise the information obtained from the minimum number of animals. Advice will be sought as necessary from statistical sources, locally or online, concerning the minimum number of experimental animals required to allow a sufficiently powerful statistical analysis.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use highly specialised techniques that have been developed for measuring the animal's response to challenges such as low or high glucose and this means we can compare much smaller groups of animals. Techniques have been developed that allow us to study the animal while awake so we can conduct repeated tests on the same animal rather than using lots of groups.

Vascular imaging will be performed in the same animal at several time points to establish a profile of disease progression/development, therefore, reducing the overall number of animals required.

In all cases, tissues will be collected and archived for subsequent analysis by both our group and others working in the field of diabetes.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse and rat models that we propose to use in this project are well-studied models used frequently in metabolic research which helps when comparing results to other groups. As sugar is a critical fuel for the brain for the rodent as it is for the human, we find that rodents like humans become fat and develop diabetes when given too much food. Also, they respond in the same way to both single and multiple episodes of low glucose as do humans with type 1 diabetes and so they are a good animal model to study.

We minimize welfare costs by using highly trained staff to conduct all our studies who have now many years' experience in working with animals and using the techniques we employ. New staff are rigorously trained. All studies are carried out following recommended guidelines under the guidance of the local veterinary team and in a facility with highly trained staff.

Why can't you use animals that are less sentient?

Diabetes is a complex disease and complications associated with diabetes develop over time. Terminal anaesthesia alters the hormonal and biochemical response to hypoglycaemia and therefore does not replicate the human condition.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Prior to any experimental procedures animals will be handled for a minimum of 1 week to acclimate the animal to the user and vice versa. Whilst on a study, animals will be weighed and body condition assessed weekly by PIL and/or trained staff at the animal resource unit. Following surgery postoperative care and pain management will be provided following advice from the NVS. We will use a refined method of diabetes induction through STZ injection by using Hanks Balanced Salt Solution
(HBSS; pH 7) rather than citric acid (pH 4.2) which is used as the standard vehicle for STZ administration. Likewise, recurrent hypoglycaemia will be performed in the animals home cage following a minimum of 2 weeks handling with blood samples from the freely moving animals from the tail vein. This is a well established procedure in the lab and we have demonstrated causes minimal suffering to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance for experiments will be acquired from LASA, NC3R and other appropriate websites.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will regularly visit the NC3Rs website and others recommended by the local named information officer.

Home Office

NON-TECHNICAL SUMMARY

27. Control of C. difficile Infection

Project duration

5 years 0 months

Project purpose

- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult
Hamsters	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our long-term aim is to develop a solution to the control of *C. difficile* infection. In the first instance this would be a prophylactic solution that prevents or reduces susceptibility to infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

C. difficile is a disease afflicting humans worldwide and in the UK almost 28,000 people are infected each year with over 1,000 deaths. Indeed, it is the predominant, antibiotic-induced hospital-acquired infection that is found in industrialised countries. This disease mostly occurs in the elderly and for those in hospital so it is important that this disease is controlled whether this be by vaccination or by the use of other interventions. No vaccine is currently available while existing treatment options are not 100% effective and often entail the use of antibiotics for which there is a globally recognised need to find alternatives.

What outputs do you think you will see at the end of this project?

This project should lead to significant improvements in our understanding of *C. difficile* infection, an important hospital-acquired infection that leads to more than 1,000 deaths annually. This work will be disseminated to the scientific community through publications and, it is hoped, to the wider community through press-releases etc. Most importantly, our work will support the development of new treatments for this disease either to prevent infection or for therapy. After 5-years, if not sooner, it is possible that we are ready to enter evaluation in humans.

Who or what will benefit from these outputs, and how?

This project should lead to the introduction of our prototype product into clinical evaluation and we anticipate applying for human studies (phase 1) within the tenure of this project.

How will you look to maximise the outputs of this work?

We would like to publicise our results and raise awareness. This would occur through publications, conferences and participation with advocacy groups with whom we sponsor.

Species and numbers of animals expected to be used

- Mice: 4,500
- Hamsters: 1,300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and hamsters will be used to evaluate the ability of vaccines or other novel interventions to prevent C. difficile infection. The scientific community working on this disease numbers several hundred groups worldwide

and all use mice and hamsters to evaluate the efficacy of emerging treatments. It is important that data generated here can be compared to related work that has been published. This is an important and critical step in developing a treatment for an unmet clinical need.

Typically, what will be done to an animal used in your project?

Animals will be given test vaccines or biological interventions by the oral route. Controls may include animals injected with the same or similar substance for comparison. Animals will then be given a course of antibiotics (in drinking water or by oral dosing) after which they will be administered an infective dose of C. difficile. This will be given orally and sufficient to cause infection. Animals will typically be housed in groups for 4-8 weeks but during the period of infection they will be housed individually in cages. In all cases animals are re-housed to 1 animal/cage 12-24h before the first administration of antibiotic in Protocols 2 and 3. Two types of infection will be assessed, a) colonisation, that is the ability of the pathogen (C. difficile) to grow and survive within the animal and b) virulence, which is the manifestation of symptoms of disease in the animal.

What are the expected impacts and/or adverse effects for the animals during your project?

For animals where colonisation is assessed animals will experience no symptoms nor discomfort. For animals where the virulence of disease is to be assessed the animals will experience some level of discomfort including lethargy, lack of appetite and mild diarrhoea. The period of this discomfort is likely to be at most 12h.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1: 100% of animals the severity is MILD
Protocol 2: Mice - 70% of infected animals will show symptoms (MODERATE) unless protection is observed. For hamsters, 100% of infected animals will show symptoms (MODERATE) unless protected.
Protocol 3: 100% of animals the severity is MILD
Protocol 4: Mice - 70% of infected animals will show symptoms (MODERATE) unless protection is observed. For hamsters, 100% of infected animals will show symptoms (MODERATE) unless protected.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

With current scientific product development a biologic with prophylactic or therapeutic properties (that is to be assessed in humans) it is required that efficacy is first demonstrated in one and preferably two animal models should they exist. In the case of C. difficile infection both mice and hamsters provide determination of whether a treatment option can prevent infection. Use of both animal systems is recognised by the worldwide scientific community as is evident from the plethora of international publications relating to this disease. Accordingly, regulators who facilitate evaluation of a biologic in humans will demand evidence that a product demonstrates efficacy using established animal models of infection.

Which non-animal alternatives did you consider for use in this project?

Currently, there are no non-animal alternatives available. It is worth emphasising that the decision to enter animal testing is itself determined by a number of in vitro tests that taken together support evaluation in animals. While in vitro tests are not confirmatory of efficacy they play an important role in the decision to evaluate in animals and the likelihood of success.

Why were they not suitable?

A disease caused by a bacterium is nearly always multi-factorial, that is, the manifestations of disease result from a number of independent events. For example, production of toxins, attachment to a substrate, induction of innate immunity etc. Each of these events can be assessed individually using in vitro tests and taken together provide an indication that a test product may work but only in an animal model can this be categorically defined as positive or negative.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous studies will have used power calculations to determine group sizes and the validity of these calculations demonstrated from previous studies. As a rule, numbers of animals used per group should be sufficient to enable statistical significance between groups. Since the studies contained here have the same primary objectives we can use the same group sizes. If the primary objective will be different a new power calculation will be performed to determine animal numbers.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In the long-term animal numbers are reduced by careful project design reducing the need for further experiments. A core tenant of the design of animal experiments is the correct use of statistics (for interpretation of significance) and power calculations (to determine group size). The level of variability in some primary endpoints necessitates larger numbers to achieve statistically and biologically meaningful data. The most appropriate statistical tests Mann-Whitney (or the students t-test) for significance and ANOVA for analysis of variance between groups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In our experience for studies are to be undertaken where large number of animals are to be used then small pilot studies using 2-3 animals/group are preferable. This is particularly important where a challenge dose must be determined or a dosing regimen established. Although statistical significance is not determined, in the long term, this avoids a negative outcome involving large numbers of animals.

Additional factors are to ensure the use of the same animal supplier (where possible) and the use of similar aged animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and hamsters (Golden Syrian) will be used to evaluate C. difficile infection using two basic approaches:
a) Asymptomatic colonisation. This model uses mice only and shows no symptoms of disease.

This model is informative for understanding whether a test product prevents proliferation of the pathogen (C. difficile) in the GI-tract. It can also provide data on the presence or absence of toxins.
b) Virulence models. In mice and hamsters using these models of infection animals will develop symptoms of disease. Using an accurate assessment of symptoms animals confirmed to be infected are killed before more acute symptoms develop ensuring minimal discomfort to the infected animal/s. To ensure accurate assessment frequent and then continuous monitoring of animals is undertaken and only using trained staff entirely familiar with the infection process and its associated symptoms in animals.

In general, vaccines and biological interventions are always tested first in mice using the asymptomatic models. Demonstration of efficacy in these models is then followed by evaluation in the asymptomatic models (mice preferred) if required and deemed necessary.
The least invasive route of substance administration and using flexible gavage needles will be used where possible. Negative control groups will be minimised whenever statistically feasible.

Why can’t you use animals that are less sentient?

Mice and hamsters are used since these are the lowest vertebrate group that can be used for in vivo evaluation of C. difficile interventions or vaccines.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Improvements in any process can always be made and we are receptive to any suggestions as well as our own assessments. We are keen to consider and if possible implement non-aversive handling of animals as well as practices for enrichment of quality of life for animals housed under solitary conditions. We will implement these where possible using only suitably trained staff and discussion with the host facility as necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R guidelines. We will follow the NC3Rs guidelines on the "Responsibility in the use of animals in bioscience research" and consult all the relevant references listed therein.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By interaction with the Facility Director. Continuous monitoring of publications and the NC3Rs website for new and alternative models that could be implemented as part of this project and relevant information is circulated by

AWERB. Whenever possible we will implement these refinements into our studies.

NON-TECHNICAL SUMMARY

28. Decision Making From Synapses To Circuits

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Decision making, value calculation, hippocampus, physiology, behaviour

Animal types	Life stages
Mice	adult, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We are working to understand how neurons in the brain communicate with each other to allow them to encode

emotional behaviours and make decisions.
A retrospective assessment of these aims will be due by 24 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Problems with the communication between neurons in the brain underlie the vast majority of neurodegenerative and neuropsychiatric diseases, and so our aim is to find novel ways to combat these diseases by gaining a greater understanding of the processes that they destroy.

What outputs do you think you will see at the end of this project?

The project comprises basic scientific research that will increase our understanding of how the brain supports decision-making behaviour. The outputs of this project will be new scientific findings, describing how neural activity in the hippocampus (and connected brain regions) supports value- and memory-based decision-making. The outputs will primarily take the form of publications in peer reviewed journals, but will also be disseminated at academic conferences and to the lay public via popular science initiatives. Materials, data and methods may, where appropriate, be disseminated online.

Who or what will benefit from these outputs, and how?

In the short timescale, the primary beneficiaries will be other scientists working in the field of learning and decision-making research. Our research will inform our fundamental understanding of how neural networks work in healthy adults, and how this is altered by experience during adolescence.
In the medium term, the basic science knowledge gained will likely inform broader fields of scientific enquiry, some of which have the potential for clinical translation. For example, understanding how memory networks malfunction after adolescent social isolation may inform strategies for developing new pharmaceutical or therapeutic interventions.
In the long-term, a detailed understanding of the neural-network level mechanisms for learning and memory will be an invaluable aid to designing interventions for mental health disorders of all types. For example, the neural circuit changes that promote the transition to mental illness are increasingly viewed to be extremely specific: effecting only specific cell types and the connections between them. Our research aims to uncover these specific alterations, and how they relate to specific behavioural phenotypes and symptoms. We hope that this will provide new druggable targets that are both potent and specific, and will allow for better, more personalised treatment, and the minimisation of off-target side effects.

How will you look to maximise the outputs of this work?

We will disseminate our research by publishing results in peer reviewed journals. We aim to publish all results, including those that do not confirm our hypotheses.
We will also present our work to academic peers at scientific conferences (national and international), and engage with the popular science media in order to disseminate our results to the general public.
Raw data and analysis methods will be shared with the scientific community (following peer-reviewed publication), to allow other groups to gain insights from our experiments, and reduce replication of work.

Species and numbers of animals expected to be used

- Mice: 7500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use adult mice. We know a lot about the anatomy and physiology of the mouse brain, and in particular of the parts of the brain to be studied in this project. Mice also offer unmatched access to genetic tools, allowing us to use genetic techniques to record from and manipulate functionally/genetically/anatomically defined ensembles of cells. Together with the ability of mice to rapidly and flexibly carry out value and memory guided decisions, this means that we are well-placed to fill in substantial missing section of our knowledge: how patterns of neural activity influences decisionmaking.

Typically, what will be done to an animal used in your project?

In the most typical experiment, mice will undergo a surgical procedure under general anaesthesia, to carry out chronic (long-term) attachment of devices for monitoring neural activity to the skull of the animal. Analgesia will be provided during the surgery and during recovery. Following recovery, the attached devices do not, in themselves, cause any pain or distress to the animal.
Animals will then undergo experiments in which neural activity is monitored simultaneously with behavioural testing. Mice will learn to play a 'game' where there are correct and incorrect answers - mice will be rewarded with sugar water when it chooses the correct answer.
Animals will typically be motivated to learn using appetitive (desirable) rewards such as sweet liquids such as strawberry milkshake, and minimal levels of water restriction. In a smaller number of experiments, mice may also learn using negative reinforcers such as air-puff to the face or mild static shock, or from psychostimulant rewards such as cocaine or amphetamine.
Neural recording and behavioural testing experiments typically continue for weeks, or even possibly months.
At the end of the experiment, animals will be euthanised, using an overdose of an anaesthetic agent.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals may feel pain or discomfort during the recovery from surgery (1-2 days). To mitigate this, analgesia will be given to the animal.
Some animals may experience more than average weight loss following food or water restriction. In these cases, animals will immediately be removed from the experiment and provided with freely accessible food and/or water.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

30% of animals will experience the severity category 'Mild'.
70% of animals will experience the severity category 'Moderate'.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 24 March 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

During this project we will investigate how the brain is connected to carry out specific functions, and how this wiring is altered by experience. Crucially we will also monitor how these circuits encode and respond to the environment during complex decision-making behaviours. In order to investigate this problem we have to study these neuronal circuits in animals as the animals carry out these behaviours.

Which non-animal alternatives did you consider for use in this project?

Computational modelling, in vitro cell culture, human research, research on less sentient animals (e.g. fruit flies / nematode worms)

Why were they not suitable?

There are no computer models or equivalent that can accurately and effectively model these phenomena, and so experiments on living tissue are required. The data obtained during this project will allow for more accurate and precise modelling in the future.
No cultured cell lines are available to study the mechanisms that control synaptic connectivity, and so acute tissue must be used.
Although implantation of chronic electrodes is possible in humans, it is only permissible in a small numbers of clinical situations, and therefore not practical to answer the questions proposed. While increasingly human brain slices are becoming feasible, again these are strictly limited, and most often from diseased tissue. In addition, the specificity required to understand the functioning of these circuits is beyond current human-based techniques.
Less sentient species do not have the homologous circuitry to the mammalian decision-making circuitry investigated in this proposal.

A retrospective assessment of replacement will be due by 24 March 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of experimental animals have been estimated using a) power analyses, b) experience from previous published studies of effect sizes, and group sizes necessary to test effects.
A pure power analysis approach is not always appropriate for in vivo neural recording experiments, as the number of animals required will depend on the success rate of neural recording (numbers of neurons per animal). It is therefore necessary also use estimates based on previous experience of similar experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will seek advice from the University's applied statistics advisors.
We will follow the ARRIVE and PREPARE guidelines and use the NC3Rs Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies, allowing us to explore whether hypothesised experimental effects may be present, before committing larger number of animals.
Technical developments which enable us to monitor the activities of larger numbers of brain cells in each animal.
Use of computational models that enable us to make highly specific testable predictions about the role of hippocampus and other structures during behaviour, minimising the number of experiments required to reach a conclusion.
Most procedures involve long-term experimentation with the same animals, which significantly reduces the number of animals needed to reach statistically significant conclusions.

A retrospective assessment of reduction will be due by 24 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The model animal used will be mice.
The major methods used will be:
Stereotaxic surgery. This is necessary in order to inject and implant substances to identify, record from and manipulate defined neuronal circuitry both in vitro and in vivo. Appropriate anaesthetic/analgesic regimens will be used to minimise pain. e.g. delivery of pre-operative analgesia, as discussed with the NVS and Animal Facility Staff.
Maximum injection / infusion parameters will be strictly adhered to. In the very unlikely case that this is not possible due to extenuating circumstances, any changes will be discussed with the NVS.
Behavioural training. This is necessary to assess cognitive capabilities in animals. The large majority of these tests will use only appetitive (rewarding) stimuli, hence the only harm is mild food or water deprivation.
In vivo neural manipulation and recording. This is necessary in order to be able to draw direct functional links between neural activity and behaviour. Neural recording implants do not cause suffering and distress in themselves, hence the potential for pain and suffering is confined to the post-surgical period (in which analgesia will be provided, see below for details).

Why can't you use animals that are less sentient?

Mice will be used for this project as they represent the least sentient species appropriate for this type of work.

Decades of research has also resulted in highly advanced and efficient techniques developed for the mouse as opposed to other species. For example, there are excellent stereotaxic maps of the mouse brain, allowing accurate targeting of injections to specific brain regions. Coupled with my expertise in stereotaxic surgery, this results in very high success rate in our experiments (greater than 80% success rate in targeting of brain regions).
The mouse is also high genetically tractable, allowing transgenic identification of specific cell types crucial to the fulfilment of the project
.
Finally, as the proposal aims to investigate how neurons are utilised during behaviour, terminally anaesthetised mice would not be appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Almost all of our behavioural tests will use appetitive (rewarding) stimuli, the only aversive tests used will involve, for example, bright lights/loud noises or mild air puffs. Animals will be motivated to seek reward using mild food (~20% of restricted animals) or water (~80% of restricted animals) deprivation. We will only use the minimum levels of deprivation necessary to achieve uniform consistent behavioural results.
Appropriate anaesthetic/analgesic regimens will be used to minimise pain. e.g. delivery of preoperative analgesia, as discussed with the NVS and Animal Facility Staff.

Maximum injection / infusion parameters will be strictly adhered to. In the very unlikely case that this is not possible due to extenuating circumstances, any changes will be discussed with the NVS.
Housing cages will be spacious and enriched with e.g. rodent toys, chewable materials such as wood, running wheels, shelter, unless these interfere with the experimental design. In addition, where possible animals will be group housed post surgery using strategies devised in collaboration with our local NVS and NACWO.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Local NVS and NACWO
Resources hosted on the NC3Rs website, in particular:
- ARRIVE guidelines on experimental design and reporting results.

- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.

- Rodent housing and husbandry

- Rat and Mouse Grimace scales

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep in constant contact with local NVS and NACWO to ensure we are maintaining best practice.
We will liaise with in-house NC3Rs representative to ensure we are up to date with current best practice.
We will use the resources published on the NC3Rs website to ensure that the group undergoes continuous training and professional development with respect to the 3Rs.
We will follow technological advances in the published scientific literature, allowing more efficient recording techniques (yielding more neuronal data per animal), miniaturising recording equipment (leading to a refined animal experience) or allowing recording in more naturalistic settings (for example, wireless recording).

A retrospective assessment of refinement will be due by 24 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

29. Defining the role of G protein coupled receptors in the brain and the therapeutic potential of targeting these receptors in neurological disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Alzheimer's disease, G protein coupled receptors, Schizophrenia, Pharmacology, Neurological behaviours

Animal types	Life stages
Mice	juvenile, adult, neonate
Rats	adult

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project licence is aimed at continuing studies on the role of G protein coupled receptors (GPCRs) in the regulation of the nervous system including brain and neuronal function and how we might target this class of cell surface receptors in the treatment of neurological disease. The GPCR family consist of many hundreds of different receptors and are the most successful drug targets known to man. Despite this the full potential of the GPCR family has yet to be realised. The reason for this is that we lack fundamental understanding of the biology of many of these receptors and how best to target them in disease. In this licence we will conduct experiments focused on the biology and therapeutic potential of GPCRs in the nervous system.
A retrospective assessment of these aims will be due by 20 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

GPCRs are involved in key neuronal processes such as learning and memory and that selective stimulation of certain types of GPCRs can relieve symptoms and slow progression of neurological diseases including neurodegenerative disease. Hence studying them can lead to better understanding of how the brain works and the design of drugs that can impact on diseases such as Alzheimer's disease.

What outputs do you think you will see at the end of this project?

In the neuroscience project we aim to establish the role of GPCRs in the regulation of neurological responses such as learning and memory, anxiety-like behaviours and locomotion. We also expect to determine the impact of GPCRs particularly the muscarinic receptor family in the symptoms and progression of neurodegenerative disease, schizophrenia and possibly other neurological diseases.
These discoveries will be disseminated in the following ways;

1. Peer review literature

2. Scientific meetings in the form of talks and poster presentations

3. To the general public in the form of press releases, public seminars and social media

We also expect these discoveries to result in further grant applications and both charitable and government grants.
In addition, we have the anticipation that these studies would change the direction of drug company research opening up new clinical trials and impact on drug discovery strategy.

Who or what will benefit from these outputs, and how?

Academic Community - will benefit from an understanding of fundamental biology of GPCRs and the understanding of the best ways to target GPCRs to regulate pathophysiological responses.
Pharmaceutical/drug discovery community – will benefit from the validation of new GPCR targets in human disease and an appreciation of the pharmacological principles that can be applied to drug design.
General public – will benefit from the prospect that new methods will be developed to apply to drug discovery against some of the currently most intractable diseases including Alzheimer's disease.

How will you look to maximise the outputs of this work?

In terms of publications in the scientific literature and presenting in research meetings we are very experienced in these areas with strong relationships with editors of the top journals as well as being well connected with organisers of major research meetings. Hence we anticipate that we will continue to have strong outputs through these routes. We have also been developing our outputs via social media with both institutional and personal social media outlets being developed. Finally we are improving our public out-reach with visits to local prisons, schools and presenting to politicians where we present our research and discuss animal research ethics.

Species and numbers of animals expected to be used

- Mice: 20,000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The overarching purpose of this protocol is to gain greater understanding of the role and therapeutic potential of GPCRs, or GPCR-regulated pathways, in later-stage neurodegenerative disease. The aim is to determine if by activating (or deactivating) GPCRs, or GPCR-regulated pathways, we can alter the electrical brain activity and biochemical processes in the brain to influence progression of neurodegenerative disease.
As such we are planning to test rodents models because we and others have established that these models closely resemble human systems and we can mimic human neurological disease. Hence by determining the activity of our drugs/substances and effects of our genetic modifications in rodent systems we are able to determine the role and therapeutic value of GPCRs. We can best do this in adult animals but we can also investigate how our receptors work by conducting studies on primary neuronal cultures derived from new born animals. Hence this study is best suited to adult and new born animals.

Typically, what will be done to an animal used in your project?

1. Animals (mainly mice but occasionally rats) will be inoculated with brain preparations made from animals or humans that have had neuroidegenerative disease e.g. brain preparation from prion diseased mice or brain preparations from humans that have died from Alzheimer's disease.

2. Animals (e.g. mice or rats that are either genetically modified and/or have neurodegenerative disease) can then undergo behavioural or neurological testing and/or live animal imaging and/or blood sampling and/or monitoring of body temperature and locomotor activity and/or monitoring electrical activity and brain signalling. These steps can be conducted both with or without administration of drugs/substances, that are either delivered minutes/hours before biochemical/electrical/behavioural testings (i.e. acutely) or days before testing (i.e. chronically).

3. The experience described in point 2 above will also be that of genetically modified mice expressing variant genes coding for GPCR receptor proteins and signalling pathways activated by GPCRs.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice are inoculated with misfolded protein such as prions/tau/alpha synuclein in order to develop progressive and terminal neurodegenerative disease. Although some of the animals in this protocol will be humanely killed before they reach late stages of disease a proportion of the animals (approximately 8%) will be maintained until late stages of disease, where they will likely develop physical symptoms, we propose a severe category. It is anticipated that some of the mice that enter late-stage disease may die before they arrive at a humane end point.
Furthermore, from our previous experience when testing for adverse responses to GPCR drugs approximately 2% of animals develop physical symptoms that can include pain, weight loss, seizures, or abnormal behaviour.

Other than this the drug/substances administration, behavioural, imaging, surgical and drug administration procedures described here will fall into mild category as described in the above protocol expect for an occasional (approximately 1%) a moderate.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 8% of mice/rats will be maintained until late stages of disease, where they will likely develop physical symptoms that result in a severe category.
Approximately 2% of animals develop physical symptoms associated with drug/substance administration that result in a severe category.
All other animals will fall into a mild category with occasional (approximately 5%) moderate .

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 20 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and

why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are using a number of sophisticated approaches to mimic brain responses thereby offering the opportunity to replace the use of animals in neuroscience research. This includes working with optic physicists to develop an "optical brain" that mimics brain activity using light and chemists who are similarly developing a "chemical brain" that responds to chemicals in the same way as a brain. However, currently none of these approaches come close to accurately mimicking brain activity. Hence to investigate the three primary areas of this project namely the processes that regulate brain activity via a group of proteins called G protein coupled receptors (GPCRs), ii) how we might change brain activity through drugs that act on GPCRs and iii) how we might cure the symptoms, and slow the progress, of neurodegenerative disease - we need to conduct experiments on animals.

Which non-animal alternatives did you consider for use in this project?

We will be using human brain tissue (both normal and disease) obtained from registered human tissue banks for the neuroscience projects described here.

Why were they not suitable?

Human tissue is preferable to mouse tissue however it is not possible to employ genetics to validate the receptor targets in human tissue. It is also not possible to trial drugs that target our receptors in humans - rather we can only test the response to our drug treatment in resected tissue or from post mortem samples. Hence we aim to combine the animal studies with human tissue studies to probe the function of GPCRs in human disease. The ultimate aim will be to subsequently develop drugs based on our findings to trial in human clinical studies.
A retrospective assessment of replacement will be due by 20 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have a great deal of experience in many of the behavioural and physiological experiments that the mice will be used in and have also a great deal of experience in the breeding and maintenance of our lines. Based on previous experience we have been able to apply power calculations in collaboration with statisticians. This has allowed us to estimate how many animals we need for the experiments described in this protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are constantly making attempts to reduce the number of animals in the following ways;

1. By conducting biochemical experiments, such as determining the changes in the proteins in the brain, we are looking for early markers of neurological disease that can give reliable indications of drug efficacy thereby reducing the number of animals and the time they are exposed to disease. This is particularly the case in the neurodegeneration studies but also in our inflammatory models.

2. We are using human tissue with increasing frequency to reduce the number of mice used. This tissue includes analysis of normal and diseased post mortem brain tissue that can be used for the determination of GPCR expression levels and testing the activity of GPCR drugs in a disease context.

3. We are using well described protocols such as elevated plus maze, novel object recognition and pavlovian fear conditioning that we are highly experienced in and therefore requires little to no training and few pilot studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have excellent management systems and data-bases in place to ensure efficient breeding and husbandry of the mice.
Where possible we also share tissue amongst users and importantly co-ordinate studies to most efficiently use mice. We also have a large tissue archive which is well indexed and stored.
These approaches will reduce the prospect of overbreeding.

A retrospective assessment of reduction will be due by 20 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

GPCR mutant mice
These will be used to directly determine the role of GPCRs in normal physiology and in disease. In particular we have developed mutant receptors that cannot be activated by the chemicals produced naturally by the body but instead be activated by drugs. In this way we can not only test the role of the target receptors in normal biology but importantly test the action of drugs that work by activating these receptors. Also we have developed GPCR mutant mice where the receptor is restricted in the number of signalling pathways that can be activated. Such receptor mutants can be used to determine the biochemical and signalling pathways used by receptors to mediate clinically important effects and distinguish these from pathways that lead to adverse responses.
These models are designed to directly test the modes of action of GPCR drugs. Without these models wild type

animals would be used. The issue is that wild type animals will display an array of responses a number of which are adverse such as pain, seizures and adnormal behaviour. These adverse responses are often due to off-target drug activity. The animal models used here reduce off-target activity and therefore reduce adverse responses.
Animals will be monitored and adverse responses measured using the criteria set out in the section keeping animals alive.
Neurodegeneration models
These strains will be used to determine the impact of GPCRs in the progression of disease and disease symptoms and whether targeting these receptors can modify disease.
Animals will be monitored and adverse responses measured using the criteria set out in the section keeping animals alive.
We will also use a range of genetically modified mice to investigate how GPCRs work in the brain and how these receptors relieve symptoms of neurodegeneration and slow disease progression.

Why can’t you use animals that are less sentient?

Where possible we will use early life stages (e.g. mouse embryos and neonates) to generate neuronal cultures and terminally anaesthetised animals for histology (e.g. perfusion fixation). However the neuroscience projects require models that most closely resemble human physiology and be models that can be genetically manipulated in this case mice are the most appropriate. Also we wish to test the action of receptors and drugs that might lead to new drugs for human use. The receptors and receptor system need therefore to closely relate to humans and therefore mammalian systems such as mice are the most appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are always looking for further refinement of procedures. For example we have been undertaking a study to determine biomarkers of neurodegeneration that can be used to establish early on in disease if targeting our receptors of interest impacts on disease before clinical signs appear. Hence, we will pilot experiments, reading the literature and discussions with collaborators be looking to minimise welfare costs.
Specially, if biomarkers can be identified then we will significantly reduce the number of prion infected animals that progress terminal stage of disease. Currently this step 1 is classified as severe since a proportion of these animals will be progressed to terminal end points. The biomarkers would predict terminal end points before the animals reached a severe category. Hence determination of disease biomarkers would reduce the number of animals progressing to a severe category.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our primary published source of guidance on 3Rs is via the national centre for replacement, refinement and reduction in animal research (NC3Rs). This organisation publishes regularly on guidance for researchers. The European Medicines Agency also publish excellent practical guidance on 3Rs. We also pay particular attention to the peer reviewed scientific literature for further methods to refine our protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have regular up-date sessions and training in new approaches run locally and nationally. We also keep abreast of the published literature and share good practice locally. Importantly, we also have expert collaborators that share good practice and we are always looking at new methods to improve our 3Rs.
A retrospective assessment of refinement will be due by 20 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

30. Detection of genotoxic substances

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  0
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs,foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

Genotoxicity studies are necessary for hazard assessment and are legally obligatory. The overall aim is to ensure that both new and existing chemicals do not present a potential carcinogenic, inheritable or otherwise toxic hazard to the public, patients and the environment.
This project will aim to evaluate the effects of chemicals, human and veterinary drugs, medical devices, food additives, biocides and plant protection products to see if they damage cells in animals. If substances damage cells it can lead to the development of diseases like cancer. The tests carried out in this project will identify genotoxic levels of these substances, to enable decisions about how hazardous they are, and so people can be better protected. These tests are legally required before products are exposed to the public by Governments around the World. **A retrospective assessment of these aims will be due by 03 January 2026**
The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A key benefit of this programme of work is the provision of safety data to facilitate sound regulatory decisions when assessing the risks to which humans when the test substances are produced, transported or used.
This work is vital to the development of safe substances (chemicals, human and veterinary drugs, medical devices, food additives, biocides and plant protection products) that people will come into contact with.

What outputs do you think you will see at the end of this project?

The output of this project will be the provision of safety data to facilitate sound regulatory decisions when assessing the risks to which humans, animals, plants or the environment are exposed when substances are produced, transported or used.

Who or what will benefit from these outputs, and how?

The overall benefit is to ensure that both new and existing chemicals do not present a potential carcinogenic, inheritable or otherwise toxic hazard to the public, patients and the environment.

How will you look to maximise the outputs of this work?

Development and validation of new tests or modifications to existing assays will lead to an improved battery of tests for hazard and risk assessment. In addition, many new tests or modifications may allow more thorough assessment of genetic hazard in one step, thus eliminating the need for extensive further testing and reducing overall animal usage. Wherever possible, data from multiple end points will be obtained from the same animal.

Species and numbers of animals expected to be used

- Mice: 5700
- Rats: 20000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rats and mice are the species specified in the regulatory test guidelines.

Typically, what will be done to an animal used in your project?

Test substance will be administered by oral, intravenous or parenteral routes of administration. Surgical procedures will be used if administration is by continuous intravenous infusion. The duration of dosing is typically 1-3 days, but may be up to 1 month to meet the scientific aim of the study; some studies may require a longer dosing period in order for adequate characterisation of dose response. Dosing may include wash out periods or interrupted dosing intervals.
Animals may be housed in specific cages for the collection of urine and faeces.
Blood samples may be taken by insertion of a hypodermic needle or from cannulae surgically implanted into blood vessels.

What are the expected impacts and/or adverse effects for the animals during your project?

In the majority of animals, there will be minimal adverse effects. Some animals are expected to exhibit some toxicity, but in these instances effects such as signs of pain or discomfort, or abnormal behaviour will mostly be short-lived, lasting for a few hours after dosing.
In range finding studies, some animals may experience severe toxicity, which could include mortality, in those instances where the effects of the substance are not yet known. Any animals showing severe signs will not be maintained and will be humanely killed at the earliest possible point. Most range finding studies will result in no more than moderate adverse effects that are tolerated for the duration of the study.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Based on previous experience, it is expected that approximately 80% of animals will be in the mild severity category, approximately 15% will be in the moderate severity category and approximately 5% will be in the severe severity category.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 03 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Regulatory guidelines require the use of animals to investigate genotoxicity. The *in vivo* tests are conducted because some agents are mutagenic *in vivo* but not *in vitro*. The *in vivo* tests also include additional relevant parameters such as absorption, distribution, metabolism and excretion, which may modulate the genotoxic effects of a test substance.

Which non-animal alternatives did you consider for use in this project?

The ECVAM database and other literature searches were conducted to determine if any non-animal alternatives were available. However, the animal study is preceded by an *in vitro* assay, the results of which are used to optimise the design of the animal study.
All studies will be assessed to verify that there is a need to conduct the study and that there is no other data or approach that could avoid *in vivo* tests.

Why were they not suitable?

No non-animal alternatives are accepted alone by Regulatory authorities. However, if there is data or previous test results available that mean *in vivo* tests are not required, procedures will not be conducted for that purpose.
A retrospective assessment of replacement will be due by 03 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These are based on the numbers used during the last five years and the expected demand for this service.
The requirements of the various tests and regulators will be followed so that only the required number of animals are used in each study.

What steps did you take during the experimental design phase to reduce the number of animals being

used in this project?

Standard study protocols are ethically reviewed against the known guidelines/recommendations, AWERB policies and any recent 3R's refinements. The reviews are undertaken by a committee comprising the Project Licence holder, NVS, NACWO and a lay person as well as other interested parties. Any study requested by a Sponsor that deviates from the approved standard design or involves a new animal related procedure or methodology is subjected to a specific ethical review by the AWERB to ensure all ethical considerations have been taken into account. Statistical advice from in-house experts may also be requested.
ICH promotes the assessment of genotoxic effects by including the relevant end-points into other toxicity studies that are required for regulatory submission. This has clear advantages in terms of animal reduction, however, the study designs must meet specific requirements, so that they are acceptable to regulators and that further animals studies can be avoided.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Regulatory guidelines define the minimum testing requirements for adequate data/statistical analyses for the majority of assays and the study plans used generally adhere to these guidelines/recommendations. Where no guideline recommendations exist, animal numbers are selected on the basis of published literature and/or internal validation data that identify the minimum number of animals required for adequate statistical power.
We will always seek to minimise the use of control groups and multiple dose levels, where this is appropriate.
A retrospective assessment of reduction will be due by 03 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rodents, specifically rats and mice, are the species of choice for these assays, as these species have the largest historical database available and have been routinely used in Genetic Toxicology testing for several decades. Genetically altered animals may also be used. Only animals without an adverse phenotype will be used.
The methods used (dosing, blood sampling techniques, handling and restraint, use of analgesia) will be reviewed during the life time of the licence and any refinements developed will be implemented.
Why can't you use animals that are less sentient?

The species used is generally the same as the rodent species used for the general toxicology studies. The toxicology and/or toxicokinetics from the general toxicology studies can then be used to inform dose selection, sample times etc for the genotoxicity tests, thus reducing animal usage. Species selection may also be driven by known absorption, distribution, metabolism or excretion (ADME) differences between rodent species.
The Regulatory test guidelines require the use of young adult animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Under current regulatory requirements, it is necessary to perform genetic toxicology studies at doses that produce a degree of toxicity, usually in terms of presence of clinical signs and body weight change. Industry guidance and best practice about dose setting are followed, to avoid unnecessary toxicity. All procedures are kept to the minimum commensurate with the study objective. Best practice guidelines for all animal care and use are followed.
Dose range finding studies may be needed to establish suitable dose levels for the genetic toxicology study. Once signs indicate that a dose is unsuitable for genotoxicity assessment, further dosing of the sex/group is usually halted and after any necessary observations have been performed, humane endpoints are applied. Additional observations are included as necessary to closely monitor the condition of the animals. Industry guidance and best practice about dose setting will be followed, to avoid unnecessary toxicity and we will use the results of other studies and data wherever possible, to avoid having to run range finding studies.
Wherever possible, we will use doses that do not produce toxicity e.g. where it is known that a limit dose can be used, or that higher doses are not required. Signs of toxicity are typically seen in mid/high dose animals. Usually these are mild/moderate, however, animals may show significant adverse effects and in this case action will be taken to alleviate signs, such as temporary or permanent withdrawal of the animal from dose, reducing the dose if appropriate or via the application of humane endpoints.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will monitor for updates and other refinements and guidance through the life of the project and apply wherever possible.
Experiments will be conducted in compliance with OECD Test Guidelines and ICH S2(R1). Dose setting will be determined by the requirements of these test guidelines.
For any surgical interventions, then the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) will be followed.
For blood sampling and dosing then the following guidelines/literature will be followed:
First report of the BVA/FRAME/RSPCA/UFAW joint working group on refinement, Laboratory Animals, 27, 1-22 (1993).
A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Journal of Applied Toxicology, 21, 15-23 (2001).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through the regular review of non-animal alternative developments / resources, attendance of scientific conferences and animal welfare forums and reviews of scientific literature. **A retrospective assessment of refinement will be due by 03 January 2026**

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

31. Determining the therapeutic potentials of cardiac signalling molecules

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

therapy, cardiac hypertrophy, cardiac arrhythmias, signalling molecules

Animal types	Life stages
Mice	neonate, adult, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine the therapeutic potentials of identified signalling molecules in heart disease conditions.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project will advance our knowledge of cardiac signalling molecules and their therapeutic potentials in cardiac disease conditions, which will translate into new therapies **What outputs do you think you will see at the end of this project?**

1. New information: the scientific community's knowledge about the cardiac signalling regulation in both health and disease.

2. New products: potential new drugs for treating heart disease, in particular the new drugs for treating heart failure, inherited hypertrophic cardiomyopathy (HCM) and ventricular arrhythmias such as catecholaminergic polymorphic ventricular tachycardia (CPVT).

3. Publications: Publish the findings in academic journals. The information is likely to be of interest to clinicians, physiologists with an interest in intracellular signalling and their roles in cardiac diseases.

4. Model system or new technology: through this project, we will be able to identify/establish suitable animal models for studying cardiac diseases and may generate new valuable technologies for the scientific communities.

Who or what will benefit from these outputs, and how?

1. The scientific community: new information, new knowledge, new animal models 2. Patients: new drugs such as novel drugs for the treatment HCM, heart failure, CPVT.

3. NHS and doctors: new treatment for HCM, heart failure, CPVT.

How will you look to maximise the outputs of this work?

1) dissemination of the new knowledge generated from the project via national and international media or newsletters, etc. 2) national and international collaboration with academic researchers; 3) publication of successful and unsuccessful approaches.
Species and numbers of animals expected to be used

- Mice: 9000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Models of heart disease including cardiac hypertrophy and heart failure in small rodents, particularly mouse models have been very useful for both mechanistic research and the assessment of pharmacological therapies for several decades. In addition, genetically modified mouse models have been widely used in heart disease research. Many of these genes being modified have proved to be crucial in the initiation and progression of heart disease.
Choice of life stage: For breeding protocol 1, it requires neonate, adult, juvenile, pregnant adult life stages of the mice for generating, characterising and maintaining the colonies, while for Protocols 2 and 3, adult, juvenile stages are required for studying the disease process and treatment that are relevant to the disease process in human life stages.
The mice will develop cardiac hypertrophy (either those drug-induced or developed spontaneously due genetic defect such as hypertrophic cardiomyopathy) that can be detestable by echocardiography or magnetic resonance imaging (MRI) but without presence of any clinical symptoms. Any animal showing clinical symptoms will be killed humanely.

Typically, what will be done to an animal used in your project?

1. multiple administration of control substances or substances that cause gene deletion/inducting/hypertrophy or treatment agents by injection, oral route (e.g. gavage) or osmotic mini pump delivery

2. one or more ECG or Echocardiography.

3, one or more recovery general anaesthesia

What are the expected impacts and/or adverse effects for the animals during your project?

1. Develop cardiac hypertrophy without clinical symptoms

90%
2. Wound break down may occur

<5%
3. Damage to the trachea/oesophagus from incorrect use of the Dosing cannulae or Misplacement of the feeding needle resulting in fluid being delivered to the lungs.

<1%
4. dehydration, local irritation, infection.

<5%

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

1. 10% (<200 animals out of 2000 animals in Protocol 2), Moderate 2.

10% (<200 animals out of 2000 animals in protocol 3), Moderate

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To assess the development of disease or efficacy of treatment, animal models are essential to achieve this goal.

Which non-animal alternatives did you consider for use in this project?

i) we will use patient specific iPSC-CMs for modelling cardiac hypertrophy and for mechanistic studies and for testing and developing new compounds developed based on our identified signalling genes in this project and for future drug development.

ii) Mathematical simulations to construct cellular, tissue and organ models to link cellular and molecular mechanistic alterations to pathophysiological and structural phenotypes at organ levels.

Computational modelling of the heart is now recognised as a powerful technique in the detailed investigation of cardiac behaviour. A biophysically detailed computer model of the heart, the virtual heart, provides a powerful tool for simulating drug-ion channel interactions and cardiac functions at normal and disease conditions, and therefore forms a powerful platform for drug cardiotoxicity screening.

Why were they not suitable?

i) we will use patient specific iPSC-CMs for modelling cardiac hypertrophy and for mechanistic studies and for testing and developing new compounds developed based on our identified signalling genes in this project and for future drug development.

ii) Mathematical simulations to construct cellular, tissue and organ models to link cellular and molecular mechanistic alterations to pathophysiological and structural phenotypes at organ levels.

Computational modelling of the heart is now recognised as a powerful technique in the detailed investigation of cardiac behaviour. A biophysically detailed computer model of the heart, the virtual heart, provides a powerful tool for simulating drug-ion channel interactions and cardiac functions at normal and disease conditions, and therefore forms a powerful platform for drug cardiotoxicity screening.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The animal requirements will be regularly reassessed to ensure minimal animal usage and to maximise our statistical analyses throughout the course of our projects. ANOVA test, Factorial ANOVA in particular, will be used in our experiments for measuring the effect of two or more independent variables on the dependent variable between experimental groups (e.g. WT and mutant groups, treated and untreated groups).
Informed decisions to carry out several or all procedures on any given strain of interest will be made based on the data obtained from one or several of these procedures in conjunction with in vitro, cellular, molecular and electrophysiological data etc.
It is expected that we will keep 10 lines of mice, resulting in approximately 5000 mice being bred during this project based on our experience. These mice will be used for subsequent analysis in regulated procedures or to be used in non-regulated procedures including biochemical analysis analysing DNA/RNA/protein extracted from heart tissue, histological analysis and analysis of Ca2+ handling, for example, in isolated cardiomyocytes. It is expected that approximately 1000 mice will be used in nonregulated procedures such as langendorff heart perfusion for cell isolation, cardiac imaging, etc.
It is expected that approximately 2000 mice will be used in physiological cardiovascular analysis. The majority of the studies carried out under this licence will utilise the mouse model for its flexibility in the generation of genetically modified lines. There are some mouse models of cardiovascular disease and cardiovascular conditions.
Up to 10 genetically modified murine lines will be analysed during the duration of project. For each line male and female GM mice and their WT littermates will be analysed; analysis will be carried out at different ages in the mice to determine the progressive effect of the genetic modification on cardiovascular performance. Each line may be expected to undergo serial echo/ECG and pacing analysis.
It is expected that approximately 2000 mice will be used in hypertrophic induction or treatment. Models of cardiac hypertrophy generated by pharmacological or exercise approaches presents no more than moderate severity phenotypes, while anti-hypertrophic treatment mitigates the hypertrophic process should also present no more than moderate severity phenotypes. The experimental design using NC3Rs EDA has been used for calculation of the number of animals needed for each experiment. We have estimated the number of experimental and control groups, the total number of animals used in each experiment and the number of animals in each experimental group, and the number of times each animal will be measured; the number of

independent replications of each experiment indicated; any steps taken to minimise the effects of bias when allocating animals to treatment (e.g. randomisation procedure) and when assessing results (e.g. blinding).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A thorough literature search was conducted to ensure that experiments that will be undertaken do not duplicate reliable data that is already published or present in data/resource repositories. Principles of experimental design have been applied in order to minimise the number of experiments required to achieve reasonable statistical significance and data reproducibility.
Three steps for optimising experimental design have been taken:

1. The study design (justification for how experimental and control groups were chosen) for each project. By using NC3R's EDA, we have made estimation of calculation of studies

2. Avoidance of bias

When two or more treatment groups are compared, the animals in the groups will be in identical environments and be similar in every way apart from the applied treatments. Bias will be minimised by:

- Randomly allocating animals to the treatment groups
- Ensuring that all subsequent treatments (including housing) are applied in a random order
- Ensuring that researchers analysing experimental outcomes are unaware of the treatment received (blinded) until the final statistical analysis.
- Using appropriate number of animals (sample size)
- Controlling inter-subject variation (e.g. using randomisation)

3. Considerations for estimating sample size

- Variation is controlled by randomly allocating animals of similar genotypes, of a similar weight and age, which have had a similar environment throughout their lives. Variation due to circadian rhythms or fluctuations in the environment can often be reduced by appropriate experimental design, for example by using blocking factors.

- Measurement error will be minimised by careful technique and good instrumentation and by blinding the researcher to treatment allocation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will take rigorous measurements to optimise experimental design, pilot studies and computation to minimise unnecessary over-use of animals. The majority of the lines are from our current licence. For the new lines required, where possible we will import previously generated GM mouse lines from

colleagues/collaborators/resource centres. Stock levels of mouse strains will be set to minimise animal breeding whilst at the same time ensuring that given strains are not lost. Colony size management will be controlled by collaboration with the animal house staff and by the use of breeding calculations.

Tissues/embryos, DNA/RNA and protein samples obtained from experimental animals/embryos will be preserved, usually by storing in liquid nitrogen or at -80 C, to allow, where scientifically justified, use in other experiments by ourselves or other scientists who may request such samples.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse is the system of choice for experimental genetic modification as applied to mammals and the only appropriate animal model for studying hypertrophic mechanisms and treatments. Mice are a wellknown source of information within the laboratory field and the techniques used here are the most refined at the moment. Breeding and maintenance of genetically modified mice is not expected to suffer any more than mild severity. The administration of transgene inducing or deleting agents will be carried out via intraperitonea injections or oral gavage as the most refined methods.
Physiological analysis: Animals are expected to suffer no more than moderate harm due to the nature of the non-invasive technique of ECG and echocardiography which are the most refined method for this procedure. Expected actual severity is mild.
Hypertrophic models: to generate drug-induced hypertrophy mimicking clinical condition, administration of potential hypertrophic agents and/or substances to potentially inhibit hypertrophy by one of the surgical routes is required. For characterisation of the phenotypes, ECG, echocardiography, magnetic resonance imaging (MRI) and other measurements are needed. Animals are expected to suffer no more than moderate harm due to the nature of the non-invasive technique of ECG and echocardiography. MRI is only taken as a terminal procedure. Implantation of osmotic mini-pump is a well-established technique in the field for delivery agents (eg. Ang II) for inducing pharmacological hypertrophy and has been used in my group routinely for many years. The animals are well tolerated. The antihypetrophic treatment will be mainly delivered by oral gavage or food supplementary whenever is possible. These are refined routes for the treatment.
Why can’t you use animals that are less sentient?

We analyse the consequences of specific genetic modifications for cardiac signalling pathways for cardiac hypertrophy that mimics human conditions. These only occurs in mammals so less sentient model organisms are not an option.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will keep up to date with all procedures and their refinements and will attend any

relevant workshops.

Minipump implant will cause no more than moderate suffering but is not expected to cause

harm. Animals are expected to make a rapid and unremarkable recovery from the implantation

procedure. Analgesic agents will be administered.

Humane endpoints
A key component of refinement is the implementation of humane endpoints.
Welfare assessment protocols and score sheets will be useful tools to monitor adverse effects and determine when humane endpoints have been reached.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3Rs and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By regularly attending the NC3Rs days available.
Regular contact with transgenic groups within our institution allow us to update each
other with advances in techniques and training.
Departmental animal welfare meetings held termly allow us to communicate any 3Rs implemented within our

group and invited members including NACWOs and NVS ensure that any new advances are disseminated.

Home Office

NON-TECHNICAL SUMMARY

32. Developing Nanoparticles for Brain Drug Delivery

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the aims mentioned in purpose (b) **Key words**

nanoparticles, Blood brain barrier, zebrafish, behaviour

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Efficient delivery of compounds to the brain represents a major challenge in the discovery and development of new therapeutics for the treatment of diseases affecting the Central Nervous System (CNS). Because of the presence of the Blood-Brain Barrier (BBB), only 3–5% of brain-directed pharmaceuticals are able to reach this

area in vivo and have been introduced into the market. The use of very small materials (i.e. in the nanometer range) as drug carriers represent a very promising approach in this field since they have shown a series of additional advantages. This project aims to identify novel nanocarriers able to cross the BBB and suitable for drug delivery. Specific objectives are:

1. to identify novel nanoparticles as candidates for CNS drug delivery

2. to determine the in vivo distribution of these candidate nanocarriers

3. to evaluate potential long-term consequences of short-term nanoparticle exposure (effects on behaviour).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project offers the opportunity to identify novel nanomaterials to be used as drug carriers capable of crossing the blood brain barrier for the treatment of brain disorders. The biosafety and ability to target the brain will be verified before moving to clinical trials.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The project uses only zebrafish as an animal model. It is envisaged to use up to 12000 animals over a period of 5 years.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Exposure to nanoparticles may cause signs of mild harm (e.g. oedema, reduced swimming at larval stages), so animals at all the stages will be assessed frequently (i.e. at least twice per day) for morphological and behavioural phenotypes. Any animal showing signs of harm will be killed by schedule 1 method. In addition, mild stress as a result of single housing and behavioural assessment may occur from the behavioural analysis. Animals will be killed at the end of the procedure or, where non-exposed animals have suffered no more than mild severity procedures during the behavioural assessment, and are not suffering or likely to suffer, they may be maintained for breeding purposes.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

It is not possible to determine the actual suitability of these novel nanomaterials as drug carriers to the central nervous system without in vivo studies. In addition, an assessment of potential behavioural changes can be only achieved through the use of an animal model. Zebrafish are the most suitable animal model to use because they are non-mammalian vertebrates that have been shown to have a translationally relevant behavioural repertoire. Similarly, it is not possible to assess the ability of nanoparticles to target specific organs or tissues in vivo without an animal model. Considering the BBB and the central nervous system are targeted, zebrafish represent a very reliable model because their BBB is both structurally and functionally similar to that of mammals.
However, all in vivo analyses will be preceded by in vitro (3D human BBB model) analysis to confirm effects on cell survival or migration before testing in vivo. All nanoparticles will be tested for harmful effects on cells in culture prior to use in animals and, in case of damage, they will not be administered in vivo

Reduction

Explain how you will assure the use of minimum numbers of animals.

Results from past work from our lab and elsewhere will be used to conduct statistical power tests to calculate the fewest number of animals required in order to achieve our objectives as stated in project plan.
Within our facility we have experienced fish technicians who regularly monitor the health of the fish, and a fully trained NACWO. These individuals are on hand to provide experimental design opinions as well as remove animals from the project if they are suffering any pain or distress, or show any signs of harmful abnormalities.

Nanoparticle preparations promising as drug carriers will initially be investigated for harmful effects in vitro. Any chemical showing to damage cells in culture will not be taken forward. Effects of chemicals on development of wild-type zebrafish embryos will be assessed after 24 hours of embryonic exposure (at 48 hours post-fertilisation). Again, any chemical that induces abnormal development will not be taken further and assessed for neither effects on behaviour nor localisation within the body. Larvae will be assessed twice daily for signs of adverse effects of exposure to these vehicles (e.g. swimming behaviour, gross morphology, oedema). Any nanovehicle inducing signs of harmful effects will not be taken further.
When the analysis will require the use of fluorescence microscopy, a single animal can be assessed at several different stages post-injection (fluorescence imaging is non-harmful).

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Zebrafish are the most appropriate model species as they are vertebrate with a high degree of conservation of human brain organisation and functions making results found in zebrafish of translational relevance.
Furthermore, they are the vertebrates with the lowest neurophysiological sensitivity likely to yield results relevant to the human condition.
Use of initial pilot studies in 24hr larvae will enable any unexpected harmful effects to be detected at the earliest stages. Only nanoparticles shown not to induce any damage at early life stages will be taken forward to older stages.

We primarily use locomotion behaviour, shoaling and appetitive learning paradigms as our means of assessing behavioural phenotypes. Appetitive paradigms can be considered less severe than those using aversive learning. All animals shall be killed at the end of a protocol unless they were only subject to control behavioural analysis that consists merely of placement in a tank with specific markings and the performance of locomotor or appetitive learning tasks (approaching lights for food). These control fish may then be returned to the breeding programme but will not be used for further behavioural analysis.
Measures of anxiety use exposure to forced light transitions to induce a startle response in 5dpf-10dpf larvae. In adults anxiety is assessed using a tank diving assay, a fish version of the open field test, where more anxious animals tend to spend more time near the bottom when transferred to a novel tank. These stressors are considered the mildest capable of inducing a robust response.
The project researcher holds a PIL and will monitor the fish for signs of harm regularly- twice daily. Within our facility we have 2 experienced fish technicians who hold PILS working on this and related projects and who regularly monitor the health of the fish in addition to a fully trained NACWO. They are on hand to remove animals from the project if they show any harmful abnormalities or signs of distress.
Regarding determination of the distribution of nanoparticles, the big advantage of using larval zebrafish lies in the optical transparency of the embryos and larvae which allows the tracking of nanoparticles by using non/invasive imaging systems.

Home Office

NON-TECHNICAL SUMMARY

33. Developing safe and efficacious cell-based therapies for kidney disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b) **Key words**

kidney injury, regenerative cell therapy, preclinical imaging, safety and efficacy, immunomodulation

Animal types	Life stages
Mice	adult, pregnant, aged, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to develop therapies to treat kidney disease, using mouse models of acute kidney injury and chronic kidney disease. For this purpose, we aim to assess efficacy and safety of cells or their products as regenerative medicine therapies

A retrospective assessment of these aims will be due by 02 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Acute kidney injury (AKI) and Chronic kidney disease (CKD) affect large numbers of patients, particularly adults but also children, and are frequently associated with underlying health problems including cardiovascular disease and diabetes.
AKI is associated with an increased mortality rate and 20% risk of progression to CKD. Treatment of AKI is limited to management of blood pressure, fluid and electrolytes, but renal replacement therapy can be needed. CKD can progress to end stage renal disease which means that dialysis or transplantation are the only remaining treatment options.
Regenerative medicine therapies, including cells or their products, have emerged as a promising avenue for the treatment of AKI or CKD, but our understanding of the mechanism of action and the safety of these cells or their products remain limited. This programme of work will address these points in preclinical studies in mice of various ages (including aged animals), and thus contribute further important knowledge towards the development of safe and efficacious regenerative medicine therapies for treatment of patients.

What outputs do you think you will see at the end of this project?

This project will provide a number of outputs, including:

- A more thorough and detailed understanding of the interactions between RMTs, damaged kidney and the immune system, including their mechanism of action, to promote or enable therapeutic efficacy in mice with kidney injury, and the influence of ageing on these processes. This may include novel insight into molecular and cellular steps that could be clinically exploited for therapeutics.

- The development of novel preclinical imaging assessment methods of renal function and tissue integrity to determine efficacy of RMTs in a non-invasive, longitudinal fashion that can be clinically translated. This includes the development of novel dyes/compounds that can be utilised in these assessments.

- The development of novel imaging tools and cell labels for preclinical imaging to track cells in order to determine their safety, both in the kidneys but also off-target in other tissues, since cell administration may be systemic and/or can lead to off-target growths. This involves the development of novel models to interpret and analyse preclinical imaging data.

- Multiple research publications in peer reviewed journals. We have a strong publication record in our team, with 2-4 publications per year in recent years. We strive to generate publications from our funded studies, not only for the benefit of the young researchers involved, but also to improve general understanding and knowledge in the field.

- Scientists with unique training and expertise in various techniques including surgery, colony maintenance of wildtype and genetically altered animals, use of a range of preclinical imaging modalities, data analysis. These skills will be invaluable for the research careers of the staff and students involved in this programme of work.

The long-term aim of this programme is to generate novel therapeutics that can be translated to the clinic for the benefit of patients with kidney injury or kidney disease.

Who or what will benefit from these outputs, and how?

Short term beneficiaries:
- The renal research community as well as the regenerative medicine research field, including the area of in vivo imaging and image analysis. Our research findings will be communicated to these communities via workshop and conference presentations, which will lead to exchange of ideas and cross-fertilisation of outcomes, ideas and concepts. The research communities will also benefit from research publications generated from our findings, with the potential to stimulate further research.

- The research community will directly benefit, in the short to medium term, from access to novel preclinical imaging techniques and analyses that we will develop during this project, including data on novel dyes and their analysis and interpretation.

Medium to long term beneficiaries:
- This will include the research team as short-term outcomes will build further expertise of the entire team, leading to continuity and consolidation as well as refinement of techniques.

- The research field (both renal, regenerative medicine as well in vivo imaging) will be beneficiaries because accumulation and consistency in outcomes will consolidate the reliability and reproducibility of our work, leading to an improvement in standards.

- Clinicians (renal and others) will benefit from access to improved understanding of mechanisms of action of RMTs and their safety. We expect that our findings will be important contributors to the development of clinically relevant RM therapeutics for treatments in renal patients that can be tested in clinical trials, as well as other diseases where RMTs have shown promise.

- The public will benefit from interactions amongst the above beneficiaries as well as their disseminations and progress in the development and anticipated validation of RMTs. This includes patients with kidney disease (AKI or CKD, possibly renal transplant patients) who would benefit from the development of RMTs as therapeutics that can be tested in clinical trials.

How will you look to maximise the outputs of this work?

Our outputs are maximised by interactions with colleagues from preclinical and clinical research fields, as well as interactions with patient representatives. We have ongoing international and national collaborations. We are strongly engaged with the UK renal research community and a large number of charities. Through these interactions, we reach a wide audience of specialist preclinical and clinical researchers and practitioners as well as lay people.

We maximise our outputs through attendance at workshops and conferences, and most importantly through publication of our findings in open access journals, including the use of pre-print serves (e.g. bioRxiv). We are keen to publish unsuccessful approaches, and datasets are made available after publication.
We have a range of international and national collaborations which arise from our active engagement with the national and international research field of renal regenerative medicine and preclinical imaging. This involves SMEs that are involved in the improvement of imaging modalities, dyes and analyses.

Species and numbers of animals expected to be used

- Mice: 4450

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We want to develop treatments for kidney disease or injury that could in the future be used in patients. We test cells or cell-derived substances as treatment, and use animals in order to find out which are the most successful cells or substances to reduce the injury in the kidneys. We use mice because their kidneys work very similarly to those in humans, and show similar injury response which we use to determine levels of damage, but also because mice are the simplest animal model with this level of similarity to humans. Therefore, mice are the most appropriate animal to achieve our aims. Because kidney injury can occur in younger and middle aged people, but also in older people, we use adult mice, but also aged mice.

Typically, what will be done to an animal used in your project?

Animals in this project may be part of studies that optimise conditions, or be part of a larger study to test and determine the success in treatment of the cells or cell-derived substances. With these studies, we also wish to understand how the successful treatment works, and where the cells that we use as treatment, go in the body. During either studies, most of the mice will get a kidney injury which has similar clinical signs to kidney injury in patients. This can be a severe acute kidney injury caused by injection of a drug, or by surgical induction under general anaesthesia. During the surgery, the blood flow to one or both kidneys is halted for a pre-determined time period in order to establish the desired level of injury in the organs. The mice will be unwell for a period of 2-7 days, but recover. Some mice will be treated so that they develop chronic kidney disease, which is milder in its onset but can show clinical symptoms for longer; mice may be monitored for this condition for up to 6 months. Some of the mice in either injury condition will receive cells or cell-derived substances as test treatment and we will monitor and measure clinical signs of progression of the injury response with our without treatment using the most non-invasive approaches possible that have also clinical relevance. These approaches involve injection of small volumes of contrast substances that can be detected in imaging instruments to determine how well the kidneys function. These steps are typically performed under general anaesthesia. These measurements can take place repeatedly over the study period but at the most appropriate times to reduce harm to the mice.
In some of the mice, we will have removed specific cell types of the immune system. We know that the immune system plays a role in the development of kidney injury and the limited natural healing process that can take place, and by removing certain immune cell types we can determine whether they are essential for development of the disease or the treatment process.

What are the expected impacts and/or adverse effects for the animals during your project?

The experimental conditions may lead to loss of weight in mice that have kidney injury. The treatments which lead to kidney injury, will lead to the most critical loss of weight, but other steps, including imaging assessments under anaesthesia, can also lead to weight loss. Because of the need for clinical signs of kidney injury in order to assess the effect of the treatments, these adverse effects are necessary.
Aged mice may be more frail than healthy adult mice and their treatment regime during the steps of protocols will be adjusted so that they are milder without preventing us from obtaining relevant information on the same question of kidney injury and effectiveness of treatments with cells or cellderived substances.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Two of the protocols have a severity level of moderate, but most mice in these protocols will experience mild conditions. In the one moderate protocol we may breed genetically modified mice which may show signs of moderate health problems, however, ageing mice will also be generated under this protocol, which can lead to moderate severity in their clinical signs. Overall, we expect that not more than 10% of the mice under this protocol show signs of moderate severity.
In the other moderate protocol we optimise conditions for removing specific immune cells. This can involve the development of clinical signs of moderate levels of severity in the mice, caused by toxicity of some of the agents. After optimisation of the treatment regime with agents used to remove immune cells, no adverse effects have been reported. Therefore, we expect that no more than 10% of mice under this protocol show signs of moderate severity.
Three of the protocols have a severity level of severe. This includes two optimisation protocols where we will optimise conditions to induce kidney injury. We expect that up to 50% of mice in these protocols will experience signs of severe severity. However, we will use small groups of mice for these optimisation protocols so overall numbers of mice experiencing severe severity from these protocols is small.
The experimental protocol with severe levels of severity can also lead to up to 30% of mice experiencing this severity. In this protocol, mice may experience kidney injury which can lead to loss of weight, but treatment with cells or cell-derived substances or modification of the immune system may alleviate the injury level. Some of these mice may experience moderate levels of severity. Also in this protocol included are mice that are not experiencing kidney injury based on experimental design of cell tracking in non-injured animals.
Our careful optimisation approach, combined with monitoring of the wellbeing of the mice throughout, should allow us to minimise adverse events.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 02 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The conditions that contribute to the development of kidney injury and possible treatment cannot currently be

reproduced in the non-animal setting since it involves the effect of blood flow, immune cells and other physiological factors beyond the interactions of cells inside the kidneys. Mammalian physiology and anatomy are complex and other organs may also contribute to the injury and any beneficial treatment response. Any beneficial treatment response observed in a non-animals condition may have to be validated using animals models before treatments can be trialled in patients.

Which non-animal alternatives did you consider for use in this project?

In vitro (cell culture) and ex vivo (kidney slice) systems offer some opportunities to replace the use of mice. Cell culture work is being performed to study effects of therapeutic cells on cells of the immune system, but only deliver limited information due to the isolated setting. Kidney slice models require optimisation of set up which we are currently trying to obtain funding for. However, both approaches will be complementary rather than full replacements of animal studies.

Why were they not suitable?

In vitro approaches cannot reproduce the entire disease setting and physiological condition of the animal. These are important aspects that contribute to the injury and treatment response. This includes interactions with other organ systems and cells as well as physiological parameters like blood flow to the kidneys. Although cell-based studies produce important information in their limited format on the response of isolated cells to specific conditions, a whole range of these conditions are not being assessed. In kidney slice models, a more complex system of various cell types and interactions can be replicated, however, they still lack the intricate interaction between various organs and systems in the animal.
Since the aim of our work is to determine the efficacy and mechanism of action of cells or cell-derived substances within the animal to kidney injury, we need to consider that these processes in the patient take place in a complex environment and that the in vitro or ex vivo experiments cannot completely replicate the animal model.
A retrospective assessment of replacement will be due by 02 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

My experience in this area of research over the last 10 years allows me to estimate with confidence the mouse numbers needed for this programme of work. Animal numbers are determined based on currently funded studies and the experience with previous project licences. These are based on effect sizes (including variances) from previous work, and also considering adverse effects.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The studies funded for this programme of work will have undergone peer review which includes providing detailed statistical analysis and power calculations. We have made use of the NC3Rs experimental design assistant but also other online power calculation tools (G star power etc) to design our studies and power our experiments so that we can achieve sound primary outcome measures. We base calculations on group sizes on estimates of effect sizes from our previous work, including preliminary data, and on published studies.
We frequently perform longitudinal studies which for example include multiple measurements of renal function parameters at various time points in the same animal. These longitudinal assessments allow for reduction of animal numbers since it reduces end point analysis at these different time points.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have optimised experimental design specifically for acute and chronic kidney injury studies where ischaemia reperfusion injury was induced by surgical approach. We recognised that animals undergo larger variability in response unless certain surgical parameters were more tightly controlled (see Refinement). The reduction in variability leads logically to a reduction in animal number as the experimental design calculations will include adjusted effect sizes, since variability in response doesn't need to be addressed in larger group sizes.
We perform pilot studies wherever necessary, especially for crucial experimental conditions like induction of injury and removal of immune cells. Optimal conditions arising from these pilot studies will lead to a reduction in animal number since they reduce variance in the experimental and control groups. This can be further refined after ANOVA-type statistical analysis for follow-on studies.
Post-mortem, tissues and other materials will be used to assess the outcome of the experiments. This may involve re-assessment of data using modelling of outputs using optimised computer programmes, for example by making use of machine learning. We are currently starting a project where this is trialled with histological data obtained from our experiments.
Analysis and interpretation of other digital data is also being constantly optimised to both drive optimisation of interpretation and also develop novel approaches to data analysis which may have relevance for applications in the clinic.
A retrospective assessment of reduction will be due by 02 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this programme of work, we use mouse models of kidney injury that are very closely replicating clinical symptoms. These injuries are required to achieve our overarching aim of developing therapies for treatment of kidney injury, using cell or cell-based treatments. These injury models are widely accepted as standard for

mouse experiments that replicate symptoms of kidney injury in patients.
The methods used to induce kidney injuries either involve the injection of a nephrotoxic substance or surgery to induce an injury to the kidneys. Mice in these studies may be administered analgesics to reduce any pain, and surgery will be performed under anaesthesia.
We need to induce acute kidney injury in a subset of the experimental animals as we can follow the generally quick injury response over a short period time; in mice where we want to model chronic kidney disease, a less distressing injury is induced and the animal's response followed over a longer time period.
Some of the mice in either experimental treatment group will receive versions of cells or cell-derived substances with the aim to reach an reduction of the level of injury, which should correlate with the level of suffering and distress.
Pilot studies will be performed to optimise conditions of treatment to induce kidney injury, and also removal of immune cells. In order to understand the mechanisms of action that underpin any therapeutic

response of the cells or cell-derived substances, we will study the response of the immune system which is intimately involved in injury and healing responses.

Why can’t you use animals that are less sentient?

In this programme of work, we study effects of cells or cell-based substances as therapeutic treatment in mouse models of kidney injury, mimicking variances of the disease found in patients. The mouse is the simplest model organism that can replicate this disease scenario because it has a very similar anatomy and physiology to the human.
Adult or even aged mice are needed to perform these studies because patients typically fall within this bracket. It is necessary to have fully functional organ systems available in the animal for the studies to yield relevant information, and early embryonic stages would not be providing the required data. It is not possible to perform the studies in terminal anaesthetised animals as various outcome measures wouldn't be able to be assessed, making this an impractical approach.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I have worked with mouse models of kidney injury for 10 years now, and during this time we have developed several models (Adriamycin glomerulosclerosis model, ischaemia reperfusion injury model). We have also established multi-modal imaging in healthy and injured mice during this time.
I have >20 years of experience in mouse models of various diseases, and have used genetic lineage tracing and ablation models under a different project licence. During this time, I have established expertise in assessing and scoring animal wellbeing, which could present stages of disease progression and injury. In order to implement the kidney injury models and other procedures within this programme of work, mice are closely monitored during the critical phases after injury induction in order to maintain the severity levels and determine when humane end points are reached. One of the main predictors is animal weight, and so animals are weighed regularly and their overall appearance monitored every few hours on the day of surgery or other induction of injury, and daily afterwards. This may involve close monitoring of wellbeing during critical phases of injury response by night visits in order to avoid unnecessary suffering of the mice.
We constantly strive to refine procedures to minimise suffering and improve welfare of the animals. This includes regular reflection of steps that could be improved. For example, we have optimised the experimental design for surgical induction of acute and chronic kidney injury, since we recognised that animal groups undergo larger variability in response unless certain surgical parameters were more tightly controlled. These observations and refinements have been published on the bioRxiv preprint server and are currently in revision at one of the leading renal physiology journals. This refinement subsequently leads to a reduction in animal number as the experimental design calculations will include adjusted effect sizes, since variability in response doesn't need to be addressed in larger group sizes.
Previously, we established the use of the ultrasound imaging instrument to refine the administration of cells into the left ventricle in order to avoid misinjections and unnecessary suffering.
We are currently working on a protocol to establish physiological and functional renal parameters (including GFR) as predictors of overall animal wellbeing. We plan to incorporate expertise by BSU staff and grimace scoring into an overall score system that allows us to monitor closely the wellbeing of the mice in an unbiased way.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow LASA guidelines on dosing and administration of agents, and withdrawal of blood.
For the scoring of ageing mice, we follow the guidance by Wilkinson and colleagues (Wilkinson et al., 2020, Lab Anim. 54(3), 225-238. DOI: 10.1177/0023677219865291), and also the internal score sheet that has been set up in collaboration with colleagues at the University with longstanding expertise in research using ageing mice.

We have sent PILs/researchers on international courses to obtain specific training in the models used in this project, including the surgically induced kidney injury model. We have taken guidance from the publication by Skrypnyk and colleagues (Skrypnyk et al., 2013, J Vis Exp (78):50495. doi: 10.3791/50495) and others.
We follow the ARRIVE guidelines for which an update (2.0) was published this year (Percie du Sert et al., 2020, PLoS Biol 18(7), e3000410. doi: 10.1371/journal.pbio.3000410).
We have sent researchers to other laboratories nationally and internationally to learn and improve on techniques that are relevant for this programme of work, for example with regards best practice in using in vivo imaging instruments. As part of the EU Marie Curie training network, that is contributing funding to our work, we are in constant exchange with other researchers in the Netherlands, Germany, Italy and Ireland to discuss and improve our experimental designs and approaches.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our Biomedical Services team is very active in announcing and organising NC3Rs meetings, workshops and conferences. I have attended several local NC3R workshops, and have presented at an international NC3R conference on severe suffering. I encourage members of the team to use the NC3Rs website, communicate information that becomes available, and attend conferences. The animal unit at our establishment is proactive in displaying important publications, posters and other information leaflets that are important for work in the NC3Rs area. The NC3Rs regional manager for the establishment is actively engaging with the animal researchers, and happy to provide support where required.
In our work, we constantly aim to apply the 3Rs principles; this includes continuous reflection on studies and subsequent optimisation so that refinements can be introduced to limit suffering, and also to reduce animal numbers. We are also keen to explore alternative model systems (ex vivo etc) in the laboratory.
A retrospective assessment of refinement will be due by 02 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

34. Development and function of neural circuits underlying perception and behaviour in the mammalian brain

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, pregnant, aged, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Animal behaviour emerges as the product of coordinated activity of neurons with different patterns of gene

expression, synaptic connections, and activity. The aim of this project is to link these levels of analysis and provide a mechanistic explanation for how the brain generates behaviour.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

All the richness of animal behaviour is the product of input-output transformations carried out by individual neurons connected into intricate networks. These neurons come in hundreds of distinct cell types, generated during brain development through the activity of different combinations of genes. The rules according to which different cell types select their input and output connections forms the backbone of the neuronal networks of the brain. Yet we still do not know how these connections are established, and how the resulting networks of neurons give rise to patterns of activity underlying cognition and behaviour.

This project will advance our understanding of how different specialised classes of neurons act together to give rise to perception, memory, decision-making and other elements of high level brain function, and how the specialised properties of these neuronal populations are influenced by cell-type specific gene expression programmes. Although understanding how genes guide the specification of input and output connections of neurons is important in its own right, it will also provide key insights into how disruption of genes leads to circuit deficits underlying the symptoms of neuropsychiatric disorders linked to perturbation of neuronal connectivity, including autism and schizophrenia.

What outputs do you think you will see at the end of this project?

This project will advance our understanding of how networks of neurons within the brain process information to give rise to behaviour and how their connections are established during brain development. This knowledge will be disseminated through presentations at scientific conferences and peer-reviewed publications. In addition, any new techniques, reagents, or software tools generated as a part of this project will be made freely available to other researchers in the field.

Who or what will benefit from these outputs, and how?

Experiments in this project will help reveal how the organisation and function of animal brains enables perception, memory, decision-making and other aspects of cognition. This knowledge will be valuable for several reasons. The neocortex of different mammalian species follows similar principles in its organisation. Therefore, studying how the mouse cortex contributes to these high-level brain functions will advance our understanding of how they are carried out in the human brain.

This project will also investigate how the circuits that carry the computations responsible for cortical functions are established during development. Currently, there is a major gap in our understanding of how molecular mechanisms influence, which synaptic connections neurons make in cortical circuits, ultimately defining the computations carried out by them. It is proposed that many neurodevelopmental disorders, most prominently autism spectrum disorders, are “connectopathies” – consequences of disrupted neuronal connectivity. Experiments in this project will disrupt individual genes during cortical development to identify their role the establishment of neuronal connections. This knowledge will reveal the molecular programmes that orchestrate the development of healthy cortical connectivity and provide insight into how their perturbations give rise to neurodevelopmental disorders.

In addition, in pursuit of the goals above we will develop a new platform that will allow us to systematically examine the consequences of knock-out of many individual genes in parallel. This platform could be applied to other research questions and in other brain regions and so could serve to accelerate research seeking to identify potential targets for treatment of neuropsychiatric or neurodegenerative diseases.

How will you look to maximise the outputs of this work?

Whenever possible, we will seek to maximise the utility of data and tools generated as a part of this project through collaboration with other experimental or theoretical groups, and online distribution of raw data and software tools. We will also make use of preprint platforms, such as bioRxiv, to rapidly disseminate our findings to a broad audience.

Species and numbers of animals expected to be used

- Mice: 17100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The overall organization of the brain is similar across mammals. Therefore, insights gained through studying the structure and function of the mouse brain will help understand how the neural circuits within the human brain give rise to perception, memory, decision-making and other aspects of cognition. In addition, the availability of genetically altered mice makes it possible to measure and manipulate neural circuits with unprecedented precision. Most experiments will be conducted in adult mice. In experiments aiming to understand how the nervous system develops and require access to the fetal or neonatal nervous system, pregnant mice and their embryos or neonates will be used. In addition, mouse embryos or oocytes will be used when required for the development and maintenance of genetically altered mouse lines.

Typically, what will be done to an animal used in your project?

To provide access to the brain in experimental procedures in this project, animals will undergo surgeries under deep anaesthesia, during which devices for recording activity of nerve cells or delivery of substances into the brain may be implanted. All animals will receive pain relief and will be closely monitored during recovery. In most cases, animals will undergo one or two surgical procedures, with sufficient time between surgeries to allow for complete recovery.

In some experiments the animals may be head-fixed to allow recording of neural activity and/or reliable presentation of sensory stimuli. In these cases, mice will be habituated to head fixation and the experimental setup to minimise stress and discomfort.

In some experiments, to motivate animals to perform complex behavioural tasks, animals' access to food or water may be restricted, and food or water rewards will be provided during the experiments. In these cases, the animals’ weight and health status will be carefully monitored, and ad libitum food or water will be provided if any adverse effects are observed.

At the end of experiments or if mice show signs of unexpected ill health, distress or suffering which cannot be ameliorated with minimal veterinary or husbandry intervention they will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Pain resulting from surgical procedures may reach moderate severity for short periods of time immediately following surgery. Animals will be closely monitored for signs of pain after surgery and appropriate analgesia will be provided.

Head fixation is expected to result in only mild stress during initial habituation to the experimental apparatus.

Animals under food or water restriction will typically maintain around 85%, but at least 80% of their normal body weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

57% of mice are expected to experience mild severity, while 43% are expected to experience moderate severity.
What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are still far from understanding how the circuits of neurons within the brain give rise to perception, memory, decision-making and other aspects of cognition, or how the disruption of these circuits leads to disease. Achieving this understanding requires measuring and manipulating neural circuits in ways that are not possible in humans. Instead, we will focus on mice, which are genetically tractable allowing highly precise measurements and manipulations of neural circuits and the development of disease models, and whose brains are organized according to similar principles to humans.
Which non-animal alternatives did you consider for use in this project?

Computer simulations

In vitro brain organoids
Why were they not suitable?

Computer simulations of neural networks require precise knowledge of the structure of connections between nerve cells and their properties. We still lack sufficient data to reproduce using simulations the behaviour of even the simplest nervous systems, such as those of nematode worms, least of all of the much more complex mammalian brains.
In vitro brain organoids have the potential to recapitulate much of the cellular diversity of the nervous system. However, this project is focused on studying how neurons within the brain process information from the environment and contribute to behaviour, which is only possible in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals are estimated based on our prior experience breeding genetically altered mouse lines

and with experimental approaches used in the project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Using our extensive experience with experimental techniques and statistical expertise, we will ensure that we use the minimal number of animals to achieve our scientific objectives. We will use state-of-the art methods to measure neural activity of many brain areas or neurons in parallel and develop sophisticated data analyses approaches to extract the maximum amount of value from these results. Whenever possible, we will use within experiment comparisons to maximise statistical power and minimise the impact of external variables. Finally, as a part of this project we will seek to develop new methods that will allow us to measure or manipulate gene expression or neural activity in many populations of neurons in parallel in the same animal, greatly reducing the total number of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be used to test the efficiency and applicability of new tools and techniques before employing them broadly to pursue the scientific objectives of the project. Computer modelling will be broadly applied to refine experimental hypotheses. Whenever possible, post-mortem brain tissue will be re-used and shared. Raw experimental data will be stored and re-used for new analyses, whenever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will exclusively use mice. Surgical procedures will be conducted under deep anaesthesia following aseptic technique and mice will be carefully monitored following surgery to ensure complete and uneventful recovery.

Why can’t you use animals that are less sentient?

While mammals, including mice, share the basic principles of brain organization with humans, the brains of other vertebrates and invertebrates are distinct. For example, the neocortex, which plays a key role in high level cognitive function, is present only in mammals. Carrying out experiments in this project solely in terminally anaesthetized animals is not feasible since studying perception and behaviour necessitates the use of awake animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Appropriate analgesia will be used during surgical procedures and mice will be closely monitored during recovery. In experiments involving head-fixation, mice will be gradually habituated to the experimental setup to minimise stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines set out in LASA Guiding Principles on Preparing for and Undertaking Aseptic Surgery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will strive to continuously improve our procedures with the help of the biological research facility staff, the Named Information Officer, Named Animal Care and Welfare Officers and the Named Veterinary Surgeons. We also consult the websites of NC3RS and RSPCA to keep up with the latest advance.

Home Office

NON-TECHNICAL SUMMARY

35. Development and function of the immune system

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Immune system, Signal transduction, Lymphocytes

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand the biochemical processes within immune cells that control their development, activation, survival, migration, differentiation and function.

Potential benefits likely to derive from the project, for example how science might be advanced or how

humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The immune system is essential for protection from infection by pathogens. An insufficient immune response will cause humans to succumb to infectious disease, whereas an over-active immune response can result in immune pathology during infections which can be a significant cause of morbidity and mortality. Furthermore, over-activity of the immune system to innocuous stimuli results in autoimmunity, again with significant adverse health consequences. Understanding how immune cells function and are regulated is critical basic research that will underpin development of more effective therapies to support or suppress the immune system when it underperforms or overreacts.

What outputs do you think you will see at the end of this project?

The main outputs of this work will be knowledge about how biochemical processes within immune cells control their development, activation, survival, migration, differentiation and function. These will be published in peer-reviewed journals, and the publications will always be open-access and thus available to all to read for free.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries of this work will be other academic researchers studying similar biochemical processes that regulate immune cell function. More broadly, it will benefit immunologists studying how the immune system responds to challenges and how autoimmunity develops. Most importantly, in the long-term, our work will provide the basis for the design of rational therapies that can modulate immune system function, which could be applied for the treatment of autoimmunity, immunodeficiency and immune pathology caused by over-exuberant immune reaction to pathogens.

How will you look to maximise the outputs of this work?

The main outputs from the work will be published in peer-reviewed journals, and the publications will always be open-access and thus available to all to read for free. We will also communicate our work through presentations, by giving seminars at other institutions or through seminars or poster presentations at conferences. Unsuccessful approaches will be discussed openly in appropriate venues, for example at internal meetings. We have an extensive track record of collaboration, helping other groups with more limited experience in these areas of research. We will continue to support such collaborative work.

Species and numbers of animals expected to be used

- Mice: 63000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the animal of choice for these studies because, like humans, they are mammals and thus their immune system is closely related to the human immune system. In addition, the immune system of mice has been studied more extensively that that of any other mammal, and huge numbers of reagents are available. Most of the animals studied will be adults, but some work on the development of the immune system will be carried out using embryos, neonates or juveniles.

Typically, what will be done to an animal used in your project?

The large majority of the animals in this project will be bred in order to generate genetically altered mice and will have no further procedures done to them. These mice will be analysed once they reach adulthood by taking tissues from them for analysis in vitro once they have been killed. For some mice they will be immunised and their immune response will be studied, which may involve taking blood at several time points. In all cases much of the analysis will be done on tissue taken from the mice after they have been killed. Typical experiments may last a month, with the mice immunised at the start, bled once a week for 4 weeks and then killed for final analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Most animals will suffer no adverse effects. A minority of animals will be injected with cells or substances to study the immune system. This will cause transient pain but no lasting harm. A small number of mice will be given viral pathogens which will cause moderate clinical symptoms.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild – 95%

Moderate – 5%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to comprehensively study the immune system outside the living organism, since its function depends on complex interactions between many different types of cells located in different tissues of the animal.

Which non-animal alternatives did you consider for use in this project?

It is possible to mimic some aspects of how immune cells behave using established cell lines, however this is very limited. Indeed, such in vitro approaches work best using immune cells taken directly from animals.

Why were they not suitable?

Established cell lines are not able to replicate the behaviour of normal immune cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on our current experience of carrying out similar studies under our current project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The efficiency of animal usage will be maximised by careful control of breeding to meet research needs with respect to numbers, phenotypic uniformity and health. This has been greatly facilitated by a custom-built mouse database in which every breeding pair and every mouse born are recorded and through which we can readily monitor the numbers of mice we hold. Many experiments will require homozygous mutant animals. Littermates of these that are heterozygous or wild type will be used as age- and gender-matched controls. This allows optimal use of mouse numbers generated as well as being best scientific practice for the study of genetic alterations.

The experimental design is always based on using the smallest number of animals that are sufficient to answer the question being posed. We expect, from experience, that 6-8 animals per treatment group should be sufficient to obtain statistically robust results. For most of the quantitative experiments, sample sizes may be set using power analysis, generally using a significance level of 5%, a power of 80%, and a difference between groups of 20%. Otherwise, we will use the minimum number of animals to provide an adequate description, generally on the basis of previous experience (ours, or from the literature).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding strategies are always set up to maximise the number of useful mice from each litter. Wherever possible we will use multiple tissues from every animal, in order to maximise the data obtained from each mouse. Cryopreservation of sperm or embryos will be used to preserve mouse strains, thereby obviating the need for continuous breeding and thus minimizing numbers of mice used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice since these are the mammal with the best studied immune system. Most of the work will be carried out using tissues from genetically altered moue strains analysed in vitro. Only a minority of the work will require further procedural work, such as immunisation. Where immunisation is needed, the methods to be preferentially used will be ones where there is no lasting harm to the animal, e.g. immunisation with model antigens.

Why can’t you use animals that are less sentient?

Mice are the animal of choice for these studies because, like humans, they are mammals and thus their immune system is closely related to the human immune system. In addition, the immune system of mice has been studied more extensively that that of any other mammal, and huge numbers of reagents are available.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will always choose procedures that cause the least amount of harm. Animals undergoing procedures will be

carefully monitored for signs of any impairment of welfare and, in rare cases, if required will be provided with pain relief.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Publications from the NC3Rs and the Institute for Animal Technology, as well as relevant articles in scientific journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay up to date via regular communication with animal facility staff at the host establishment, other scientists in our fields, via e-mail and other updates and publications from, and occasional attendance at meetings held by, the NC3Rs, the Institute for Animal Technology, and the International Society for Transgenic Technology, and through regular visits to their websites: https://www.nc3rs.org.uk/3rs-resources https://www.transtechsociety.org/ https://www.iat.org.uk/

NON-TECHNICAL SUMMARY

36. Development and validation of animal models for neurodevelopmental disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	pregnant, neonate, adult, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to understand how activation of the mother's immune system by viral or bacterial infection during pregnancy can cause of neurodevelopment disorders in the young, principally schizophrenia. From this understanding, we also aim to develop therapies to treat and prevent neurodevelopmental disorders.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Public health science has shown that maternal immune activation (mIA) is an important risk factor for neurodevelopmental disorders (NDDs) in the offspring. These disorders reduce the quality of life for patients and carers. They are poorly treated by existing medication and have a large economic cost burden. Both the pre and post-natal environments are critical for normal development of the fetus and offspring. Our multidisciplinary team has established a rat mIA model, work this application aims to continue. Evidence suggests that mIA, when accompanied by trauma in or around puberty, elevates the risk for later development of NDDs, particularly schizophrenia, above either risk in isolation. In this regard, the 'Second-Hit' appears critical for exaggeration of a pre-existing risk. For this reason we now want to extend our model to include a second hit. An animal model that translates to the human illness will enable new treatments to be developed.
What outputs do you think you will see at the end of this project?

Scientific publications, new information for people working to develop better treatments. A validated neurodevelopmental animal model to test new treatments.
Who or what will benefit from these outputs, and how?

Scientific publications, new information for people working to develop better treatments. A validated neurodevelopmental animal model to test new treatments.
The scientific community and general public, furthering knowledge, and improving understanding. The pharmaceutical industry, and drug discovery groups, as we will provide new treatment targets. We have close links with the pharmaceutical industry and will inform their drug discovery strategy through these links and via publication of our findings. Patients, carers and the NHS as ultimately this work will lead to new improved medicines for patients.
How will you look to maximise the outputs of this work?

We are committed to publication of positive and negative results, and to public engagement. We have already published our work refining the model and our methods. Several members of the team are experienced in public engagement.
This work started as a collaboration with a large pharmaceutical company, we will continue to collaborate with this sector. We will bring in more collaborators as the project evolves. The team currently consists of experts in behaviour, genetics, placental biology and development. We also engage with psychiatrist experts in this area.
Species and numbers of animals expected to be used

- Rats: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats are a popular choice for experimental work because of the detailed existing knowledge of their brain anatomy and behaviour. The rat has been chosen for the present work as much is already known about its cognitive behaviour and the brain functions controlling behaviour. We have extensive experience of studying behaviour in rats. All our current tests and protocols are validated for rats. Rats breed well in captivity and are well suited to longitudinal studies.
To allow us a better understanding of how schizophrenia develops from pre-birth to adulthood we have chosen to study the effects of mIA at critical stages of development. This is, pre-birth, young, adolescent and adult stages in male and female rats.

Typically, what will be done to an animal used in your project?

Pregnancy

Pregnant rats may be given a drug treatment regimen by mouth or by injection, or environmental treatment such as enrichment or exercise. This will be done before or after administration of an immune activating agent. A small blood sample will be taken from the tail vein at specified times after this to measure the immune response of the mother. The mothers will be checked regularly for behavioural and physical changes such as changes in grooming, general activity, body temperature and body weight caused by the infection. Some pregnant mothers will be humanely killed to allow collection and analysis of tissue from pregnant females and fetuses. Some pregnant females may be stressed by short term restraint at selected times during pregnancy.

Offspring

Following weaning, behaviour will be analysed in the offspring. The effect of treatments on offspring memory, behaviour and physiology will be investigated. The offspring may be given a drug treatment by mouth or injection, or environmental treatment such as enrichment or exercise. Some offspring will receive an anaesthetic to implant mini pumps for long-term administration of drugs. Some offspring will receive an anaesthetic to record brain activity while unconscious. These animals will be humanely killed at the end of the recording session without waking.
Some groups of offspring will be stressed by mixing up cage groups or short-term social isolation. At the end of the study, or as part of the experimental procedure the rats will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

The administration of a maternal immune activator is likely to induce a mild and short-lived infection, slightly increased body temperature or mild sickness in the mother, lasting less than 24 hours. The treatments may cause mild short-term pain from the injection site and also cause mild and short-lived changes in behaviour such as increase/decrease in activity. Stress inducing techniques, such as restraint of the dam, introduction of a male in close proximity to the cage, may be used on some pregnant females and her pups which may cause short-lived, mild changes in behaviour, appearance and general well-being. Behavioural techniques, applied to the offspring, are generally not stressful and can, in certain cases, be considered enrichment for the animals. Some animals will be placed on mild food restriction during behavioural testing and lose no more than 10% of their free feeding body weight. We intend to stress some offspring in adolescence by mixing up cage groups or short-term social isolation. Some rats may undergo anaesthesia for surgery to implant drug delivery pumps under their skin. They recover from this procedure quickly and in most cases no untoward effects are observed. At the end of the study, or as part of the experimental procedure, rats will be killed humanely.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected maximum severity for both protocols in this license is moderate. Approximately 75% of the animals used will reach moderate severity and 25% of the animals will reach mild severity.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work is complex and involves understanding the interactions between several body systems. In addition to the changes in the brain function of patients, these disorders are characterised by deficits in social behaviour, memory and mood. Such aspects of NDDs are not possible to model using cells or simulations. This work therefore must entail the use of animals as behaviour is a central feature of the project.
Which non-animal alternatives did you consider for use in this project?

None. However we did consider lower order animals such as drosophila.
Why were they not suitable?

Their behaviour and brain and life cycle is too far away from mammalian species to provide a translational model. On consultation with pharmaceutical company colleagues, they considered rodents the most suitable species for this work.
We did not consider non-animal alternatives because there are no non-animal models or systems that replicate the complex interactions and architecture of the central nervous system and the way it communicates with the immune system. If any relevant non-animal alternatives (or less sentient species that are suitable) become available during the course of the project, we will implement these in our studies. The animal studies will be accompanied by in depth analysis of brain and placenta tissue which may identify a biological marker that could allow us to develop subsequent isolated culture systems to study the pathology of these disorders.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on data generated from similar studies under the same experimental conditions. We consulted a statistician who advised on the minimum number of animals required to give us the maximum statistical power.

What steps did you take during the experimental design phase to reduce the number of animals being

used in this project?

We have optimised our statistical analysis through work conducted on our previous licence. We will also use the NC3R's Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will follow efficient breeding protocols in consultation with experts, carry out pilot studies with small numbers of animals and always aim to share tissue with team members and other colleagues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are continually refining our behavioural procedures to enhance animal welfare (using species relevant tests, minimum food restriction, food rewards). When we started this project, we optimised our methodology through an extensive study in non-pregnant rats. Since then, we have refined our methods.

Why can’t you use animals that are less sentient?

It is not possible to mimic complex interactions outside a living organism. Furthermore, this work must entail the use of animals as behaviour is a central feature of the project. We are unable to measure complex behaviour patterns in immature life stages, animals that are less sentient or that have been terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Specific on-going refinements include: reduced use of food restriction for the behavioural tests, increasing use of species-relevant tasks, implementing enrichment such as play pens and tummy tickling. We have also optimised our dosing regimens, handling and dosing techniques in collaboration with experts in rodent handling, including reduced restraint. Where animals will be subjected to potentially painful procedures, we will use suitable pain relief to minimise any pain and suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We consult with experts to implement improvements in animal welfare. We have access to the extensive library of NC3Rs resources which includes guidelines, practical information and themed hubs. Links to publications, other online resources, and video and training materials.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are registered to the NC3Rs and subscribe to CRACK IT innovation platform and receive updates on advances through NC3Rs newsletters. We are working with our local NC3Rs manager, on implementing environmental enrichment using play pens.

Home Office

NON-TECHNICAL SUMMARY

37.Development of a new generation of AAV vectors to treat monogenetic disorders and acquired conditions

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

AAV, Gene therapy

Animal types	Life stages
Mice	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our research programmes focus on the development of potentially curative treatments for several monogenetic disorders and rare acquired diseases, with a largely unmet therapeutic need, using advances in gene therapy technology. Over the next 5 years our focus is on inherited and immune-mediated disorders, using new vector designs that enable therapeutic expression of transgenic protein in appropriate mouse models without toxicity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We have used our gene therapy approach for treatment of patients with blood and metabolic disorders, with some patients now up to four years post treatment. So far, we have observed that endogenous 24/7 expression of the missing or non-functional protein and have learnt that the expression and efficacy of our gene therapy approach in mice predicted human response, indicating that evaluation of any new vector in a mouse model is essential. We have also learnt that immune response to gene therapy (pre-existing and/or acquired) can hinder the efficacy of gene therapy and prevent re-dosing. Understanding the mechanisms underlying this immune response is of crucial importance for future success of the AAV-focused gene therapy.

What outputs do you think you will see at the end of this project?

We expect to demonstrate that gene therapy with AAV vectors will be safe and effective in the treatment of a range of monogenetic disorders, especially those that remain a significant burden on the healthcare and society. The new vectors being constructed for these disorders are likely to be more potent than has been the case to date. In addition, the quality of vector is improving over time. These advances reduce the risk of toxicity whilst reducing the amount of vector required for the effective gene transfer. The results we obtain with our new vectors will provide new information about the new therapeutic approaches for the explored diseases and will be published in scientific publications to disseminate the knowledge acquire to a wider scientific/clinical community.

Who or what will benefit from these outputs, and how?

Gene therapy has transformed the lives of patients without persistent or late toxicity to date with three approved AAV gene therapies and two for haemophilia submitted for approval. Single dose AAV gene therapies are anticipated to be durable resulting in health savings on protein/enzyme replacement therapies (~£150k to £350k per patient per annum for life for protein/enzyme replacement), ~£70k for surgeries such as kidney or liver transplants. Successful gene therapy can also have benefits for the whole society via reduction in economic and societal loss due to absence from work or school and

reduction in demand on hospital care and social services. The work proposed will help us develop novel gene therapy approaches for other disorders where current treatments are not optimal or not available.

How will you look to maximise the outputs of this work?

In our pursuit of the most appropriate methods for testing our vectors, we will form many international collaborations with key opinion leaders in the field, both academic and industrial to join efforts in our attempts to find the best AAV approach for various indications with not just therapeutic but curative potential. We will make sure our results, both positive and negative, will be published in peer-reviewed scientific publications and made available for the wider community.

Species and numbers of animals expected to be used

- Mice: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the lowest vertebrate with well characterised disease models including genetic manipulation that is used to model human inherited diseases. No other species could fulfil the requirement of this programme, especially in term of generation of pre-clinical proof of concepts, to the same extent as the mouse. Most of our proposed protocols will use animals at the adult stage to ensure that all the physiological systems are functionally and fully developed. This is also relevant in terms of refinement, as we will avoid using juvenile or aged mice, without a valid scientific objective.

Typically, what will be done to an animal used in your project?

In a typical experiment, animals will be allowed a period of acclimatisation before any procedure is performed to reduce stress. Biological samples are collected before starting any treatments to have a benchmark data. The animals are then injected with a gene therapy vector and the biological samples are collected at regular intervals to monitor the effects of the gene therapy. The minimum duration of an experiment can be 4 weeks or up to 24 months in long-term experiments. At the end of the experiment, the animals are humanely killed and several samples and biological fluids are collected for extensive analysis. In the experiments focused on specific disease models, animals will be allowed a period of acclimatisation before any procedure is performed to reduce stress. Biological samples are collected before starting any treatments to have a benchmark data. The animals are then injected with a gene therapy vector and allowed a period of up to 4 weeks before the pre-clinical models of diseases are started. For example, changing the standard rodent diet to a diet that causes the animals to accumulate fat in the liver (a model of non-alcoholic steatohepatitis), or injecting or applying chemicals that cause local or systemic inflammation and tissue scarring (similar to a range of auto-immune diseases). During the progression of the disease models, biological samples may be collected at

regular intervals to monitor the disease progress. At the end of each respective pre-clinical model of disease, the animals are humanely killed and tissue samples, in addition to biological fluids are collected for extensive analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of our protocols and procedures are not expected to cause adverse effects that are long-lasting. However, animals can experience discomfort and pain from the injections and/or sample collections. We will monitor these and provide pain-relief as needed. Other effects of treatments that we will monitor include changes in body weight and behaviour and general overall condition. We anticipate that adverse events will be transient (1-6 hours) and any animal showing adverse events that do not improve within will be humanely killed. In the experiments focused on specific disease models, we have proposed the most refined disease models that result in similar clinical outcomes that are observed in humans. Most of the disease models are expected to cause mild-moderate adverse effects as the disease models progress. This can typically cause modest weight loss which will be an important indicator of the welfare of the animal. We will monitor the animals frequently and provide appetising gel diet to counter the weight loss. If this does not cause an improvement, animals will be humanely killed. We have established clear endpoints in all models that do not cause unnecessary discomfort and pain to the animals, yet will allow us to address our scientific questions.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The degree of severity is expected to be moderate or less depending on the procedures we propose to use. All of our protocols will be performed on mice. Mice will be closely monitored for development of any adverse clinical signs and clear endpoints are defined in the protocols in order to minimise conditions of distress. At the end of each experiment and at well specified humane endpoints, mice will be humanely killed, and blood and tissues will be collected for analyses.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

All of our proposed work using animals will be preceded by studies using mouse/human cell lines including stem cells, and organoids (miniature organ-like 3D cluster of cells), co-culture and organ-on-chip cellular assays which are becoming increasingly important in modelling different disease

conditions. These crucial studies will allow us to select the appropriate gene therapy vectors for evaluation in mice.

The core physiological systems of the body, including the immune system, are controlled by complicated inter-dependent mechanisms that are not replicated by cells grown in a laboratory. The mouse represents the lowest vertebrate species that is accessible to genetic manipulation for the understanding of mechanisms of diseases, penetration of liver expressed therapeutic proteins into deep tissues associated with disease and disease substrate clearance/pathology resolution, transport and protein targeting mechanisms. Additionally, mouse and human genes are similar by approximately 80%, which would allow us to predict the therapeutic effects of our gene therapy vectors in human patients. There is a large amount of published scientific body of work that shows that our proposed models have a good degree of translation to the effects observed in humans. Importantly, all of the procedures that will be undertaken have been refined to minimise suffering.

Which non-animal alternatives did you consider for use in this project?

1. Cell culture-based approaches - Where possible the gene therapy vectors we develop are assessed during in vitro assays using commercially available mouse and human cell lines to ensure efficacy. This is employed for all our approaches and for each new batch of vector.

2. We are developing and evaluating disease specific human cell models obtained from stem cells to determine if these can replace animal models for evaluation of gene therapy vectors.

3. We are evaluating human liver cells grown in 3D cultures (organoids) to see if these can substitute mice for assessment of gene therapy vectors.

4. We are currently evaluating ‘organ-on-chips’ assays that use human cells to model a physiological system (e.g., the liver) and which can be manipulated to mimic clinical conditions (e.g., fatty liver disease). This will allow us to assess the efficacy of our candidate vectors in the therapeutic indication before commencing animal studies.

Why were they not suitable?

Murine models of human disease serve as an important tool for establishing pre-clinical proof-of-concept, and for assessing the efficacy and safety profile and immunological consequences of our gene therapy approaches. Based on the clinical data becoming available from clinical trials, it is becoming increasingly important to understand the effect of the host immune response on the efficiency of gene transfer after gene therapy treatment. The body’s response to gene therapy vectors involves multiple systems, organs and cell types. Additionally, the complexity of the immune response cannot be assessed in in-vitro settings. The use of in vivo models is essential to refine existing therapies, and develop new therapies, as they will allow us to detect the persistence of the gene therapy, their efficacy in modifying/preventing diseases, and any potential toxicity. In vitro systems, while useful, do not fully replicate the complexity of immune interactions or disease mechanisms in vivo and it is essential to use appropriate and robust animal models to understand these processes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimation of the numbers of animals intended to be used under this PPL has been agreed with project leads at our company and aligned with our strategic goals for the next 5 years. Additionally, we have also used our experience from our previous project licence to estimate the number of animals that we will use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used Power calculations using the NC3R's Experimental Design Assistant and statistical consultants to reduce the number of animals being used whilst ensuring that sufficient data is obtained to answer the research question. Additionally, we have designed longitudinal pharmacokinetic/pharmacodynamic experiments that will allow us to obtain data from the same animal at different time-points, instead of using different animals for the distinct time-points. These experiments will be performed at the highest standard that will not compromise the welfare of the animals and will also allow us to significantly reduce the numbers of animals being used in this project. Similarly, we designed experiments that will allow us to maximise the information obtained from each animal via advanced molecular biological assays on post-mortem tissue/biological samples following the completion of in vivo experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In addition to good experimental design, we will extensively use computer modelling and cell-based evaluations to reduce the number of animals used in our project. We will also assess sharing tissue samples from different experiments to address specific objectives, if feasible. We will consult with the experienced animal care support staff at our animal facility to implement strategies that will allow us to maintain efficient breeding of animals. This may involve freezing of sperm and embryos to reduce the number of animals kept alive for specific disease models. Importantly, our study designs will be reviewed by statisticians to ensure that we design experiments that will use the minimum number of animals to achieve our objectives.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of our animal models are genetic or induced to resemble human disease conditions. For example, we will use mice that are genetically modified to model inherited human conditions (for example inherited metabolic disorders). These mice do not have the full clinical phenotype seen in human patients but have the same dysfunction (i.e. disease substrate build up), which allowed us to use this model to successfully develop a treatment for patients. We are now proposing the use of additional pre-clinical models of chronic diseases using models that are known as gold standard. These models closely resemble the human patients with the least suffering and distress caused to the animal. We will design experiments that will allow us to determine the efficacy of our candidate gene therapy vectors in improving these conditions by injecting the gene therapy vector by different routes. The number and volumes of administrations and blood samples will be minimised while ensuring scientific validity and minimising discomfort. Before any experiment is performed, animals will be acclimatised to procedures.
Environmental enrichment will be provided in home cages.

Why can’t you use animals that are less sentient?

We have chosen to work with mice as they are the lowest vertebrate group with well characterised disease models. The mouse models we propose to use in this project license are already well established, characterised and described in the scientific literature.

As described before, unfortunately, in vitro studies do not completely predict outcomes in humans. For example, a common gene therapy vector (AAV8) performed poorly in vitro but were highly efficient in animal models including mice. Efficacy in mice predicted the outcomes in human patients with inherited bleeding disorders (haemophilia B). Importantly, the mouse immune system is the best characterised amongst vertebrates and there is a strong degree of similarity between aspects of the human and mouse immune systems. Most reagents and tools required for the proposed plan of work have been designed for use in mouse models and for the detection and tracking of murine immune cells. Immunological assessments are going to be an important part of the studies we will perform over the next five years.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All the protocols have well defined end points and mice will be humanely killed with an appropriate Schedule 1 or non-schedule 1 methods within 12 months of receiving gene therapy vector or earlier where indicated. In some studies, an extended duration may be required (16-24 months). Full effort will be made to ensure animal well-being and comfort, and to minimise pain and distress. Good handling will minimise discomfort of the animal during the procedure. Sites of injection will be monitored carefully to prevent wound infection. If needed, we will apply local analgesics over the affected region to improve recovery. Aseptic techniques will be used at all times. Experimental animals will be monitored at least daily by our research group and staff within the animal unit. Details of animal experiments in progress will be shared between our research team and the staff within the animal unit to ensure that unexpected adverse events are quickly resolved to minimise harms to the animal.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines in addition to Home Office published guidelines (e.g., Guidance on the Operation of the Animals (Scientific Procedures) Act 1986) and relevant LASA guidelines. Additionally, all murine models that we propose to use have extensive literature resources available which will allow us to conduct our experiments in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We currently receive news bulletins and invitations to specialist seminars organised by the NC3Rs and our animal facility is very engaged with the NC3Rs community. We will maintain this engagement to stay informed about the advances in the 3Rs, in addition to staying up-to-date with scientific publications that highlight 3Rs principles. We will implement these advances effectively by working with the animal facility technical staff and our research team.

Home Office

NON-TECHNICAL SUMMARY

38.Development of Treatments for Degenerative and Traumatic Retinal Disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Exosomes, Glaucoma, Optic nerve injury, stem cells, neuroprotection

Animal types	Life stages
Rats	adult, aged
Mice	aged, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to test multiple therapeutic agents as treatments for blinding diseases of the retina. These agents include stem cells, exosomes/extracellular vesicles, and genetic compounds known as miRNA. We also aim to develop animal-free models of retinal disease that are comparable to those currently used in eye research.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Vision is the most important sense for humans, and it is required for individuals to maintain their independence in today's society. Vision loss is a devastating condition and is associated with some of the lowest quality of life scores. Many diseases that lead to vision loss are age-related and are thus becoming an increasing problem in a society whose life expectancy increases. For example, glaucoma
affects 80 million individuals and is estimated to affect 120 million by 2040. In this example, no treatment exists that directly prevents the retina from degenerating. This proposed project seeks to develop the first novel treatment to directly protect the retina and prevent visual decline. In the development of treatments, it is also important to consider the models utilized. There are huge differences between human and animal retina, which although do not invalidate the use of animals in eye research, do create a need for good human in vitro models. As part of this project, human retina generated from human embryonic stem cell lines will be injured in a variety of ways in an attempt to recapitulate human disease and therefore act as an animal-free replacement to eye research.

What outputs do you think you will see at the end of this project?

This project will generate a number of outputs.
Firstly, the work described in this project is covered under a patent and we seek to generate the first neuroprotective treatment for patients with glaucoma and other retinal diseases, preventing visual decline and blindness.
Secondly, publications describing exosomes and their mechanisms of action will continue to be published, in an effort to aid other research groups assessing their clinical efficacy in a range of other diseases including spinal cord injury, stroke, and Alzheimer's disease.
Finally, the project will generate data integral to obtaining further grant funding which will help see the above two outputs realized.

Who or what will benefit from these outputs, and how?

Firstly, this project benefits the vesicle/exosome research community as it seeks to understand the importance of exosomes, their role in homeostasis as well as their therapeutic potential as well as the potential for the presence of distinct
subtypes. For example, the exosome research committee at the National Institutes of Health is a collection of researchers working within this field. Equally multiple researchers in UK institutes all lead research groups focusing on exosomes/microvesicles and will directly benefit from the data derived in this project. Many groups have begun working within the field of exosome subtypes and part of this proposal seeks to add to this field, understanding not just the differences between each subtype but also how this effects their therapeutic efficacy. We will also conduct miRNA next generation sequencing (RO4) whereby data will be uploaded and

made available to researchers*.
The second beneficiary is the neuroscience community and in particular, the neuroprotection, axon regeneration and, eye field. The importance of this research to the field is exemplified by the current Audacious Goals Initiative (AGI) set out by
the National Institutes of Health, National Eye Institute which is "tackling the most devastating and difficult-to-treat eye
disease". Institutes all across the United Kingdom have many researchers actively engaged in this research field. Collaborations between this proposal and their own research projects as data is accrued provide mutual benefit.
Finally, one of our aims is to develop a human in vitro model of optic nerve injury (and test exosome treatments in this model), using genetically modified human embryonic stem cells. Many research groups are utilizing these cells as they have been made widely available and all data published helps researchers understand these cells and their strengths/limitations as a human model of retinal disease
. By developing a model of eye disease that is animal free, it also seeks to push the field away from the use of animals. This will greatly benefit animal welfare as less animals will be used in eye research without detriment to research output.
*All results will be published in high impact open-access journals. Published manuscripts will be placed into the home establishment's dedicated repository. After the required timeframe (6 months STEM/12 months SSAH) and based upon the publisher's rules, articles will be made open access as part of the Green Open Access Route. If the publisher's rules prohibit the Green
Open Access Route, the home establishment will pay Article Processing Charges and publish in the Gold Open Access Route.
Embargo times will be checked to be compliant with the journal and MRC, and the University will automatically make the
article available after the embargo. Bibliographic metadata will be made accessible with author set restrictions to maintain any confidentiality requested. The information will be added to the Open Archives Initiative Protocol for Metadata
harvesting (OAI-PMH) under the keyword "MRC" and indexed into frequently used search engines such as Web of
Knowledge and Google Scholar. Metadata will also link to the Universities Published Data Archive where data produced during this fellowship with be published in accordance with Open Data requirements. Data will be managed continuously to ensure it maintains a high standard with emphasis on clarity and will abide by the relevant institutional and departmental policies.

Impact Summary
Currently, no neuroprotective treatment
exists for glaucoma. Visual deficits have serious consequences to patient well-being and health (>80m individuals) and a loss of vision is associated with some of the lowest quality of life scores. This project is of particular importance as it focuses on "healthy ageing", of which glaucoma, an irreversible condition, can be considered the prototypical ageing disease. Finally, the pro-regenerative aspects of this project stand to not only benefit the eye but other central nervous system disorders such as spinal cord injury.
This project seeks to benefit those patients with glaucoma and other similar eye disorders as well as the ageing population of which a significant portion will develop such diseases.
Commercial beneficiaries are based on ensuring my research is patented and exploited. The work discussed in this
proposal is covered under a patent for which I am listed as the inventor. Future discoveries that come about from this proposal will be effectively exploited in the same manner. Knowledge and IP management will be based on the requirements defined in the official documentation as well as the Grant Agreement. University teams are available to provide support regarding the exploitation of IP and will maintain dialogue with my research group to ensure IP is protected. They will continually monitor the nature and size of commercial

markets to determine possibilities for exploitation via identifying potential licensees, customers, partners and collaborators. The team has experience and provides support for proof of concept, creation of spin-off companies, venture development and start-up incubation.
With regards to training, funded post-doctoral researchers (as well as potential PhD/MSc/summer students) will gain a highly interdisciplinary background, being trained in neuroscience, molecular biology, vesicle biology and bioinformatics.
They will be trained to utilize the most cutting-edge in vitro and in vivo techniques as well having the opportunity to gain supervisory skills (MSc students will be joint supervised by myself and the post-doc). Students will attend training sessions held by the University, such as the post-doc development centre which provides skills in communication, organisation, grant/paper writing and presentations. The post-doc will also attend international conferences and present their findings to world leaders in the field.

How will you look to maximise the outputs of this work?

As described above, all publications will be made open access and annual conferences will be attended to ensure data is disseminated in an open and timely fashion. We will maintain strong collaborations with the National Institutes of Health, the largest research institute in the world, and continue to work together publishing papers and applying for patents. We will work closely with the commercialization teams, as discussed above, to ensure the maximal impact can be achieved. Unsuccessful/non-significant results will be made available, either as an inclusion in published manuscripts as supplemental data, or being uploaded to research communities such as ResearchGate.

Species and numbers of animals expected to be used

- Rats: 500 per 5 year
- Mice: 80 per 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To study eye research, an animal is required whose visual system best represents that of a human. It is also important that the animal is an adult, as the adult visual system is distinct from that of a young animal whose regenerative potential is greater. Since glaucoma and other ocular diseases occur predominately in adults and often in the aged population, this must be represented in the animal model. Between mice and rats, rats are the optimal choice for several reasons. Firstly, rats are larger which makes the surgery easier and reduces complications. Injections into the eye can be delicate and this is made easier with the larger eye of the rat, particularly when injected into the anterior chamber.
Secondly, the injury response to nervous system injury is more similar to humans in rats than mice.
Finally, in glaucoma, damage occurs in a particular structure of the eye known as the lamina cribrosa.
While this structure is present in humans and rats, it is not present in mice. For these reasons, rat models of glaucoma and traumatic optic neuropathy are the most ideal. The mouse DBA/2J model is however a long-term model and does have the advantages of testing the long-term effects of candidate treatments.

Typically, what will be done to an animal used in your project?

With regards to glaucoma, animals will receive injections into the front chamber of the eye, either beads or cytokines, which will induce an elevation in eye pressure and thus, glaucoma. Pressure is monitored using a painless rebound tonometer. Treatments are delivered into the eye similarly by intraocular injection, identical to how many other treatments are given to patients with eye disease. Ocular injections as well as ocular pressure recording require the animal to be anaesthetised, not to minimize pain as none is expected, but to prevent the animal moving during the delicate injection.
The second model is optic neuropathy. This surgery requires a small incision on the head, identification of the optic nerve that runs out the back of the eye, and the crushing of said optic nerve using forceps/tweezers. The wound is sutured afterwards, and animals recover completely in 1-2 days. Analgesic is given during these 1-2 days of recovery.
All animal models are expected to last 1-2 months and the surgery is only done once at the beginning of the procedure. Treatments are given either once a week, or once a month depending on the efficacy. Visual assessments (imaging) are also done (once a week/month) and are painless but require anaesthesia to immobilize the animal.
The DBA/2J mouse model is a strain of mouse that develops ocular hypertension without intervention and is kept for 9 months from age 3 to 12 months. Injections, described above, are delivered once a month.

What are the expected impacts and/or adverse effects for the animals during your project?

The induction of elevated intraocular pressure is used to model glaucoma and although visual decline is expected in animals, few adverse effects are expected. Rodents are not dependent on their vision and thus their behaviour is not affected by this perturbation. The most common adverse effect is dry eyes which is treated easily with eye lubrication drops. Other less common side effects such as pain and irritation of the eye, and inflammation are possible and are a consequence of infection resulting from the injection. These are detailed in the score sheet and their management may include anti-septic eye cream/ointment or schedule 1, depending on the severity.
Optic neuropathy involves a head wound and thus, pain and discomfort is expected for the first 2 days of recovery. An expected adverse effect is wound reopening which can occur if rats irritate the surgical site (scratching or cage-mates biting). Analgesia is provided to animals during these recovery days and the pain and discomfort is managed according to the score sheet.
In the DBA/2J mouse strain, development of cataracts is common and is typically permanent but not painful. Aged animals (10+ months) of this particular strain are also susceptible to cardiac calcification and tend to die sooner than other mouse strains. Between 10-12 months of age, which is an important step in this project as this is when the majority of visual decline will occur; approximately 10% of animals will not recover from anaesthesia during pressure recordings due to the above mentioned cardiac calcification.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected category for all animals associated with this procedure is moderate severity (100%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The eye is a complex tissue with multiple interconnected cell types. To ascertain that our candidate therapies would have a clinical benefit on patients, multiple tests are required that would not be possible on anything but an in vivo system. These include live imaging of the retinal morphology overtime using optical coherence tomography, and live recordings of the electrical function of the retina in response to light using electroretinography. Both of these techniques are used in the diagnosis process in patients as well as to monitor disease and treatment progression. We also wish to understand the longevity of this treatment when it is administered into the eye, how often the treatment must be re-administered and any interactions with the rest of the body *via* the systemic circulation. All of these require the use of an in vivo system.
Given the novelty of exosomes/extracellular vesicles as a signalling mechanism, it is not currently understood what role they play in maintaining tissue homeostasis. Homeostasis is complex involving signals between multiple cell types and, by definition, involves the tissue acting in its normal environment which necessitates the use of animals.

Which non-animal alternatives did you consider for use in this project?

My work utilizes two non-animal alternatives, both of which are considered (as well as replace certain elements of this project).
Partial Replacement - Rodents are sacrificed and the eyes/retinae are removed and cultured. Since the optic nerve is severed, these cells will die in culture in a way which recapitulates the death seen after optic nerve injury *in vivo*. Treatments can be added to the culture medium and neuroprotective and neuritogenic effects can be measured.
Total Replacement - Human Embryonic Stem Cell lines are differentiated into retinal cells using a well published 35-day small molecule regime. Unlike in the above model, retinal cells do not die in culture so a microtubule poison (colchicine) is added to instigate retinal degeneration. Treatments can be added to the culture medium and neuroprotective and neuritogenic effects can be measured.

Why were they not suitable?

Rodent retinal cultures do not full recapitulate the complexity of retinal disease, and are more associated with traumatic injury as opposed to the slow progressive degeneration seen in glaucoma. Retinal cultures are only viable for 3-4 days and so while they are very useful for providing hints as to which therapies may have clinical efficacy, they do not serve as a suitable replacement for *in vivo* models.
Human retinal cultures are a strong contender for the replacement of animals however they are held back by a lack of good methods on how to injure them in a way which fully recapitulates the disease seen *in vivo.* Since they do not degenerate spontaneously in culture like rodent retina, degeneration must be induced externally. One particular project within this licence is to develop this model further, testing new injury systems to better model human disease (and comparing them to current regulated procedures and established treatments). As of now however, the system serves as a useful approach to ensure that therapies are applicable to human retina, but cannot as of yet model the complex disease in full.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The models used in this proposal are those I have used routinely in the last 8 years and thus, a large amount of data is available to aid in the estimation of animal numbers. Indeed, one of my open-access publications focused entirely on study design and power calculation-informed decisions on the number of animals required to determine varying effect sizes in eye research. These power calculations are available to all eye researchers utilising these models and have been used in the estimations in this proposal. Briefly, the rat model of optic nerve crush is incredibly reliable and power calculations (alpha value = 0.05, Beta value = 0.2) determine that 5 animals per group are required to detect a difference in retinal cell numbers by 20%. Regarding glaucoma models, standard deviations are higher and thus 7 animals per group are required for the same variables. One additional animal than that identified via power calculation is utilised. Thus, for every treatment measured, 6 animals for optic nerve crush and 16 animals for glaucoma (2 different models) are used. While it is not currently known how many treatments groups we will utilise as more candidates will inevitably be discovered, we have currently identified 8-10 treatments which would require 220 animals as part of objective 2. Some groups will require 5 extra animals which will provide the tissues necessary for sequencing as part of Objective 4. Objective 3 will aim to recycle data from animals used above but it will likely be necessary that some groups are specifically set up to derive data for Objective 3. A further 60 animals are required to address Objective 1 of this proposal which involves mainly retinal sampling before or after treatment. The numbers are based on the power calculation above but the only treatments used for further analysis are those that show the greatest promise in Objective 2.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals used we employ retinal cultures (described in the replacement section) to confirm therapeutic potential in our drug candidates prior to the move to *in vivo* testing. If certain exosome/extracellular vesicle formulations are ineffective at promoting any therapeutic efficacy *in vitro*, they are excluded from the *in vivo* study. We also generate as much data as possible from the same animal cohort. A single animal can be live imaged, functionally and behaviourally tested as well as histologically analysed post-mortem. By incorporating all of these tests from the onset, we do not need to use more animals in the future to test the same treatment. When using histology, the retina can be taken as a whole-mount or as tissue sections. While the retinal whole-mount is considered more reliable, tissue sections reduce animal numbers as a variety of analyses can be done on the 100+ sections that can be collected per eye. Our previous publication has demonstrated that retinal sections are as reliable as whole-mounts and thus, using sections, animal numbers will be reduced significantly.
The experiment is planned on the basis that both males and females will be used, within the same study. This will allow us to compare any sex-specific effects while not reducing the reliability of the overall study as we can use a statistical blocking approach on the collected data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

While the number of rats per group cannot be reduced further, we can reduce the number of animals used in *in vitro* tissue culture experiments. As the culture experiments require eyes, we will collaborate with other research groups working on brain tissue. Coordinating with their group can mean that the same animal can donate tissue for both studies.

With regards to the development of a human *in vitro* model retina disease (objective 3), its reliability needs to be compared to the currently used rodent models. While as a stand alone project this would mean animals are required to test these models and compare data to the developed *in vitro* systems, by joining the two project aims, significant reductions in animal numbers can be achieved. As an example, testing three formulations of exosomes in a model of glaucoma will also include a 4th control group where no treatment is added. This very same data will be compared to the developing *in vitro* models, assessing their reliability. Thus, the same animals will address two distinct project aims.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models detailed in this project licence application all seek to reduce vision in animals.
Distress/suffering - removing an animal's primary sense can be considered distressing to said animal and indeed the basis of this application is to prevent and treat vision loss in human, which is associated with significant loss of quality of life. However, rodents, unlike we humans, do not depend on vision. A rat's vision is estimated to be 20/600 (20/20 is normal healthy vision in humans) with an albino rat going down to 20/1200. It is worth noting a vision of 20/200 is considered legally blind. It is not possible to discriminate between control animals and animals subjected to the models described in this licence as their behaviours are identical. Considering that only one eye is affected in these models, it can thus be strongly argued that animals do not suffer any lasting distress/harm.
Pain - The glaucoma models typically involve ocular injections under anaesthesia. Note that these are routinely done in humans (without general anaesthesia) and thus are known to not cause any lasting pain any more than an intravenous or intraperitoneal injection. The optic nerve crush model utilises an intra-orbital approach and thus require an incision on the scalp as well as a small incision through the anterior portion of temporalis (jaw muscle) and mobilisation of the harderian gland. It is thus expected that following recovery, the animal will be in some mild pain for 1-2 days. This is adequately managed with analgesics and animals return to normal behaviour within 24 hours. These models have been developed over several decades to produce the least suffering in animals and are routinely used as the gold-standard in eye research.
DBA/2J mice are more susceptible cardiac calcification as they age and subsequently not recovering from anaesthesia (approximately 10% of mice). This effect becomes significantly more pronounced past 12 months and hence, stopping the experiment at 12 months prevent much of the detrimental effects while also allowing the acquisition of usable data.

Why can’t you use animals that are less sentient?

The central nervous system has evolved measures to prevent repair and regeneration, and these measures are not present in lower order animals. For example, injury to the visual system of a zebrafish is temporary and the eye and optic nerve completely repair over several days. Thus, testing treatments in these models becomes more difficult, as does trying to elevate pressure in their eye due to distinct differences in their physiology. Lower order life forms such as insects lack the complex eye structures seen in humans and again, glaucomatous damage of the optic nerve cannot be modelled.
There are distinct differences between rats and mice that make rats the more suitable choice. Firstly, given injections are being given into the eye, or surgery is being done around the eye, the increased size of the rat is hugely beneficial to surgical success and well-being of the animal. When injecting the rat's eye, avoiding the large lens is a requirement to ensure the results are viable. This potential complication is rarely seen when using rats compared to mice. In glaucoma, damage to the optic nerve occurs in a structure called the lamina cribrosa, an area just behind the eye. This structure is present in the rat but not in the mouse. Finally, the scarring and fibrotic response that occurs after central nervous system injury is distinct in rats and mice, and is more similar to the human process in rats than mice.
One benefit to using mice is the genetic models and strains available. One such strain is a DBA/2J mouse that spontaneously generates elevated intraocular pressure and glaucoma. Despite the disadvantages discussed above, the one benefit to this model/strain is that it occurs without intervention and is a 12 month process. This extended timescale is more similar to the human condition than the models used in rats and thus is useful for ensuring therapies are still viable over long periods of time.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Optic Nerve Crush - Animals will receive increased monitoring for the first few days following the procedure to ensure animals are not experiencing any pain and the wound heals effectively. VetBond glue (or other adhesive) as opposed to sutures will be strongly considered for wound sealing as we have demonstrated that recovery is faster and wound reopening is less likely. It can be argued that it is more uncomfortable for the animals so this will also need to be considered. Animals tend to open each other's head wounds when sutures are used, which then occasionally requires isolation of said animal. VetBond ensure animals can be housed together for the entirety of the project and will be mandatory if wound re-opening occurs to a greater frequency than detailed in our adverse effects. Only one optic nerve will be crushed so animals will retain their vision.
Glaucoma - The induction of glaucoma is done through the intraocular injection of substances and thus, refinements below are equally valid here. To monitor the pressure, a Tonometer must be used.
Typically, animals are anaesthetised to prevent variable stress reactions from influencing the pressure reading, since the animal must comfortably sit still as the rebound tonometer gently touches the eye. We will however consider training the animal the sit still for the tonometer recording, and some labs have had success in this regard.
Intravitreal injection - Ocular injections are a simple procedure but due to the delicacy of the injection site, anaesthesia is still required. Adequate training will ensure that the duration of anaesthesia is kept to a minimum. An efficiently training surgeon can perform the injection in under 5 minutes, including anaesthetic induction. Regular needles are too wide and thus cause excessive damage to the eye. We instead will use pulled glass capillary rods typically used to patch clamping cells, or Hamilton syringes.
Micro-needles are narrower than any commercially available needle and thus minimally damage the eye, allowing rapid healing.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Regarding eye research, we will follow the ARVO (Association for Research in Vision and Ophthalmology) guidelines for the use of animals in research. We will also adhere to the ARRIVE guidelines.

https://www.arvo.org/About/policies/statement-for-the-use-of-animals-in-ophthalmic-and-visionresearch/ https://www.nc3rs.org.uk/arrive-guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

A significant part of this project is the development of a human in vitro model of retinal disease, and thus, the 3Rs are intrinsic to this project. We will constantly engage with other eye researchers as well as the large amount of information available on the NC3Rs website. The project will incorporate new refinements as and when they are developed. We also hope that through the development of a in vitro model, certain aspects of the project can be replaced by these animal-free techniques.

Home Office

NON-TECHNICAL SUMMARY

39. Development, functions and programming of embryonic and adult immune cells

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project investigates (i) the **development and functions** of embryonic and adult immune cells as well as (ii) the effects of **early life adversity** on immune development and function and the consequences of this **"programming"** on later life health and disease.

A retrospective assessment of these aims will be due by 03 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We currently have a **limited understanding** of what functions embryonic immune cells exert during gestation. Likewise, it remains controversial if their functions are distinct from those of immune cells generated at later stages. This is of particular interest for conditions where embryo-derived cells persist and co-exist with adult immune cells, like female reproductive organs and tumours. Similarly, we do not know if and how adverse early life environments change the normal developmental sequence and functions of immune cells, and if this predisposes for later life disease. This work is important to fill these **critical gaps**. In the future, it might help stratify individuals at risk for chronic inflammatory diseases like rheumatoid arthritis, and identify new avenues for preventive or early therapeutic intervention. It might also guide novel therapeutic approaches for pregnancy-related complications such as preterm birth as well as tumour immuno-therapy. Although fundamental in nature, this project thus has immediate **translational relevance**.

What outputs do you think you will see at the end of this project?

This project will primarily generate **new information** related to several scientific questions that are fundamental in nature, but nonetheless of immediate biomedical relevance: Our work will further improve our understanding of how the immune system normally develops, what functions the very first immune cells have in the embryo and in pregnancy, and if these functions are "hijacked" in tumours. We will also generate new information concerning the role of immune cells in maternal tissue remodelling in the context of pregnancy. Lastly, we hope to generate new insights in how adversity experienced early in life changes the normal course of immune development, and if and how this in

later life increases the susceptibility to tumours and chronic inflammatory disease like rheumatoid arthritis. We thus hope to provide a mechanistic understanding of cause-consequence relationships underlying observations made in human epidemiological data. These findings will be **published** in scientific journals, but may also be disseminated to the general public. Moreover, while the project will not directly generate products for therapeutic use, it might inform **new strategies** for medical purposes.

Who or what will benefit from these outputs, and how?

In the first instance, this project will benefit the **scientific community** by filling critical gaps in our understanding of immune development. It will also benefit the research field by generating new models with which to address questions that have remained unanswered or controversial. It might also benefit **society** by increasing **awareness** of how early life adversities can have long-lasting impact on the immune system. In the **future**, this work might also help **meet clinical needs**. Specifically, it might aid stratification of individuals at risk for chronic inflammatory diseases like rheumatoid arthritis, and identify new avenues for preventive or early therapeutic intervention. It might also guide novel therapeutic approaches for pregnancy-related complications such as preterm birth, as well as tumour immunotherapy.

How will you look to maximise the outputs of this work?

We aim to maximise the output of this project in several ways:

- This work will be highly **collaborative**. It will involve existing and new collaborations, both locally and internationally, and regular exchange on technical aspects and progress of the project.
- We plan to **disseminate** the data and knowledge generated within the **research community** through participation in expert **congresses** in relevant fields (e.g. Immunology, Developmental and Reproductive Biology, Rheumatology), **seminars** at other research institutions and **publications** in peer-reviewed journals. We also plan on disseminating our findings to the larger public through in science communication efforts and **public outreach** activities. These are strongly supported by our Centre and the University. We also intend to share within the scientific community any **unsuccessful approaches**, with the aims of troubleshooting these and preventing unnecessary unknowing duplication efforts. Where possible will we also publish negative data in scientific journals. Although unfortunately rather uncommon, there has been a recent surge in publications reporting the absence of phenotypes in studies aimed at understanding mast cell functions, or studies refuting functions previously attributed to these cells using different models. This example illustrates that the field is growing increasingly susceptible for sharing negative findings.
- Where appropriate, we also aim to interact with and share our efforts and findings with more specific public bodies such as **patient initiatives** (e.g. for rheumatoid arthritis) and **charities.**

Species and numbers of animals expected to be used

- Mice: 12.000 + 30.000 additional offspring

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Central questions underlying this project are how the immune system develops, and what its functions are at different life stages. Immune development is initiated early in gestation. We are therefore interested in animals across the entire lifespan, ranging from embryos to newborn, juvenile and adult animals as well as pregnant females. In addition to our interest in embryos that necessitates pregnant adults, we are also interested in them in their own right where the role of maternal immune cells in pregnancy-related tissue remodelling are concerned.

While we are using and analysing animals of all life stages, experimental procedures will only be directly performed on adult animals, with very few exceptions in which substances or cells are delivered directly to embryos or newborn mice.

Typically, what will be done to an animal used in your project?

Experiments are aimed at studying either (1) the origins and functions of immune cells in development and pregnancy or (2) the effects of prenatal adversity on immune development and disease susceptibility.

(1) Origins and functions of foetal or maternal immune cells in development and pregnancy. (1.1) Successfully mated female mice will proceed through pregnancy with or without an inflammatory challenge. Where inflammation is induced, this models acute inflammatory episodes or infections and in most cases will induce partial loss of foetuses or preterm birth. Inflammatory agents will be delivered typically by injection or orally. (1.2) Pregnant mice will undergo usually one additional treatment aimed at modulation of inflammation, the immune response or gene expression and again consisting of one or several injections or oral deliveries. Exceptionally, this will be replaced by so-called "minipumps" that deliver substances more continuously and that are surgically implanted, usually before pregnancy. In some cases, blood will be drawn on up to two occasions. Other experimental readouts will be non-invasive and include ultrasound imaging and monitoring by cameras. (1.3) Animals will be terminated without additional treatments and tissues analysed either before or after giving birth.

(2) Effects of prenatal adversity on immune development and disease susceptibility. (2.1) To generate mice that have prenatally experienced adversity, inflammation or arthritis will be induced during pregnancy. Where inflammation is induced, these models chronic low-grade inflammation and does not normally affect pregnancy success. To do so, substances will be delivered to pregnant mice either orally or by injection, typically on one or several occasions at different stages of pregnancy. In some instances, embryos will be injected directly using an ultrasound-guided method. In addition to injections, blood will be drawn from some pregnant mice in order to measure inflammation and disease parameters. A very limited number of mice will undergo surgery before pregnancy, with the aim of placing pumps that will continuously deliver substances to these animals. (2.2) The offspring of these pregnancies will be allowed to grow adult. (2.3) These offspring mice will then be subjected to treatments that either label immune cells according to their developmental origins, induce tumour growth or arthritis as well as additional treatments that modulate the immune response, disease or

gene expression. Typically, animals will undergo maximally two procedures that consist of one or several injections. In a small minority of mice, surgery will be performed instead of injections to place minipumps that deliver substances continuously. In addition, blood will be analysed from some of these animals. In most cases, additional analyses will be non-invasive, such as clinical scoring of joint swelling or tumour size. (2.4) Experiments will be terminated and tissue analysed at different disease stages.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects on animals may be caused either by genetic modifications or by experimental procedures and disease models.

Genetic effects: We will be using genetically modified animals, some of which may show preterm birth or foetal death during pregnancy. Although we are also using animals that are genetically predisposed to developing diabetes, we will normally only use these prior to disease onset for breeding.

Experimental effects:

- **Substance administration**: The nature and delivery regimens of most substances administered in this Project are not expected to cause persistent adverse effects. In rare exceptions, irritation may occur. Some substances used to modify gene expression may interfere with the ability of pregnant animals to give birth. In such cases, mothers will be humanely terminated, their pups delivered and transferred to foster mothers.

- **Surgical complications**: Surgical and post-surgical complications such as infections are extremely uncommon. Nonetheless, we strive to use refined methods circumventing the need for surgery and expect to perform only a very restricted number of surgeries.

Disease models:

- **Acute inflammation**: will be induced in pregnant animals at different time points of gestation. While inflammation may be accompanied by symptoms of discomfort, these are usually of only transient nature.

- **Rheumatoid arthritis**: is a chronic inflammatory disease characterised by joint swelling. Further symptoms may include weakness, loss of body weight, lameness and a hunched appearance. In many cases however, experiments will be terminated before animals experience these symptoms. We are using models that usually result in a self-limited disease.

- **Tumour growth**: will be induced in some animals and followed for up to several weeks. While tumours can in rare instances be associated with additional clinical symptoms like skin necrosis, hypothermia, weakness
, diarrhoea and body weight loss, we will normally terminate experiments before.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

- **Sub-threshold**: The vast majority of all mice (more than 85%) is not expected to experience any pain, suffering, distress or harm that are more than transient or mild.
- **Mild**: A minority of animals (approx. 3.5%) will suffer mild harm.
- **Moderate**: In a further minority of all animals (approx. 8%), we expect to observe moderate severity, usually associated with experimentally induced inflammation, arthritis or tumours.
- **Severe**: We expect only a small fraction (no more than 1%) of all animals to experience severe symptoms, likely associated with advanced rheumatoid arthritis.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 03 March 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project studies complex interactions between immune cells and their environment in both physiological and pathological conditions like pregnancy, tumours and inflamed joints. We aim for a mechanistic understanding of these interactions, their cause-consequence relationships and long-term effects, such as the impact of early exposure to adverse environments on health and disease later in life. Even refined in vitro or ex vivo studies cannot replicate the complexity of the cell-cell communication underlying these processes, or their long-term consequences in such intricate biological systems. Therefore, the need to study these biological responses using in vivo models remains.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of cell lines, primary cell culture (i.e. ex vivo culture of cells derived from human or animal tissues), more complex co-culture systems, in which for example immune cells and non-immune cells are cultured together, as well as organ explant cultures and organoids (i.e. "miniorgans" grown in culture that contain multiple cell types and may model some organ functionality).

Why were they not suitable?

Neither relatively simple approaches like cell lines and ex vivo culture of primary cells, nor more sophisticated ones like organ explants and organoids can fully replicate the complexity of the cell-cell communication underlying immune functions in pregnancy and embryonic development, tumour growth and chronic inflammatory disease. There are two main reasons for that: One, these interactions are not simply binary e.g. between one specific immune and one epithelial cell type. Second, they occur over an extended period of time, e.g. spanning all of gestation, and have long-term consequences on multiple organ systems. Co-culture systems for example are limited to binary or a restricted number of cell-cell interactions, and even though organoids can be cultured for extended periods and contain multiple organ-specific cell types, these are of epithelial nature in the classical models, and immune cells have to be added exogenously in a co-culture manner. Therefore, these non-animal alternatives are not suitable for addressing our scientific questions. However, they may complement in vivo studies and represent promising reductionist models in which to address e.g. the involvement of a specific inflammatory mediator produced by immune cells at the maternal-foetal interface. Moreover, animal experiments will be complemented with in silico approaches wherever possible. Gene expression analyses will maximally exploit published datasets and publicly available databases of relevant immune cell types, tissues and developmental stages, e.g. the ImmGen consortium or recently published single cell atlases for mouse gastrulation and organogenesis, as well as comparable resources for human data.

A retrospective assessment of replacement will be due by 03 March 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

The number of animals we estimate to be used throughout this project is based on statistical and experimental design considerations as well as project-specific ones:

- Our target is the smallest number per experimental group that still has the capacity to generated statistically powerful data. For the sake of this estimation, this number is based on experience, but we will initially perform a formal sample size analysis and pilot experiments wherever this has not previously been done.

- This project generates and uses genetically modified animals. In many breeding schemes, not all offspring animals can be used in experiments, because they do not carry the right genetic modification. These animals are, however, accounted for in the total estimation.

- This also applies to experiments in which pregnant animals are undergoing experimental procedures. In some cases, our scientific interest is in maternal processes rather than the offspring. However, our estimation does take into account any offspring that is produced.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- For many of the experiments in this project, we or our collaborators have previously established treatment regimens and in some instances have obtained preliminary data that have guided experimental design. In many other cases, the scientific literature has been consulted, in which similar experimental approaches have been reported. For further refinement, we will be closely working with the local veterinary services team and routinely consult the NC3R’s website.

- An experimental design consideration that is of particular importance for this project is that of the experimental unit. In accordance with its definition as "the smallest division of the experimental material such that any two experimental units can receive different treatments”, the experimental unit in experiments addressing the effects of maternal treatments on the offspring is a given pregnancy or an entire offspring litter, and not individual offspring animals. To reduce the overall use of experimental animals with this aspect in mind, we will therefore use the offspring of a given litter for different readouts wherever possible. Conversely, for a given experimental readout, we aim to use individual mice from different litters.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Efficient breeding: In many of our experiments, we will use genetically modified animals. Wherever possible will we follow breeding strategies in which most if not all offspring animals can be used for experimental purposes, thereby reducing production of surplus animals.

- For most experimental procedures, treatment regimens have previously been optimised by ourselves, our collaborators or published in the literature. As a starting point, we will closely adhere to these protocols.

- We will also share tissues from experimental animals wherever possible, either for different projects within the group or with other researchers interested in and authorised for studying immune development.

A retrospective assessment of reduction will be due by 03 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project uses in vivo mouse models of embryonic development, pregnancy and adult disease. Specifically, we will study pregnancy in normal and conditions challenged by inflammation, chronic inflammatory disease that resembles rheumatoid arthritis in humans as well as tumour development. Although clinical symptoms cannot be avoided altogether, the precise models and methods we will use are designed to minimise pain, suffering, distress and lasting harm to the treated animals.

- **Substance delivery, prenatal inflammation**: For the vast majority of substances that we will deliver, treatment regimens (i.e. dosage, timing and duration, delivery route) have previously been optimised by ourselves and our collaborators, or published in the scientific literature. Where there are several options available we will always opt for the less invasive or more refined method. For example, where substances shall be administered orally and in a non-punctual manner, we will do so e.g. via the food or drinking water. Where substances shall be delivered directly to embryos during pregnancy, we will opt for an ultrasound-guided rather than the classical surgical technique. Treatment regimens will also be tailored to the specific scientific question. For example, we will elicit inflammation during pregnancy, either to study the involvement of foetal and maternal immune cells in preventing preterm birth, which requires stronger inflammation, or in order to study its long-term consequences on offspring immune development and disease susceptibility, for which lower-grade inflammation will be induced. Finally, wherever possible, substances will be provided in sterile solutions.

- **Immune development**: We and others have previously established refined models that allow pinpointing the developmental origins and kinetics of immune cells across the lifespan. For example, instead of using whole-body irradiation, which is known to induce systemic inflammation and often tissue damage or even radiation sickness, we will use refined models in which cells are transferred into unconditioned mice or animals that have undergone only partial irradiation, leaving the rest of the body protected.

- **Arthritis models**: We will use several well-established arthritis models in pregnant and non-pregnant adult mice. These models have distinct advantages for our questions. For example, arthritis induced by administration of serum from already arthritic mice or antibodies generally causes rapid, self-sustained disease are ideally suited to model maternal arthritis with minimal suffering for the pregnant animals. Arthritis induced by immunisation with collagen, on the other hand, represents a valuable model to test if animals that have prenatally been exposed to adversity are more likely to develop arthritis, since the mice we use are normally rather resistant to this model. In all instances we will minimise suffering by environmental enrichment e.g. with soft bedding, which maximises comfort for arthritic animals.

- **Tumour development**: We will use a model in which tumour cells are engrafted into unconditioned, immunocompetent mice. This significantly reduces suffering associated with many other tumour models. The humane endpoints for this model are well defined and take into consideration tumour growth and other clinical symptoms such as substantial weight loss and general weakness, however, these are rarely observed in this particular model.

Why can’t you use animals that are less sentient?

Our aim is to establish a mechanistic understanding of how immune cells contribute to embryonic development, pregnancy, arthritis and tumour development and establish cause-consequence relationships between e.g. deleting a particular cell type and an observed biological effect. We therefore depend on genetic tools, for which mice remain the species of choice. Moreover, stages of immune development are relatively conserved between mammals, and much of our knowledge has been established in mice. They thus represent the best model organism for our scientific questions.

Owing to our interest in immune development, we will study animals at an immature life stage (e.g. embryos or newborns) in many of our experiments. However, we also study long-term consequences of experimental treatments, such as the effects of prenatal exposure to adversity on offspring immunity or disease susceptibility. In these cases, we therefore cannot terminate the experiment at such early stages. Moreover, where we study rheumatoid disease or tumour development, we are often required to monitor disease longitudinally. However, we will always use the earliest possible experimental time point that produces meaningful scientific data, and have implemented well-defined humane endpoints as well as refinements.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The following measures will be applied throughout the project:

- **Monitoring:** In general, all animals will be regularly observed by trained staff and animal caretakers. Experimental animals will be additionally monitored at intervals and by means tailored to the experimental treatment. Immediately following treatment, e.g. substance administration by injection, animals will be inspected for any signs of distress. Animals that have been subjected to disease models will be monitored and clinically scored e.g. every 1-2 days for arthritic and tumour bearing animals. Wherever possible will we use non-invasive means of monitoring that also enable longitudinal analyses. For example, camera monitoring and ultrasound imaging will be used to monitor preterm birth or other pregnancy complications. Ultrasound or e.g. bioluminescent imaging approaches may also be used to follow tumour growth.

- **Surgery and post-operative care**: Although post-surgical infections and death resulting from anaesthesia or surgical complications are very uncommon, in the few cases where surgery is performed, great attention will be paid to post-operative care: Anaesthetics will be used at correct doses in accordance with local and HO guidelines, and body temperature will be maintained post surgery e.g. via heat pads. Pain will be controlled during surgery by general anaesthesia and post surgery by pain killers, unless these interfere with the scientific purpose. Risk of post-surgical infection will be minimised by good surgical and aseptic techniques. Surgical sites will be monitored for signs of inflammation and infection. Post-surgical infection is unlikely and antibiotic cover may be given under the advice of local veterinary services.

- **Pain management**: In both the arthritis and tumour models, mice will be provided pain relief at defined clinical scores, unless these interfere with the scientific question, e.g. where the inflammatory response shall be studied, but is impaired by administration of non-steroidal anti-inflammatory drugs.

- **Animal handling, environment:** Mice will be handled gently and via tunnel handling at all times, and we will also provide an environment enriched e.g. with nesting material. Tumour-bearing and arthritic as well as pregnant animals will be handled with particular care and may be provided additionally e.g. with soft bedding to maximise comfort. Where experimental regimens require repeated treatments, animals may be trained to the procedures prior to initiating the experiment to minimise stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

In addition to the aforementioned resources (webpages of local veterinary services, NC3R), which include ARRIVE and PREPARE guidelines, we will specifically follow published guidelines for the welfare and use of animals in cancer research
(*Workman et al. British Journal of Cancer 2010, DOI: 10.1038/sj.bjc.6605642*), as well as refinement in arthritis research (*Hawkins et al. Inflammopharmacol 2015, DOI 10.1007/s10787-015-0241-4*), as well as their updates and similar guidelines published in the meantime.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult with local veterinary services and stay informed via the NC3R website as well as other resources concerned with animal welfare in biomedical research). We will also regularly participate in HO "road show" events and those organised by our local AWERB committee.

A retrospective assessment of refinement will be due by 03 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

40.The role of adiponectin in equine endocrinopathic laminitis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

laminitis, adipose-tissue derived hormones, insulin, endocrinopathy

Animal types	Life stages
Ponies	adult
Horses	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To further elucidate the role of specific adipose tissue derived hormones in the pathogenesis of equine endocrinopathic laminitis.
A retrospective assessment of these aims will be due by 16 June 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Laminitis is a painful condition of the equine foot that affects approximately 4% of the horse and pony population in the UK and worldwide. In addition, it is frequently recurrent, with up to 70% of animals suffering from repeated episodes. There are three forms of laminitis, namely sepsis-associated, endocrinopathic and supporting limb laminitis. Endocrinopathic laminitis is the commonest form, accounting for up to 90% of cases and encompasses laminitis associated with the endocrine (hormone) diseases equine metabolic syndrome (EMS) and pituitary pars intermedia dysfunction (PPID). The key feature of EMS is insulin dysregulation (ID), which is abnormal insulin metabolism in response to a normal physiologic process, such as eating. In horses, this manifests as high blood insulin concentrations (hyperinsulinaemia) and/or an excessive insulin response to ingested carbohydrate and/or resistance to insulin at the level of the tissues. Additional features include obesity, high blood fat concentrations (hypertriglyceridaemia) and abnormal fat tissue metabolism (adipose dysregulation) manifesting as abnormal plasma adipokine (hormones produced by fat tissue) concentrations. It is well established that high blood insulin concentrations for a prolonged period (48-72 hours) can induce laminitis, but the underlying mechanism remains unclear. Current research has focused on insulin binding to and inappropriately stimulating the receptors for the hormone insulin-like growth factor-1 (IGF-1) which are found in the equine foot. Some adipokines have anti-inflammatory and insulin-sensitising actions and low circulating concentrations of some adipokines, as well as high blood insulin concentrations, is a risk factor for endocrinopathic laminitis. In other species, specific adipokine and insulin signaling pathways within cells converge at the level of the adaptor protein APPL1 and there is emerging evidence of cross talk between specific adipokines via its receptors and both the insulin and IGF-1 receptors, resulting in increased and decreased signaling respectively. This project will firstly investigate the effect of high blood insulin concentrations, induction of tissue insulin resistance (using corticosteroids) and obesity (via pasture-induced weight gain) on circulating concentrations of specific adipokines *in vivo*. Human metabolic syndrome (HMS) is very similar to equine metabolic syndrome in terms of the metabolic alternations that occur and it is associated with an increase risk of certain cardiovascular diseases. Dietary manipulation and pharmacologic agents are used to increase circulating concentrations of certain adipokines in people with HMS and this in turn reduces the associated cardiovascular disease risk. Thus, this project will also determine whether similar approaches can be used in EMS. The effect of weight loss with or without dietary supplementation and/or pharmacologic agents on circulating concentrations of specific adipokines will be evaluated. Potential pharmacologic agents will first be screened *in vitro* through evaluation of their effects on equine fat tissue (adipocyte) adipokine production.
What outputs do you think you will see at the end of this project?

This project seeks to further elucidate the role played by specific adipokines in endocrinopathic laminitis and to

identify potential pharmacologic agents and management interventions that will increase circulating concentrations of these adipokines. This in turn may reduce the risk of endocrinopathic laminitis in high risk animals. This new information will be disseminated in the form of presentations at suitable equine veterinary and research conferences and publications in suitable journals.

Who or what will benefit from these outputs, and how?

The project has a potential beneficial welfare impact for horses and ponies worldwide and an economic impact for their owners through reduced veterinary expenditure and athletic performance loss. This impact will not be fully realised until the project is completed.

How will you look to maximise the outputs of this work?

New knowledge gained will be disseminated through presentation at suitable conferences to researchers working in this field, veterinarians and horse caregivers and publication in suitable journals and lay articles. This will include publication of unsuccessful approaches.

Species and numbers of animals expected to be used

- Ponies: 25
- Horses: 25

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is not possible to achieve the objectives of this project without using animals, as we are studying complex metabolic pathways and physiological responses, that cannot with our current state of knowledge, be modeled using isolated tissues, cells or computer simulations.
Laminitis is a disease which affects adult horses and ponies and it is therefore most appropriate to undertake these studies in these animals. Whilst we can model some aspects of digital vascular physiology and fat, muscle and caecal function *in vitro, t*he unique metabolism of the horse is central to the pathophysiology of the endocrinopathic laminitis. Thus, our studies to further elucidate the role of specific adipokines in the pathogenesis of the disease require *in vivo* experiments.

Typically, what will be done to an animal used in your project?

Typically, animals will undergo each of the procedures a maximum of twice in this project.
Protocol 1 involves placement of intravenous catheters in each jugular vein under local anaesthesia and infusion of glucose and infusion via one catheter and collection of blood samples via the second catheter. It also involves a single intramuscular injection of corticosteroid followed by blood sample collection via jugular venepuncture.
Protocol 2 involves consuming sufficient pasture to promote natural weight gain. Blood samples will be obtained weekly by jugular venepuncture until each animal becomes overweight. This will be followed by weight loss achieved through consuming a hay-based diet with or without supplementation using nutritional supplements or pharmacologic agents administered orally. Blood samples will be obtained weekly by jugular venepuncture until each animal reaches ideal weight.

What are the expected impacts and/or adverse effects for the animals during your project?

Studies conducted under this licence should not induce long term adverse effects in the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All protocols will be mild for all animals.

What will happen to animals at the end of this project?

- Kept alive
- Rehomed
- Used in other projects

A retrospective assessment of these predicted harms will be due by 16 June 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to achieve the objectives of this project without using animals as we are studying complex metabolic pathways and physiological responses, including some that are influenced by season, that cannot with our current state of knowledge, be modelled using isolated tissues, cells or computer simulations.

Which non-animal alternatives did you consider for use in this project?

Isolated equine tissues or cells and computer simulations were considered for use in this project. *In vitro* studies will inform which drugs to use in protocol 3 and help understanding of the mechanisms involved in adipokine release from cultured adipocytes. The combination of *in vitro* and *in vivo* approaches is more powerful scientifically than either on its own.

Why were they not suitable?

Whilst *in vitro* studies will be used to inform the choice of pharmacologic agents used in protocol 3, they are not suitable as they do not take into account the complex physiological responses and complex metabolic pathways that all interact in the pathogenesis of endocrinopathic laminitis.

A retrospective assessment of replacement will be due by 16 June 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be included in this project has been based on sample size calculations and on the assumption that animals will be re-used between protocols in order to reduce the overall number of animals used. Data from our previous studies involving measurement of circulating adipokine concentrations in healthy ponies as well as weight gain and weight loss studies have been used to inform these studies. In each case, group sizes of six animals are sufficient. In addition, in previous *in vivo* equine studies, we have found that group sizes of six animals have been sufficient to produce robust results. Protocol 3 requires three groups of animals equating to a total of 18 animals. Thus, it is estimated that 25 animals will be used in total to allow for illness, accidental injury and the need to repeat a study in an individual animal for experimental reasons.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The number of animals to be included in this project has been based on sample size calculations and on the assumption that animals will be re-used between protocols in order to reduce the overall number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The numbers to be used in this project are based on sample size calculations and previous experience.
A retrospective assessment of reduction will be due by 16 June 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and

methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocol 1

The methods used to induce hyperinsulinaemia (high blood insulin concentrations) and tissue insulin resistance have been previously validated for ponies. The duration of the hyperinsulinaemia chosen is much shorter than that which has been previously reported to induce laminitis in healthy ponies. In addition, there is no scientific evidence to link corticosteroid administration with the development of laminitis in healthy animals, only in those with other laminitis risk factors. thus, only healthy, ideal weight animals with no history of previous laminitis will be used. Jugular catheters will be placed using local anaesthetic in order to minimise any pain and distress potentially associated with repeated blood sampling.

Protocol 2 and 3

The pasture-induced weight gain will be undertaken in consultation with an equine nutrition specialist to ensure that there is a gradual gain in weight over 9-12 weeks. Previous studies using this approach have not resulted in any adverse effects. The weight loss will be induced by feeding a diet low in non structural carbohydrate (<10% dry matter) at 1.25% (dry matter intake; DMI) of body weight. This is standard dietary change that is recommended by veterinary surgeons for weight loss in clinical cases of equine obesity when owners have allowed their animals to become obese. Thus, this will mimic somethings that happens in the real world. In those animals with weight loss resistance (animals that fail to lose weight despite dietary restriction), the diet may need to be reduced to 1% (DMI) of body weight, but no lower as lower percentages are associated with gastrointestinal disturbances such as gastric ulcers and the development of stereotypies (repetitive abnormal behaviours). The methods that will be used to assess the effect of the weight gain and subsequent weight loss on insulin metabolism (i.e. oral sugar test and insulin tolerance test) are methods that are commonly used in equine clinical practice.
Thus, all of these methods proposed have been previously validated for use in ponies in either the clinical or the research setting. Animals will be returned to their normal management regime between protocols which will involved continuous access to pasture. All of the protocols are mild in severity and none of the methods will cause lasting harm to the animals.

Why can’t you use animals that are less sentient?

As previously explained, all of the experiments proposed need to be performed in horses and ponies. As equine metabolism differs significantly between the foetus, neonate and adult, and laminitis is a disease that only affects adult horses and ponies, we are unable to use a less sentient stage of life.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be habituated over several days to the room and the stocks in which the insulin infusion will be undertaken prior to commencement of the protocol.
All animals will be constantly monitored for the duration of all protocols and for the next 3 days to ensure that no adverse effects develop. If any adverse effects are noted, appropriate treatment will be provided immediately in consultation with the named veterinary surgeon.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs advice on the 3Rs for project licence holders.
The NC3Rs General Principles for blood sampling applicable to horses will be followed as well as the recommendations relating to use of vascular catheters.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed of advances in 3Rs via the 3Rs Liaison, as well as via the NC3Rs website and attending relevant seminars/talks. Wherever we find an opportunity to improve our technique/experimental design to minimise animal numbers and/or suffering, we will rapidly incorporate it into our protocols. We will closely work to ensure that our animal care is always optimal, which ultimately ensure high quality results.

A retrospective assessment of refinement will be due by 16 June 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

41. Direct MR and Optical Imaging of neuronal cell swelling.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The project aims to determine if an MRI scanner can be used to directly measure brain activity (via neuronal cell swelling). Currently this is not possible.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Current clinical based MRI methods used to investigate how your brain works do not directly probe brain function. Instead brain activity is inferred from changes in oxygen level in your blood (with cells using more oxygen when active). Unfortunately, to date scientists are unable to fully describe the relationship between brain activity and blood changes. This complicates the use of MRI for studying brain function.

If MRI methods were able to measure brain activity directly it would help doctors learn how normal, diseased or injured brains function. In turn this would help them to track and treat conditions like Alzheimer's or Autism.

A new MRI method, believed to measure changes in brain cell size has been proposed to meet this need. When brain cells are active they get bigger. Our research will use high resolution optical imaging in the rat model to look directly at cell size while we also make MRI measurements. This will therefore confirm or disprove if this new MRI method is measuring brain activity directly.

What outputs do you think you will see at the end of this project?

This project will produce data and information as to whether a new MRI method can in fact measure brain activity directly. The data will be presented to leading brain scientists and doctors via journal articles and at national/international conferences.

Who or what will benefit from these outputs, and how?

Short-term (0-5 year) benefits: The methods developed as part of this project will offer brain scientists a new way, based on brain cell size, to investigate brain function. This presents as a new direction/different strategy for measuring brain function and could offer novel insight into the workings of the human brain.

Medium-term (5 year) benefits: Based on this validated method, new treatments for brain conditions could be proposed.

Long-term (6 year+) benefits: The new MRI method could become the clinical method of choice for looking at brain function. It would allow doctors to map the working brain and detect the effects of tumours, stroke, head and brain injury, or diseases such as Alzheimer's. In addition, it could be used to assess the risk of brain surgery or similar invasive treatment for a patient.

How will you look to maximise the outputs of this work?

Data will be published even if unsuccessful to prevent repetition. We are working closely with a neurosurgeon at a leading hospital NHS trust. This collaborator is keen to see swift uptake of this imaging technology in theatre and explore applications within his patient cohorts. **Species and numbers of animals expected to be used**

- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The rat brain is a well-defined model for imaging research. Areas with specific functions (responding to for example paw or whisker sensing) are easily identifiable in rats.

Typically, what will be done to an animal used in your project?

All animals will be put to sleep with deep anaesthesia administered via injection. In addition, we will use pain killers to ensure the animals feel no pain. Throughout our experiments the animal vitals will be carefully monitored and maintained.
The animal will undergo delicate surgery. Their skull will be exposed and thinned to translucency so we can see their brain directly. We can then assess with light if their brain cells change size when we touch their whiskers (one of their primary sensing organs – like our hands). MRI scans will be recorded of the animals at the same time and the data compared to light measurements.
The surgical procedures are expected to take around 2 hours. The animal will be in the MRI scanner for no more than 6 hours. Due to the nature of the surgery, once the experiment is complete animals will be killed. However, their brain tissue will be preserved for continued study.

What are the expected impacts and/or adverse effects for the animals during your project?

There will be very little adverse effects of our procedures.
We will use pain killers to ensure the animals feel no pain.
All experiments use non-recovery anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Non-recovery - all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The brain is one of the most complex organs in the living body. No computer can yet model the brains complex biology or function. MRI is non-invasive and safe for human use, but in order to determine whether the new MRI method is indeed measuring changes in brain cell size we must use high resolution optical imaging. Visible light does not pass through the scalp and skull and these must be removed in order for the light to reach the brain. The use of animals is therefore unavoidable.

Which non-animal alternatives did you consider for use in this project?

Imaging techniques have been used on ex-vivo brain slices already.

Why were they not suitable?

Brain slices do not contain live blood vessels. Therefore this model is not representative of what we would image on a person in and MRI scanner.
Operations where human brain is exposed for light measurements are rare and in most cases already demanding procedures. Adding time to make these measurements during surgery is not always ethical.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were estimated based on previous experience and published data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The light and MRI measurements can be taken at the same time. This inherently reduces animal numbers (compared to completing separate experiments with each technique).
In addition, by using a long lasting anaesthetic and maintaining animal vitals we can maximise the amount of data obtained from individual subjects, this reduces the overall number of animals needed to meet the project

objectives.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

I have extensive experience in the field of brain imaging. The blood responses we are measuring are typically large and reliable for the given methods. Therefore, if a standard blood response is not measured in response to the stimulus we will know immediately that something is wrong with our setup and the NVS can be consulted immediately.
Following the experiments animals will be killed and brain tissue preserved for further study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project uses a non-recovery rat model. Brain function data is collected with MRI and optical/light imaging scanners.
Pain killers and analgesia will be applied in conjunction with anaesthetics to make sure the animals feel no pain which will limit suffering, distress and lasting harm.
If any procedural complications do arise veterinary advice will be sought immediately.

Why can’t you use animals that are less sentient?

Data needs to be collected on the developed/mature brain meaning we need adult subjects.
The physical limitations of the optics and MRI system mean that less sentient species (usually smaller e.g. mouse) would be difficult to work with in terms of both required surgery and size of the equipment involved.
Animals are used at a terminal, non-recovery anaesthesia model.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pain killers/analgesia will be applied in conjunction with anaesthetics to make sure the animals feel no pain. Top-up doses of anaesthetic will be delivered as required. This ensures animals do not wake up during experiments. All experiments have to be approved by a NACWO and NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

PREPARE guidelines for experimental planning: S*mith, AJ, Clutton, RE, Lilley, E, Hansen KEAa, Brattelid, T. (2018): PREPARE: Guidelines for planning animal research and testing. Laboratory Animals, 52(2): 135-141.*

The Experimental Design Assistant (EDA): https://www.nc3rs.org.uk/experimental-design-assistant-eda
LASA for aseptic practice: http://www.lasa.co.uk/wp-content/uploads/2017/04/Aseptic-surgery-final.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Biological Services Facility at our institute holds quarterly meetings for updates and support for the 3R's. We will also engage with the national centre for the replacement, refinement and reduction of animals in research via their dedicated website, blogs and social media accounts.

NON-TECHNICAL SUMMARY

42. Discovery of novel compounds for the treatment of dementia.

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Dementia, Neurodegeneration, Drug discovery, Alzheimer's disease, Parkinson's disease

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to identify and validate new mechanisms for treating dementia, to identify novel, drug-like compounds that work through these mechanisms and to demonstrate their efficacy in animal models of brain disorders such as Alzheimer's and Parkinson's disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Dementia is a significant global health problem. There are already approximately 50 million people worldwide with dementia, and as the general population ages, this has been predicted to increase to 150 million by 2050. Dementia causes an increasing burden to sufferers, their carers and to society as a whole through the cost of healthcare.

There are currently no treatments available that stop or reverse the progression of dementia. Our project aims to identify chemical compounds that have the potential to be developed as drugs for treatment of this disorder.

What outputs do you think you will see at the end of this project?

Outputs expected at the end of this project

Information on potential targets for drug discovery.

Our first objective is to identify novel "drug targets". These are the molecules in the body which drugs interact with to exert their effects. We need to validate drug targets by demonstrating that interfering with their action causes the appropriate changes in the animal, including reducing the symptoms of disease.

- A successfully validated drug target may be the subject of a drug discovery project for further investigation as part of our internal program.
- Occasionally a drug target may be successfully validated but does not fit within our strategic aims or objectives. In this rare scenario we aim to partner with other organisations or publish the data to generate interest in the wider scientific community.
- Validation of a particular target may be unsuccessful but our data may indicate that the target molecule forms part of a pathway which may include other possible drug targets.
- Where target validation is unsuccessful, this information will also be made publicly available through publication, particularly where there is broader interest in the biology, for example in other disease areas.

Demonstration of compound efficacy in disease models

The second objective is to discover drug-like molecules that may interact with the drug target and to show that these molecules reduce disease symptoms in animal models of dementia.

- If a drug discovery project results in a novel drug-like compound with efficacy in a relevant model for dementia this will initiate efforts to further develop the compound towards clinical testing in humans, for example through partnership with a pharmaceutical company.
- Compounds that do not achieve efficacy, but nonetheless have appropriate drug-like properties may be repurposed for use in other disease areas or as tool compounds for research.

Who or what will benefit from these outputs, and how?

Data on new drug targets may be available in the short term and will benefit our Institute through feeding into more long-term objectives or may benefit the wider field on neurodegenerative disease. We collaborate with other groups working in the same field and may share data, samples, reagents and animal models with these groups. (1-5 years).

Favourable data on compound efficacy that leads to clinical research will take longer to generate, but may have a major impact on drug discovery for dementia, due to the current lack of research in this area within the pharmaceutical industry. (3-10 years).
It is our intention that compounds we develop will eventually reach approval as drugs for dementia. The likelihood of this occurring is relatively low but the benefits to society would be considerable. (10-15 years).

How will you look to maximise the outputs of this work?

Our institute is an academic group with expertise in preclinical drug discovery methodologies used within the pharmaceutical industry and applying these in an academic setting. We work with a wide network of collaborators in the academic sector to investigate and validate interesting and novel drug targets and have strong connections within the pharmaceutical industry to facilitate the eventual development of these ideas into drugs to benefit patients suffering from neurodegenerative disease and dementia.
As an academic group we seek to publish our findings whenever possible.
Chemical structures of molecules originating in our laboratory and the properties of these molecules may be published in the form of patents. This is necessary to protect intellectual property, but also provides a valuable source of information on the viability of drug targets and chemical structures and activity to the wider pharmaceutical industry.
Where projects are unsuccessful or no longer of interest to us, we will seek every opportunity to disseminate the work at scientific and public meetings as well as publish data in scientific journals.
Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

All of the procedures on this project will be carried out using adult mice. Some of the mice used in our studies will have genetic modifications. In the majority of cases this will not have any impact on the health and wellbeing of the animals. In some cases we will need to use mice that have been genetically altered so that they develop symptoms of neurodegenerative disease.

Typically, what will be done to an animal used in your project?

There are several different scenarios which a mouse may experience, the following are examples:
Example 1: In many cases mice will be given a single dose of a compound by injection. After an interval of up to 48 hours the mouse will be given a terminal overdose of anaesthetic and a blood sample withdrawn from the heart.

Example 2: Genetically altered disease model mice will have their diet reduced at 6 weeks of age and be tested in touchscreen apparatus daily for three weeks. This comprises an automated testing system for learning, memory and other aspects of cognition in which mice are taught to respond by touching an image on a screen in return for a food reward. The mice will then be dosed with a virus to induce a genetic change in the brain. This will be done through a vein in the tail while the mouse is anaesthetised. The mice will be tested again in the touchscreen apparatus once a day for five weeks. At 15 weeks of age they will be given an overdose of anaesthetic and killed by perfusing a substance through the heart to preserve the animal's tissues for microscopic examination.
Example 3: At six weeks of age mice will undergo surgery under general anaesthetic to inject a substance directly into the brain. The mice will be allowed to recover for two weeks, and then will be dosed with a substance once a day using a feeding tube through the mouth. Over the same period, behavioural tests will be carried out once a week to test their ability to remain on a rotating cylinder and to cross a narrow beam. During this time the mice are expected to experience a gradual deterioration in their movement abilities, experiencing tremors and impaired coordination. At the end of the dosing period the mice will be given an overdose of anaesthetic and killed by perfusing a substance through the heart to preserve the animal's tissues for microscopic examination.

What are the expected impacts and/or adverse effects for the animals during your project?

Dosing either by injection or through a feeding tube and blood sampling will cause mild pain and distress to an animal, but this will be short-lived.
The techniques used for behavioural testing in this project are not expected to cause pain or distress other than transient stress due to being handled. For some behavioural tests the animals' food is restricted. This will lead to weight loss, but the general condition of the animals is not expected to be affected in other ways.
Surgical techniques involve a greater degree of pain and distress which may last for a few days after surgery. Pain relief will be given routinely to animals undergoing surgery. Occasionally (less than 2%) a surgical wound may fail to heal properly, in which case the named veterinary surgeon will be consulted. One attempt may be made to re-close the wound if this is within 48 hours of surgery, otherwise the animal will be humanely killed.

Most genetic alterations to animals used in this project do not result in any apparent change to the wellbeing or behaviour of the animals. In some of the disease models that we use, genetic alterations do lead to a progressive impairment in the animal's ability to function normally, especially where these lead to impairments in the animal's movement (loss of balance and coordination, tremors). Typically these symptoms worsen over a number of weeks (depending on the model). Once symptoms appear, mice are monitored at least three times per week and the mice are humanely killed when specified limits are reached.
Dosing of substances to induce disease symptoms may result in similar changes to the genetically altered models mentioned above. We will monitor these animals in the same way, and apply the same limits before humanely killing the animals.
Some of the substances we dose will be completely novel, and may have potential unknown side effects. These substances will be dosed at low doses initially and the animals will be closely observed for any adverse effects before we proceed to higher doses.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities are mild (approximately 75% of mice) and moderate (approximately 25% of mice).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

When investigating novel drug treatments for disease it is necessary to understand how manipulation of the target for the drug impacts on the biology of the whole animal. There may be unwanted effects of drug treatment in other tissues or organs which would indicate a risk of side effects if the drug were to be dosed in humans. Furthermore, we need to gain a thorough understanding of what happens to the drug when it enters the body, including the rate it is absorbed from the gut into the bloodstream, where it is distributed in the body and how quickly it is eliminated.
When considering the effects of drugs or manipulating drug targets in the brain it is important to recognise the unique complexity of this organ, with many different cell types and networks of connections between nerve cells which cannot be fully replicated outside a living animal. Furthermore, if we want to understand how potential drugs may impact on symptoms of dementia we need to be able to test their effects on learning and memory in mouse models of disease.

Which non-animal alternatives did you consider for use in this project?

We have considered, and already use many non-animal alternatives wherever possible. These include assays using cells grown in culture for testing the activity of potential drugs and understanding the basic biology underlying their mechanism of action. In addition we make extensive use of computer based modelling of drug properties to understand how the structure of drug molecules may affect their interactions within the cell and how they are likely to be absorbed and cleared from the body.

Why were they not suitable?

These approaches are suitable for much of the work that we carry out. However, in order to fully evaluate novel drugs and their targets, which may have the potential to progress to studies in human volunteers, it is necessary to gain a thorough understanding of how they behave in a whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is based on estimates of:

- the number of projects that we anticipate running the expected number of studies to
- validate and test potential drugs for each project

- the number of animals needed per study, using the minimum number of animals to give a

statistically valid result

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In designing experiments there are several factors that we will use to reduce unwanted variability in our data, this will reduce the number of animals needed to show that a result is not just due to chance:

- The number of animals used per treatment group will be carefully worked out using data from previous studies to carry out these calculations
- Randomisation when assigning animals to treatment groups to avoid unwanted bias from factors like cage differences, time of treatment
- When appropriate, use of baseline data when assigning animals to treatment groups to ensure that baseline measurements between groups do not differ
- We have many years of experience in study design and statistics within our group and in addition we will draw on support from colleagues who are specialists in biostatistics.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Other steps we will take to reduce the number of animals used in our project:

- Using animals from the same colonies, or if possible the same litters for comparison, to ensure that genetic variation between animals is kept to a minimum
- Pilot studies will be used to determine the optimal conditions for experiments, e.g. the appropriate dose levels of drugs, the length of treatment time, the age at which experiments should be started in mice
- Where possible the same individual will carry out procedures, collect and analyse the data within a single experiment, and this person will be blind to the treatment which each animal receives
- Wherever possible we will collect multiple samples from each experiment to avoid unnecessary repetition of studies, these include taking samples to determine drug efficacy, measure drug levels within tissues and investigate possible side effects all from the same experiment
- Where possible we will share information, biological samples and mouse strains with other researchers in the field.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Wherever possible, non-genetically altered mice will be used in studies.
When genetically altered mice are used we will take a number of steps to avoid harm to these animals:

- In some cases the genetic alteration can be "switched on" by giving a drug either by injection or in the food. This ensures that any harm resulting from the genetic modification is experienced only during the experiment, rather than for the lifetime of the animal

- Genetically altered mouse models of disease show a progressive worsening of symptoms with age. When using these mice we will use models with the mildest symptoms and at the earliest age that are compatible with our scientific objectives.

- When using animals that have been dosed with a substance to induce disease we will carry out pilot studies to determine the minimum doses and length of time necessary for treatment that are compatible with our scientific aims.

Surgery to dose a substance directly into the brain will only be carried out if the substance cannot be dosed non-surgically by a different route, and all surgery will be carried out under general anaesthetic using aseptic techniques to minimise the chance of infection. Medication will be given for pain relief and to prevent infection.

Why can’t you use animals that are less sentient?

Adult mice will be used in our project. Mice are regarded as a good experimental substitute for humans as much of our genetics, anatomy and physiology are closely replicated in this species. Furthermore, there are existing mouse models of neurodegenerative disease which replicate many of the features of these disorders that are seen in human patients. Adult mice need to be used as the brain does not complete development until adulthood.
We already carry out studies in lower animals (zebrafish) which contribute to this program of work. This is carried out through a collaboration on a separate licence.
It is not possible to carry out our experiments in anaesthetised animals as due to the length of time the studies typically last.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Examples of refinement in our experimental procedures include the following:
rTG4510 mice are a model of a group of diseases known as tauopathies. These miceshow a tendency to be hyperactive, causing them to run inside the cage. This behaviour can occasionally cause injury through the bedding becoming tangled around the leg of the animal. We will use a softer bedding type to prevent injury. We will also investigate providing running wheels for these mice.
In some of our studies, we may need to dose substances using a small pump placed under the skin. We will adopt as standard practice the soaking of these pumps in saline overnight prior to implantation so as to reduce the formation adhesions in which the pumps stick to the skin of the animals. All surgery is completed using aseptic techniques. Local anaesthetics are given after surgery and monitoring in a separate recovery room is

also carried out to ensure animals return to normal activity before being transferred back to normal housing. Following surgery and re-housing, they are monitored for activity, weight and wound healing for up to 7 days. This is recorded on welfare monitoring sheets.
Compounds are also delivered via oral gavage through a flexible tube into the animal’s stomach. The tip of the tube is dipped in a sweet solution before starting the procedure to make it more palatable for the mice to swallow.
In genetically altered mice that do show disease signs, such as a mouse model of Huntington’s disease, welfare is regularly monitored. Since a major symptom of disease progression in these animals is weight loss, we use this to monitor welfare. They are weighed at least weekly, increasing to daily as the disease signs become clear. Before weight loss reaches 15% of maximum body weight animals are humanely killed.
When administering drugs in the animals' diet it has been found that the texture and composition of the modified diet is different from the regular diet which the mice usually eat. This has sometimes led to aversion to the modified diet and reduced food, and drug intake. When dosing drugs in the diet, we will acclimatise the mice to the modified diet without the drug for a number of days before switching to the diet with the drug.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

PREPARE guidelines checklist for designing and planning experiments
ARRIVE guidelines to ensure reporting quality of data is optimised
LASA Guidelines for Aseptic Surgery - https://www.lasa.co.uk/current_publications
NC3Rs - https://www.nc3rs.org.uk/3rs-resources

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Regular awareness of developments via websites of organisations such as NC3Rs, LASA.

Communications from internal supporting services, via the internal 3Rs research tool and through consultation with Named Persons.

43. Drug Abuse-related Tests

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Drug abuse liability, Addiction therapy, Mechanism of action, Behavioural responses

Animal types	Life stages
Rats	adult, juvenile
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To support the overall assessment of a new medicinal treatment for an abuse potential and/or to assess its potential to treat substance use disorders or reduce the risk of abuse.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Substance use disorder is a growing and global concern. In 2019 (England), there were 7,376 hospital admissions for drug-related mental and behavioural disorders, 9.4% adults (16 to 59) had taken an illicit drug in the last year, 20.3% of young adults (16-24) had taken an illicit drug in the last year, and there were 2,917 deaths related to poisoning by drug misuse (NHS Digital, UK). In the USA, there were approximately 71,000 overdose deaths between 2018 and 2019 (400,000 deaths between 1999 to 2017).
In the UK, alcohol abuse has a significant impact on health, with an estimated 586,780 dependent drinkers in England alone. Alcohol consumption is associated with medical conditions including mouth, throat, stomach, liver and breast cancers, high blood pressure, cirrhosis of the liver and depression. Liver disease has increased by approximately 40% over the last decade and hospital omissions for mental disorders associated with alcohol by 150%; accidents, violence and general risk taking behaviours also contribute to alcohol-related harms.
A survey carried out involving 8518 drug users in Scotland to determine the most popular drugs of choice (individuals could select more than 1) found cannabis at the top of the charts with 78% of drug users stating that they had taken this drug in the last 12 months. This was followed by cocaine or crack (70%), MDMA (46%), prescription medication (29%) and Valium or diazepam (27%) - (source: Addiction Scotland). Such findings are not geographically restricted, with similar trends seen worldwide.

Drug abuse not only has a direct negative impact on the health and well-being of the individual, it has an adverse effect on industry, education, family, and child development. It also is associated with violence, crime, financial problems, housing problems, homelessness, and the spread of transmissible disease such at HIV. The latter largely a result from the sharing of needles and/or promiscuous risk taking behaviours whilst under the influence of drugs.

For many people, the gateway into substance abuse starts with prescription drugs, such as analgesic, anti-depressant, anxiolytic and attention-deficit/hyperactivity disorder drugs. The on-going opioid crisis has largely resulted from the excessive prescribing of opioid analgesics.
On occasion it may be necessary to reassess a particular marketed medicine for an abuse liability. An example of this is Gabapentin, a treatment for neuropathic pain and epilepsy which was first approved as an uncontrolled drug by the FDA in 1993. However, in recent years Gabapentin (street name 'Gabbies') has become increasingly misused and abused for its euphoric effects and as a result, in 2019, Gabapentin was reclassified as a Schedule 3 controlled drug.
In order to fully understand the risk to human health from an abuse or misuse viewpoint, all new CNS active drugs (including approved drugs looking to be approved in different counties (for which an abuse liability assessment according to current regulatory guidance has not previously been assessed), or those with a change of formulation, indication or route of administration) require to be assessed for an abuse liability risk. This information is important for practitioners to know so that prescribing can be carefully controlled, and patients can be withdrawn off medications in such a way that a withdrawal syndrome is avoided.
With the increasing addiction rate across a broad range of drug classes, treatments for substance use disorders are required. These include the development of drugs with an abuse deterrent formulation; drugs with equal effectiveness, but lower abuse potential; drugs to prevent relapse; and those intended to counteract overdose.

What outputs do you think you will see at the end of this project?

Reports and data which will be submitted for support the regulatory filing of new drugs.
The refinement of models and associated publications sharing such data and best practices.

Who or what will benefit from these outputs, and how?

The primary benefit of work carried out under this licence will be to allow regulatory authorities (who are totally independent from the commercial interests behind every marketing application) to come to informed decisions, based upon data generated in these studies, regarding the risks and/or benefits when humans are exposed to medicinal products.
Achievement of the objectives of this Licence will enable medicinal products to progress into clinical testing and onwards to marketing authorisation and ultimately improving the health and welfare of humans. Without these pre-clinical studies, progression of new medicines to early human studies and on to patients/marketing could not occur. There is also a major benefit when using early drug selection type experiments, as the most promising compounds for further development will be selected and then fully tested so that they can reach the market sooner and as such benefit the health and welfare of humans. The work carried out under this project licence will 1) reduce the risk of new medicines entering the market for which there is an unknown associated abuse liability, 2) help identify potential treatments for substance use disorders, and 3) identify medicines (e.g., analgesics) which have a lower abuse liability risk than many presently used to treat pain.
The use of the experiments described in this licence may indicate major safety concerns or lack of effectiveness with the substance under evaluation at an early stage thus precluding requirement for additional experiments after these screening studies. This can greatly reduce the number of animals required in a programme of work.
In addition, scientific knowledge gained in one programme of work will often be applied to future experiments in order to reduce animal numbers and/or reduce pain and stress to those animals used in the subsequent work, or to target investigations to a particular organ or tissue during toxicity testing or clinical trials.
Sponsors will benefit from work undertaken within this project licence, by obtaining data which allows them to make decisions on the development of the drugs and to support regulatory filings.

How will you look to maximise the outputs of this work?

Where confidentiality permits, data, study design and best practice will be openly shared at conferences, workshops, webinars, blogs and publications.

Species and numbers of animals expected to be used

- Mice: 7000
- Rats: 12000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Animals used during the course of this licence will be rodents. There is wide knowledge of the behavioural response of rats and mice in response to a wide range of substances and a wealth of background literature.
Rats are large enough to provide repeated blood samples for toxicokinetics, thus requiring significantly fewer rats than mice to achieve
the same objective. Mice may be used when considered a more appropriate species, this may include availability of test material which may be limited during the early phases of drug development. Mice may also be appropriate if previous work has been carried out in that species.
In the majority of cases, rodents are the preferred and regulatory acceptable species for the work carried out under this project licence.
Adult animals will be used.

Typically, what will be done to an animal used in your project?

Studies conducted under this project licence fall into the following main categories in terms of procedures and observations. In all cases, upon completion of testing the animals are humanely killed. **1) Learned behaviour in response to positive reinforcement (reward).**

Animals used under these protocols may be surgically prepared with an indwelling cannula to allow for the intravenous administration of the reward. Animals are placed in operant chambers where they are able to access and press levers, which when selected correctly provide a reward (e.g. cocaine or sucrose). Blood samples may be taken on occasion so that test agent exposure levels can be determined and related to the human situation. These tests are used to

- Determine if a new medicine has a rewarding effect and as such a potential abuse liability. Assess the potential of a new drug to modify drug taking (addiction therapy).
- Determine if a new medicine produces effects, as perceived by the animals, as being similar to those of a known drug of abuse.
- Due to the lengthy training associated with these tests, the duration of these studies is many months (e.g. 4- 12 months). On rare occasions animals used for this tests may be re-used on one occasion, providing that they are not suffering from adverse effects. Re-use avoids the need to use naive animals which would need to undergo the extensive training procedures and surgery.

2) Tolerance, dependence, withdrawal

The majority of animals within these protocols will be administered test agents as a daily administration for up to 4 weeks. At various time-points animals will be observed for physiological or behavioural changes (e.g. body temperature, body weight, reaction to a stimulus, and general activity). Blood samples may be taken on occasion so that test agent exposure levels can be determined and related to the human situation. These tests are generally used to

- Determine if a new medicine has the potential to induce a withdrawal syndrome ('bad feelings') upon cessation of dosing.
- Determine if the pharmacological effect (e.g. analgesia) of a new medicine reduces with duration of dosing
- Determine if a new medicine can prevent the development of a withdrawal syndrome.

3) Analgesia

The majority of animals within this protocol will be administered test agents on a single occasion, with a study duration of less than 1 week. The response of the animal to either a thermal or mechanical (pressure) stimuli will be assessed as an indication of analgesic efficacy. On occasion, repeat dosing may be employed in order to assess the development of tolerance and withdrawal, along side efficacy and by doing so, reduce the need for a second study to be conducted to address these potential side effects.

4) Cannabinoid

This test is conducted to assess the potential of a new medicine to produce cannabinoid-like effects (CB1 activity). Animals are dosed on a single occasion. At a single, defined time-point post-dose, the animals are subjected to a thermal or mechanical (pressure) stimuli in order to assess analgesic effects, body temperature, locomotor activity and their reluctance to immediately move when placed in a 'sitting' position. The typical duration of this study type is 1 day.

5) Behavioral sensitisation

Animals used for this purpose are typically dosed (sensitised) on 6 occasions, followed by a week for example of no treatment before receiving a final challenge dose. At defined time-points, locomotor activity is recorded, typically on each day of dosing, for 2 hours on each occasion.

This test is conducted to assess the potential of a new medicine to induce behavioural sensitisation as demonstrated by an increasing trend of hyperactivity with each dose, or to see if it prevents the sensitisation effects of a known drug of abuse. Data may be used to determine if the new medicine has a 'flag' for a potential abuse liability or has the potential to be used to treat addiction, respectively.

What are the expected impacts and/or adverse effects for the animals during your project?

Humane endpoints as documented within this project licence will be applied to animals used under the protocols specified in this licence.
These studies are typically conducted following early toxicology/pharmacokinetic studies and as such the dose levels can be carefully selected in order to avoid undue toxicity. The majority of the protocols within this licence are behaviourally based (e.g. require animals to learn to lever press for a positive reward) and as such adverse effects are not desirable.
For a number of models performed under this licence surgical implantation of catheters is required. In such cases animals are anticipated to show minimal or no adverse effects resulting from surgery following recovery; analgesics will be provided as required throughout the recovery phase.
Animals within this licence may regularly experience the psychoactive effects of known drugs of abuse, and on occasion the associated withdrawal effects once dosing has ceased. The actual effects seen during dosing are largely drug and dose-level dependent. In the case of stimulants at low doses a slight increase in activity may be observed, whereas, at higher doses (rarely used) stereotype behaviours may be seen; withdrawal effects from stimulants are subtle and short lived. For cannabinoids, low doses are not expected to produce overt effects, whereas at higher doses, decreased activity and temperature, analgesia and cataleptic-like behaviour may be seen; withdrawal effects are difficult to detect. Opioids are associated with analgesia, freezing behaviour and straub (elevated) tail; withdrawal effects are pronounced, although relatively short in duration (peaking within 48 hours of dose cessation) with unkempt appearance, decreased activity, and increased sensitivity to touch being key features. For studies conducted under this project licence any such effects are transient, and in general, with repeat dosing begin to lessen.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity limit specified (moderate) is considered to be the minimum commensurate with achieving study objectives. For the majority of studies conducted under this licence, the severity limit is moderate due to the cumulative procedures required to achieve the protocol objectives. Repeat dosing, surgical cannulation for dose administration and transient restricted access to water during test sessions (e.g. whilst in respiratory chambers, photobeam activity cages, or operant chambers), are primarily responsible for the moderate severity imposed. In the majority of cases animals will not experience more than mild signs as a result of administration of the test agents.
Marked effects anticipated are primarily those related to the known pharmacology of drugs e.g. sedation or stimulation.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

As a service provider we do not own the test materials under evaluation, therefore, in silico screening tools for candidate selection are not appropriate, however, available literature is searched prior to commencing any in vivo procedures. Prior to conducting in vivo studies, sponsors are requested to provide information relating to their test material candidate, together with details of other work performed, relevant regulatory requirements and a justification for conducting in vivo investigations.
Due to the studies within this project requiring the assessment of behavioural and learned responses, the use of animals is essential.

Which non-animal alternatives did you consider for use in this project?

Regulatory guidance documents require non-animal studies to support the data obtained from the animal studies within this licence. These include in receptor binding/function assays, transporter and ion channel effects and chemical structural evaluation.

Literature searches were conducted to determine if any non-animal alternatives were available, however, as these studies rely heavily on behavioural responses, such studies are not presently available. Where possible, data from in vitro assays are used to optimise the design of the animal studies.

Why were they not suitable?

Non-animal studies alone are not sufficient to fully evaluate the potential abuse risk of a drug or its effectiveness as a treatment for substance abuse disorders.
To fully assess the pharmacodynamic effects (effects of a drug on the body) of a new drug testing in animals is necessary. Only in a fully operational circulating system can the drug's distribution, metabolism, excretion which may alter or intensify the efficacy or adverse effects of the new medicine be fully understood. In addition, behavioural effects can only be assessed in live animals.
For these reasons animal models remain essential in the development and safety assessment of new medicines.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The total estimated numbers of animals to be used have been determined based on previous projects over the past 10 years, regulatory trends and anticipated future requirement, and in review of future services being developed and offered globally for regulatory non-clinical studies.

What steps did you take during the experimental design phase to reduce the number of animals being

used in this project?

Studies will be designed under this licence such that the minimum number of animals will be used in order to obtain the maximum information, whilst the scientific objectives of each study are met, in accordance with regulatory requirements and agreed standard practices.
Data generated from pivotal studies will be statistically analysed, with comparisons drawn between control and treated groups, and reported in a format consistent with the ARRIVE guidelines published by the NC3Rs.
For studies within this project which are primarily designed for efficacy or investigative purposes, side effects may be detected which if considered unacceptable for the therapeutic area for which the drug is intended may lead to the cessation of its development early on. Having the opportunity to terminate the development of a drug as early as possible in the development process reduces the unnecessary use of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our Company has a wealth of experience and knowledge regarding regulatory requirements and the industry standards used, hence we are in an ideal situation to influence study designs when discussing requirements with our sponsors and will always consider ways of reducing animal requirements. In-house access to professionally trained statisticians is available who are able to help with study design.
Study protocols are reviewed by the AWERB against known guidelines and the Company's ethical compliance policies. For regulatory studies, guidelines require the appropriate number of groups to clearly demonstrate the presence or absence of effects of the substance; core study designs are based on international guidelines where these exist. If not, use is made of literature and scientific principles of experimental design. Where appropriate, use is made of removing or limiting control groups and challenging the need for the use of both sexes. Additional justification will be requested from the study sponsor and reviewed by the PLH/AWERB for studies requiring a greater number of animals in order to better characterise the variability of a scientific endpoint.
Statistical input is sought, where appropriate, to strengthen the overall scientific quality and relevance of studies, with power-sample size calculations performed for specific studies if necessary to determine group size. Where group sizes allow, data are analysed statistically. However, due to the behavioural nature of studies within this project licence test agent effects are made by examination of data from each animal, rather than or in addition to simply assessing group mean values and statistical parameters.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animals used during the course of this licence will be rodents. The models within this licence are behaviour based and as such animals are required to be in a good state of health in order to perform tasks associated with some protocols (e.g. lever pressing).
Animal welfare costs are minimised by the careful selection of dose levels to reduce the likelihood of unexpected toxicity, and the application of rigorous and comprehensive humane endpoints.
Individual studies will be designed to cause the least possible suffering by frequent review of practices, provision of highly skilled technical staff and veterinary support, purpose built facilities and a clear focus on animal welfare.

Surgical cannulation of animals for the administration of test agents or blood withdrawal has been refined in-house by adopting the pinport method for tether attachment. This method allows the animals to move freely within the home cage, and where possible allows animals to remain socially housed.

Why can't you use animals that are less sentient?

Rodents are the animals with the lowest neurophysiological sensitivity that allows the aims of the studies to be met. Scientific opinion, including that of the regulatory agencies, indicates the use of rodents within these study types are appropriate, and to use other species should only be done if there is strong scientific justification to do so.

The studies within this licence are strongly behaviourally based and as such require the use of conscious animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The severity limits specified are considered to be the minimum commensurate with achieving study objectives. Studies conducted under this licence are within the moderate severity category and it is expected that the majority of animals will have an actual severity that is the low end of moderate or mild, with the actual severity being largely determined by procedural effects (such as surgery or repeat administration) rather than clinical signs resulting from administration of test agents.

All procedures are kept to the minimum commensurate with the study objective. Best practice guidelines for all animal care and use are followed.

In several protocols it is necessary to take serial blood samples from the study animals to monitor plasma levels of the test compound. Where blood samples are required we will take them using the sampling site, volume, and frequency that has least welfare impact on the animals. Where possible samples will be taken under non-recovery anaesthesia. Micro-sampling (using very small volumes of blood, which causes less distress to an animal) will be utilized where methodology is available to do so.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Technical, scientific and regulatory developments will be monitored throughout the duration of this licence. Opportunities to introduce refinements will be evaluated by the Project Licence Holder and Animal Welfare Ethical Review Body to ensure the regulatory and scientific objectives of individual studies can be met whilst achieving the intended benefit. If required, validation studies will be conducted under this licence to ensure these objectives can be met.

Surgical procedures will be conducted in accordance with LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery, LASA, 2017. Analgesia following surgery and other procedures will be provided in accordance with veterinary advice.

Prior to the start of a particular programme or study, the client will be requested to provide information regarding known or potential effects/drug interactions that could be confounded by routine veterinary

treatments or standard husbandry practices. Any such interactions are rare but with pre-planning, alternative treatments may be available (e.g. opioid vs NSAID analgesia, different bedding types etc).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information issued by regulating authorities, the Home Office, cross company consortiums, in-house projects and scientific associations (e.g. the NC3Rs) will be reviewed and adopted as appropriate in accordance with best practice.
The methods used (dosing, blood sampling techniques, handling and restraint, use of analgesia) will be reviewed during the life time of the licence and any refinements developed will be implemented.

Home Office

NON-TECHNICAL SUMMARY

44. Dynamic regulation of immune responses

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunology, antibody responses, lymphocyte migration, pulmonary immunity, splenic immune responses

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify mechanisms that regulate the generation of long-lasting antibody-mediated protection from pathogens.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Effective activation of B cells leads to the generation of highly specific and long-lasting antibody responses. This process is fundamental for host defence and is the **basis for nearly all currently available vaccines**. However, despite their enormous protective potential, antibody responses against several clinically important viruses such as influenza, respiratory syncytial virus (RSV), tuberculosis, HIV and other pathogens fail to confer long-term protection. **This poses a significant medical challenge and highlights the need to better understand the mechanistic basis of humoral memory.**
While antibody responses are critical for protection from primary and secondary infections, abnormal differentiation of pathogenic antibodies can lead to chronic diseases such as **allergy and autoimmune disorders**. Thus, defining the specific pathways that control this process remains an important challenge for the development of therapies against such disorders.
In this proposal, we aim to provide deep mechanistic insights into key steps that lead to induction of long-lasting antibody responses within secondary lymphoid tissues (e.g. lymph nodes and spleen) and to identify factors that regulate the delivery, maintenance and timely termination of these responses in peripheral sites (e.g. the lung). Our main focus is to understand how cell trafficking and interactions with defined niches within living tissues regulate these events, leading to a balanced and efficient immune response.
These studies will have important implications for our ability to **develop novel vaccines that will induce better antibodies with long-term immunological memory against pathogenic microbes.** In addition, these studies may also promote our understanding of how abnormal antibody response develop and persist, **knowledge that may help to identify new strategies to treat immunological disorders (e.g. autoimmune diseases, allergy, chronic inflammation).**

What outputs do you think you will see at the end of this project?

The main goal of this PPL is to enhance our understanding of mechanisms that regulate the generation and maintenance of antibodies. We expect this output to be disseminated via publications in peer reviewed journals and conferences.
Who or what will benefit from these outputs, and how?

In the short run, our studies will advance our understanding of the immune system by addressing key questions that are currently poorly understood:

- How splenic immunity is orchestrated- Long-term immune responses are induced within secondary lymphoid organs, including the lymph nodes and spleen. Among those, the spleen is the largest immunological organ, which contains the greatest number of lymphocytes. As such, targeting immune responses to the spleen may be a powerful approach to induce a strong and effective immune response, for example when vaccinating against challenging pathogens (e.g. influenza virus, tuberculosis, malaria). To induce such a response, it is essential that lymphocytes are able to access specific compartments within the spleen. In this project, we aim to identify the molecules that regulate this process, and which allow immune cells to migrate into the spleen and become activated effectively. Better knowledge of the

basic mechanisms that control these events will be important for future efforts to develop approaches to regulate immune responses for therapeutic purposes.

- How regional humoral immunity is regulated in the lung- Memory B cells play a critical role in our ability to resist repeated infections with the same pathogens and their development is important for the success of most current vaccines. Following infection with influenza virus, a subset of memory B cells has been identified to develop within the infected lung. Localization of memory B cells directly near regions, where viral entry occurs, provides them with a great advantage to respond to new infections quickly and efficiently. However, the molecular mechanisms that allow the cells to remain and survive in the lung are not known. It is also not clear how these cells function during exposure to a secondary infection. In this project we aim to address these questions and to identify molecules that regulate lung memory B cell development, survival and function.

In the longer run, our studies may lead to development of therapeutic agents that aim to enhance or inhibit antibody responses and to prevent cell recirculation (i.e. ability of T and B cells to continuously move from one secondary organ to the next). This may help to:

- Develop ways to treat autoimmune diseases, or to block entry of cancer cells into sanctuaries located within secondary lymphoid tissues.
- Guide the development of vaccines that enhance immune responses in the spleen in order to use its enormous immunological potential.
- Guide the development of vaccines aiming to enhance local antibody production in response to influenza virus and possibly other respiratory pathogens.
- Lead to the development of possible therapeutic agents to antibody-mediated lung allergy.

How will you look to maximise the outputs of this work?

The outputs from this work will be maximised through the dissemination of our findings in publications and conferences. We also aim to expand our collaboration network with the industry (e.g. we are currently in discussion with a US based company aiming to use our recent findings to improve the capacity of CAR T cells to traffic into tumours).
In addition, we will continue to publish our negative results (when relevant) primarily in supplementary data section of manuscript in hope to minimize redundant work.

Species and numbers of animals expected to be used

- Mice: 28000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is a suitable animal model for our scientific questions because many of the molecular factors that regulate lymphocyte migration and interactions with other cells (e.g. key chemokine receptors, structural elements such as the high endothelial venules, integrins etc) are highly conserved between mice and other vertebrates including humans. This high level of similarity allowed the translation of studies performed in mice to clinical use in humans (e.g. Fingolimod/Gilenya™, which blocks the chemotactic receptor S1PR1. This drug was developed and studied extensively in mice before being approved as the first oral treatment for multiple sclerosis).
The overall structural organisation of lymphoid organs (including lymph nodes and spleen) and the mechanisms that underline B cell activation are very similar in mice and humans. This, again, allows researchers to use mice-based studies as a baseline to generate clinically relevant agents (e.g. vaccines and adjuvants).
Adaptive immunity has evolved in vertebrates and the maturation of the cells and structures that regulate it mature over time (typically 8 weeks in mice). It is therefore not possible to use lower organisms or embryos to address In some cases, procedures may be applied on juvenile or embryos mice in order to induce specific changes early during development. However, the end point of such experiments will be explored in the adult animal.

Typically, what will be done to an animal used in your project?

Many of the animals in this project will be immunized with vaccine-based agents or infected with live pathogens such as Influenza virus, Salmonella or Listeria monocytogenes. In most cases, immunizations are not expected to cause significant discomfort that goes beyond that which is associated with vaccination in humans. Infection with live pathogens is expected to cause disease that will resolve within 7-14 days and which is not associated with mortality. Mice that are infected with virulent Salmonella strains will be killed within 5 days post infection, at a time when the clinical symptoms do not exceed the moderate severity limits.
Some mice may be subjected to re-challenge. Importantly, re-challenged mice are expected to develop a-symptomatic disease due to the existence of immunological memory induced in response to the primary infection or immunisation.
Some mice may be subjected to whole body irradiation and bone marrow transplantation. This procedure is associated with a 14 days recovery period. Symptoms associated with this procedure are very similar to those observed in humans receiving bone marrow transplantation.

What are the expected impacts and/or adverse effects for the animals during your project?

Following infection with live pathogens or bone marrow transplantation, mice are expected to lose body weight and to experience general discomfort leading to symptoms such as temporary reduced social behaviour, loss of coat grooming and partial hunched posture. These symptoms are expected to last 3-5 days, depending on the treatment. However, full recovery is expected to be achieved within 7-14 days. When un-immunized mice are infected with non-attenuated Salmonella strains, they will be killed within 5 days post infection, before developing severe clinical symptoms.
Injections are expected to cause local temporal pain, with no longer term effect.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols (which takes up to 55% of the mice on this project) we expected the majority to experience sub-threshold (approximately 95%) a small number to experience mild severity (approximately 4%) and less than 1% to suffer moderate severity.
For the mice on experimental protocols (3, 4 and 5), we expected the majority (approximately 90%) to experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our studies directly investigate the complex interactions between immune cells and their physiological environment. Many of the processes we explore involve cell moving between organs, moving between different environment within minutes, processes that often depend on the intact blood and lymph flow.
A mammalian species is required to investigate the behaviour of immune cells in distinct anatomical niches, a dynamic and complex process that cannot be reproduced in vitro. For example, to study the migratory patterns of lymphocytes in the blood-rich compartments of the spleen, the intact blood flow must be maintained. Similarly, to investigate where and when a lymphocyte receives activation signals during an immune response the anatomical structure of the organ and its cellular composition must be preserved. To understand how cells cross in and out of restricted tissues (e.g. when entering or exiting to and from lymphoid organs), the intact entry and egress site of these structures and their connectivity to the circulatory fluids must be maintained. Notably, in many cases, the exact anatomical location and the cellular composition of niches are not known, therefore requiring direct approaches to discover them and study them.
Given that the adaptive immune system is an attribute restricted to vertebrates and reaches its full maturation in adults, addressing the scientific question in our studies requires the use of adult mice, with a fully mature immune system. In some cases, we may initially apply procedures on juvenile or embryos mice in order to induce specific changes that occur early during development and which subsequently affect the adult animal. However, the end point of such experiments will be explored in the adult animal.

Which non-animal alternatives did you consider for use in this project?

In some cases, cell culture systems may replace animal tissue in experiments that characterise the biochemical effects of specific genes; these approaches can complement in vivo studies. For example, we have recently established a collaboration with a group in Japan that allows us to use a cell line that can promote differentiation of specific stages of B cells in vitro. This system can replace and complement some of the in vivo procedures. In other cases, we use in vitro trans well analysis to explore the biochemical pathways that regulate cell migration.

Why were they not suitable?

Currently, we have limited understanding of the cellular composition, structural organisation and plasticity of most of the anatomical sites in which immunity is induced. There is therefore not enough knowledge to design artificial whole animal systems that will mimic the complexity of living organisms and allow us to explore how interactions with the tissue regulate immune responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice was estimated based on my extensive experience with the experimental approaches used in this proposal and the records of mice usage we have been keeping over the past 5 years.
These take into account both the statistical power of the different types of experiments involved, the various time points required for different assays and the frequencies by which multiple allele genotypes are generated in different crosses.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. **Appropriate use of statistics**:

The majority of our experiments produce data that can be analysed by pragmatic approaches such as test. We typically seek to uncover large differences in behaviour and function (~40%) and therefore do not normally need to use large numbers of animals to reach a statistically meaningful result in each experiment.
In most cases, animal numbers have been calculated based on our previous studies, assuming a standard deviation at the range of ~0.25 for imaging studies, and ~0.2 for most functional studies. Therefore, to obtain a statistically significant measurement (assuming one-tailed t test, significance level of <0.05 and the minimal acceptable power of 0.8), between 4-5 mice will be required to uncover differences of 40% (or more). Typically, 3 repeats will be sufficient to obtain statistically meaningful results.
When appropriate (e.g. when analysing histological sections), we use blinding to minimize biases.

2. **Minimise random variation and increase uniformity within and between experiments**. This is necessary to detect significant differences with minimal numbers of animals:

We use age and sex matching approaches to reduce variability between mice within experiments.
We only use fully backcrossed mice with the same genetic background.
We often co-house experimental animals in order to further increase uniformity between the different experimental groups.
When possible, we include intrinsic controls (e.g. using mixed bone marrow chimeras) to reduce the numbers of mice required per experiment by 50% and to further increase uniformity.

3. **Improved analysis methods**:

We develop new algorithms to improve statistical strength- Many of our studies are based on live imaging assays. These assays require multiple repeats due to a relatively high level of noise; an issue commercial software packages are unable to resolve. We have been working in collaboration with other groups to develop algorithms to overcome some of these limitations and extract more reliable data from each movie.

4. **Avoid experimental repetition**:

In some cases, we perform several experiments simultaneously, such that one cohort of control mice can be used as reference for more than one experimental question.
Similarly, we reduce experimental repetition and increase internal consistency (and therefore statistical strength)

by collecting all the relevant tissues from mice allowing us to compare different parameters within the same animals.
Frozen tissues are often archived to permit multi-factorial analysis without additional in vivo experiments (e.g. for using in histology).

5. Reducing number of donor mice:

In some cases, we use bone marrow chimeras and genetically engineered mouse models to generate mice in which specific lymphoid and non-lymphoid niches are highlighted endogenously, allowing live imaging of defined sites within living organs. This approach replaces the need to transfer large number of lymphocytes to achieve similar labelling of compartments, thus reduces the number of donors and provides a consistent system to address complex questions in vivo.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. Performing new experiments-

When performing a new assay, we first attempt to find labs that are routinely performing the assay and work with well-established protocols obtained from experienced researchers.
For novel assays, we first perform a pilot test to determine intra and inter group variations.

2. Optimised breeding strategy –

We review animal requirements frequently. I personally supervise this process.
We keep a careful documentation of the number and type of breeders to help organize the colony and ensure no unnecessary breeding is carried out. Our colony is managed directly by myself. I visit the mouse house very frequently and put a lot of efforts to ensure we do not generate unnecessary mice and use the pups born on our colony as best as we can.
We optimize breeding strategy by crossing homozygous breeder pairs when possible. Similarly, most transgenic animals are maintained as homozygous.
Embryos of strains that are not currently in use are frozen.
Some of our studies depend on complicated crosses that require expression of at least 3 alleles. In these cases, we typically use bone marrow chimeras to expand the desired genotype, such that one breeder is enough to obtain dozens of useful mice.

3. Sharing mice with other groups and resources-

When available, we obtain genetically modified mice from a relevant supplier or from colleagues. When specific lines do not exist, we generate them ourselves. We typically use external companies to make genetically altered mice, which is much more efficient and given that we are not experts in the area. Once we produce a new line and publish it, we make it available for the wider scientific community.
Our institute has an email list that allows us to distribute or obtain surplus mice, whenever they are available.

4. In vitro experiments-

1. Whenever possible, we use tissue culture and ex-vivo approaches to test our hypothesis.

2. In some cases, e.g. when studying dynamics of immune cell responses in niches in which cell behaviour does not depend on intact blood flow (such as the follicular regions in the spleen, lung or other peripheral sites) we use an explant instead of an intravital imaging approach. For this purpose, we have recently purchased a vibratome in the institute that allows gentle cutting of explant organs, maintaining the integrity of the tissue and have optimized a protocol to image explants successfully. Since multiple slices can be imaged from a single mouse, this approach also reduces the number mice required to obtain statistically meaningful information.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This proposal is limited to mice models. In this proposal, we will focus on experimental mouse models aiming to investigate basic mechanisms that regulate activation of adaptive immunity and generation of long-lasting antibody responses. To address these goals, we will use a range of approaches including immunisation with attenuated pathogens (e.g. such as attenuated vaccina virus which is used for vaccines), engineered proteins or responses and to test the mode of action of vaccines (such as the current anti-tuberculosis vaccine), infection models (e.g. influenza virus, to explore how antibodies against respiratory pathogens can be better induced and maintained). We will combine these approaches with cutting edge imaging techniques, which will allow us to obtain unique information about the dynamic of immune responses (how cells are able to respond accurately and quickly enough to invading pathogens).

Why can't you use animals that are less sentient?

Our studies focus on the regulation of adaptive immune responses, which have evolved in vertebrates, therefore excluding the usage of lower organisms. Because the adaptive immune system takes time to mature (e.g. marginal zone B cells take 8 weeks to develop in mice), using adult animals is necessary.
The mice we are using have to be alive during the experimental procedure. This is because we are studying mechanisms of cell trafficking via niches and organs that are not only complex but also often uncharacterized and therefore cannot be recapitulated in vitro (e.g. we search for the egress site from spleen, which currently remains an unknown anatomical structure). Furthermore, we depend on live animals because our studies explore responses that require cell trafficking between and within organs, a process that depends on intact blood and lymph circulation and tissue integrity.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We pay careful attention to animal husbandry and provide environmental enrichment and co-housing to avoid social isolation. For example, we keep careful track of weaning days to ensure that if a single male or females are due to be weaned, they are co-housed with other pups that are weaned on the same day from different lines.
We make every effort to reduce the number of procedures per animals and to minimize the discomfort involved during each procedure. For example, we previously amended the protocol to allow us to use implanted mini pumps and slow release pellets to reduce number of injections, in some experiments
We also minimize the suffering of animals through careful experimental design and by ensuring that the researcher performing the procedure is fully competent and understands the protocol and its limitations. For this reason, I discuss the aim and design of every in vivo experiment in the lab and I monitor routinely the competency level of researchers both by observing their performance as well as by evaluating the accuracy and consistency of their results.
We always aim to use the least painful substance and route of administration. For example, we have recently begun a scientific collaboration allowing us to use virion-like particles as a means to induce or re-activate local immune responses in the lung. This procedure causes no detectable adverse effects and so whenever possible, we use it instead of live viral infection.
When possible and necessary, we use anaesthetics to reduce temporary discomfort during a procedure. In these cases, animals are allowed to fully recover between the two restraint anaesthetics.
Our preferred choice of anaesthetic is inhalation, which we use whenever possible. Our institute's facility invested in new excellent Isoflurane equipment distributed by a local producer that worked with us to optimise it for our live imaging purposes. This equipment is highly reliable in ensuring the appropriate level of anaesthetic is delivered during surgical procedures and we now use it to fully replace injectable anaesthetic for our intravital imaging studies.
When surgery is involved, we use appropriate aseptic techniques, monitor the animals before during and after the procedure. Special attention is given to the husbandry of animals after surgery to monitor that they recover well.

When mice are subjected to treatments that may cause them moderate pain, a humane practice is exercised to limit the length of procedure to the shortest possible time.
When mice are infected with live pathogens, we aim to use the least virulent pathogenic strains, in order to reduce suffering. For example, we have obtained attenuated influenza strains that are capable of a single round of replication. We use these strains whenever possible, to prevent necessary suffering for the animals. Similarly, infection with Listeria will be primarily done using the attenuated Act A deficient strain, which significantly reduces the severity of adverse effects.
In all protocols, we follow clearly defined action points, monitoring schemes and humane end points to minimize suffering of animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use our extensive experience as well as various online tools to calculate the number of mice for each experiment (e.g. using the NC3Rs Experimental Design Assistant (EDA) on-line tool). We will use ARRIVE guidelines for conducting and reporting our experiments for publication. If new or complicated statistical analysis is required, we will seek the advice of a statistician. Such help is readily available to us.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly attend welfare meetings and continue to use the NC3R website (https://www.nc3rs.org.uk) to follow up on news and updates. When introducing new treatments or approaches, we will seek the advice of experts in the field as well as that of the vet and NACWO regarding the latest relevant refinements.

NON-TECHNICAL SUMMARY

45. Early behaviour and cognitive abilities in chickens (Gallus gallus)

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

predispositions, filial imprinting, chicks, controlled-rearing, cognitive development

Animal types	Life stages
Gallus gallus	neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the developmental origins of early cognitive abilities using chicks of the

domestic fowl (*Gallus gallus*) as a model system. I plan to clarify how spontaneous preferences (predispositions) of inexperienced chicks affect/enhance learning, generalisation and social behaviour, and which is the role of the right and left brain hemispheres in cognitive development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Due to ethical and practical constraints, the role of predisposed knowledge on cognitive traits such as learning and exploratory behaviour cannot be conveniently investigated in human infants, rodents and other species immature at birth, producing an important knowledge gap in understanding how the mind works and develops. Using chicks, that are precocial (hatch with a mature sensory and motor system) and are able to quickly learn through filial imprinting (a quick learning mechanism that is based on mere exposure and is in place at the beginning of life in precocial species such as chickens), we will clarify which are the building blocks of cognition in the first stages of life. In this way, we will obtain a better understanding of the cognitive abilities that support human cognitive development, learning and social behaviour. This project is important to understand healthy cognitive development. Given that these abilities are compromised in neurodevelopmental disorders such as autism, and that chicks are a model also for neurodevelopmental disorders, this research has also clinical relevance; moreover, it can lead to the development of better biologically-inspired artificial intelligence.

What outputs do you think you will see at the end of this project?

Predispositions: we will clarify which features are preferred by chicks in terms of colour, shape, motion dynamics, social engagement.
Generalisation and learning: we will clarify whether predispositions (spontaneous preferences) enhance learning and generalisation in new situations. We will determine the minimal experience required for spontaneous generalisation.
Our data will inform experts in artificial networks on effective strategies for generalisation.
We will integrate the information gained on chicks' performance with artificial intelligence models to advance the understanding of animal minds, cognitive and behavioural development and artificial intelligence.
Publications: our findings and models will be published on peer-reviewed publications accessible to the scientific community and the public. To reach a cross-disciplinary audience, we will make our findings available to the scientific community and public through open servers before experts review and target interdisciplinary and open access expert-reviewed journals.
Data will be made available on public repositories and presented at international and national conferences/webinars.

Who or what will benefit from these outputs, and how?

The problem of the origins of knowledge has been investigated for centuries, with implications that span from philosophy to linguistics, psychology, neuroscience and artificial intelligence.
Developmental psychologists will be informed on the early mechanisms of generalisation with visual stimuli, paving the way to studies in different modalities and domains, including language, and in human learning and education. The potential of the chick as a model relevant for humans is shown by the fact that previous experiments conducted by my research group and other groups have shown that the same/similar deficits/delays present in children at high risk of autism are present in chicks exposed to substances that increase the risk of autism in humans (such as valproic acid). The proposed behavioural work, hence, builds on previous data that suggest a benefit of our studies not only to better understand the behaviour of chicks but also to understand human behaviour.
Thanks to our work, researchers interested in the neurobiological basis of spontaneous preferences and generalisation will have an established animal model system and setting to investigate the responsiveness of different brain areas using methods that require refined behavioural methods and few animals.

Our findings and models are expected to move artificial intelligence towards general intelligence. This can have a significant socio-economic impact in industrial applications (e.g. artificial intelligence, robotics, automation) and for the everyday life of the general public.

How will you look to maximise the outputs of this work?

To reach a cross-disciplinary and broad audience, we will make our findings available to the scientific community and the public through: open repositories; interdisciplinary and open access peer-reviewed journals; presentations and posters at international and national conferences/webinars. Data and protocols will be made available on public repositories.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To study the cognitive abilities and behaviours described in this project, we need to work with live animals, given that there is little or no evidence available on the topic. Only intact animals will allow to identify valid behavioural responses.
We will use newborn domestic chicks (*Gallus gallus*) because we are interested in shedding light on the early cognitive abilities and behavioural skills, at the beginning of life, when little experience is available.
It has not been possible to identify animal models that have a lower neurological development than the chick, that with a comparable sensory and cognitive development provide the same behavioural complexity in such as precocial developmental phase, and that have mechanisms of learning as efficient as those present in young chicks in terms of speed and flexibility, and that is an established model in the previous literature.
The choice of using domestic chicks (instead for instance of rodents) is well supported by virtue of their peculiar maturity at hatching. Chicks in fact hatch with a mature sensory and motor system. This facilitates testing newborn animals, fully controlled until the moment of test. This reduces the need of external carers that would influence the results, and minimises the amount of time that chicks spend in the laboratory setting. The fact that chicks can establish social attachment for artificial objects and not only for the hen, also helps our research and reduces the impact of social restrictions.

Typically, what will be done to an animal used in your project?

We will run behavioural experiments, exposing young individual animals to determine visual/acoustic/tactile stimuli and observing their approach preferences and other measures of interaction (e.g. pecking). Chicks will be exposed only to the stimuli delivered experimentally in a restricted/controlled space, and their social companions will be artificial tridimensional objects or computer displays.

Some animals will undergo behavioural tests that will help identify the different function of the right and left brain hemisphere in learning and other behaviours. To this aim, one eye will be temporarily covered with an eye patch, such that only one hemisphere receives visual input at a time in relevant experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

Only healthy chicks will be tested.
Based on the previous literature and on the principal investigator's experience with this animal model and procedures, only temporary mild adverse effects are expected. One possible source of mild suffering is the reduction of space and environmental and social enrichment in the controlled-rearing environment, since animals may be housed with artificial partners (e.g. a cube, a cylinder, a computer display) rather than in groups with conspecifics, in basic accommodation with minimal inclusions (food, water), to avoid chicks imprinting on any items that would affect experimental outcomes.
However, this is well tolerated and no long-term adverse effects are regularly observed. We will monitor the health parameters and behavioural responses of chicks to prevent distress. Any runts or those that show signs of ill health that cannot be quickly ameliorated will be humanely killed. Care will be taken to ensure those under experimental conditions can readily access food and water at all times.
Another source of potential mild distress is the covering of one eye with an eye-patch. The discomfort will be reduced avoiding to touch the eye with sticky material. This procedure has been used for decades and it is well tolerated by chicks. No long-term adverse effects have been observed. Shall for any reason a chick show signs of sustained distress in response to the eye-patch, it won't be tested and the patch will be removed to prevent further distress.
When tested in a new apparatus, a few animals might be distressed by the detachment from the home cage. In case the chick shows sign of distress (pecking at arena wall, trying to jump out while producing distress calls) for more than 2 minutes, the test will be aborted and the animal located back in its home cage. In these cases, while moving the chick back to its home cage, the experimenter will comfort the chick with a gentle touch.
The overall health of the flock will be checked also by looking at the overall mortality rate, to make sure it does not exceed the spontaneous mortality rate observed in the first 2 weeks of age.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The maximum severity of experience for animals on the project will be mild, because any pain or suffering experienced by an animal will only be slight, transitory and minor. We expect that most animals may experience a subthreshold severe experience.
100% of animals will be controlled-reared with limited exposure to environmental and/or social enrichment. We expect adverse effects in less than 10% of the animals.
50% of animals will be tested in a new apparatus. We expect adverse effects in less than 10% of the animals.
10% of animals will be tested with an eye-patch. We expect adverse effects in less than 10% of the animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ethical and practical limitations prevent us to keep and test humans in a controlled-rearing environment. The

investigation of cognitive abilities and behaviours described in this project requires to work with live animals, given that there is little or no evidence available on the topic. Only intact animals will allow us to identify valid behavioural responses.
It has not been possible to identify animal models other than the chicks with a lower neurological development that, with a comparable degree of development at the sensory and cognitive level, provide the same behavioural complexity in such an early developmental phase and that have mechanisms of learning as efficient as filial imprinting in the terms of speed and flexibility, and so well studied in the previous literature.
The choice of using the domestic chick is well supported also by virtue of its peculiar precocial features, that minimise the duration of time spent in the laboratory setting, ease of experimental handling, similarity to human responses.

Which non-animal alternatives did you consider for use in this project?

In-silico models are not suitable given the little knowledge available on the topic. For this reason, the domestic chick is widely used to address questions about early cognition.
This project will provide evidence to develop artificial intelligence that in the future could substitute or reduce animal use.

Why were they not suitable?

We are interested in the building blocks of animal cognition and behaviour, for this reason only intact living animals will allow to identify valid behavioural responses.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We plan to test the minimum number of animals that enables to draw valid statistical conclusions: 40-50 animals depending on the procedure. Animals will be tested only once because we want to identify the role of a particular experience regime at a time.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Based on power calculations on the previous literature and pilot experiments we have calculated that each experimental condition will require 40-50 animals, depending on the experimental condition.

What measures, apart from good experimental design, will you use to optimise the number of animals you

plan to use in your project?

Random behavioural variability will be reduced by careful and standardized handling of the eggs (e.g. egg development synchronized by locating eggs in a fridge before starting incubation, identical temperature and humidity settings) and of the chicks before and during the test. Moreover, the incubation room, maintenance room and testing room will be climatically standardized.
We have run pilot studies that confirm the suitability of 40-50 animals to detect a medium size effect which will be of statistical significance.
Measurement variability will be reduced using automated behavioural tracking based on machine learning.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use newly-hatched domestic chicks (*Gallus gallus*), that present several advantages in terms of reducing the suffering in the required controlled-rearing procedures:

- they are mature and can take part in the experiments soon after hatching, thus reducing the time spent in the laboratory

- they can become attached to the simple artificial objects required by this study and do not require care from other living animals

- because in birds the right and left hemispheres have few connections, lateralised functions can be studied using non-invasive eye patches

- the literature shows that the suggested procedures are well tolerated

Why can’t you use animals that are less sentient?

We have not identified animal models with a lower neurological development that, with a comparable degree of development at the sensory and cognitive level, provide the same behavioural complexity in such as precocial developmental phase and that have mechanisms of learning as efficient as filial imprinting in the terms of speed and flexibility, and so well studied in the previous literature.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will carefully monitor the health and behaviour of chicks. The use of automated behavioural tracking enables us to carefully inspect animal behaviour, reduces the number of animals required in the tests and provides data that can be subsequently analysed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experimental protocols on the procedures suggested in this project are shared by the scientific community and

have already been published in open source journals. We keep up to date with the relevant scientific literature to refine our procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am regularly in touch with the officers at my establishment, that organise outreach/instruction events, and with colleagues that work with poultry. I also check the NC3R website and I keep up to date with the literature. Moreover, I am a member of the Association for the Study of Animal Behaviour and I participate in its activities, as well as to the Animal Welfare Research Network.

Home Office

NON-TECHNICAL SUMMARY

46.Early Diagnosis and Therapy through the Eye

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

retinal neurodegeneration, ocular surface disorder, disease models, imaging, therapy

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterise disease models with retinal neurodegeneration or with dry eye in order to develop therapeutic strategies for the treatment of ocular diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Retinal neurodegeneration (RN) is the major cause of irreversible blindness worldwide. There is currently no early diagnosis and no cure. The retinal degenerative condition occurs not only in eye diseases, such as glaucoma and age-related macular degeneration (AMD) but also in neurodegenerative disorders, including Alzheimer's (AD) and Parkinson's (PD). Dry eye disease (DED) is a multifactorial ocular surface disease characterised by symptoms of discomfort, irritation, and visual disturbance. DED is a very common condition with a high prevalence among the elderly and has no cure. In monitoring the basic mechanisms of retinal neuronal loss in RN and ocular surface abnormality in DED, this work aims to shed light on poorly understood ocular diseases and characterise the ocular manifestation of systemic conditions. These approaches would allow us to develop new strategies for treating widespread diseases thus prevent or delay the onset of blindness. The wider implications would impact on any conditions associated with neuronal loss and ocular surface disorder, where our findings can help to enhance the clinical diagnosis and refine the therapeutic intervention.

What outputs do you think you will see at the end of this project?

- This work is expected to shed light on poorly understood ocular diseases and to identify and characterise the ocular manifestation of systemic diseases.
- Our findings are expected to potentially help to enhance the clinical diagnosis and refine the therapeutic intervention.
- The primary expected benefit is the publication of new therapeutic strategies for retinal neurodegenerative diseases and dry eye.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will provide a new understanding of the mechanisms behind retinal neuronal death and identify new strategies to reduce or halt neuronal loss in neurodegenerative diseases. We will also promote and publish any refinements or best practices we identify during this project. We will use post-mortem tissue to correlate ocular changes elsewhere in the body to make maximum use of a single animal.

In the medium-term, the pharmaceutical industry will be interested in potential novel therapeutic targets we identify.

The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of neurodegenerative diseases, both in humans, benefitting patients and clinicians by contributing to the development of effective neuroprotective therapies, which will ultimately reduce the economic and health

burden caused by the devastating conditions.

How will you look to maximise the outputs of this work?

We will collaborate with other researchers and share new data and knowledge as well as unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 3000
- Rats: 2000
- Rabbits: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice are the main species to be used in this project because the rodent is the lowest vertebrate group with many similarities to human tissues in structure and function. We now have a great experience with these models in imaging nerve cell death in the back of the eye and making different disease models.

We will only use transgenic rodent models that have been closely linked to human disease. Transgenic animals provide a chronic model of disease that is not easily achievable in surgically or substance induced models, such as mouse models of Alzheimer's and Parkinson's disease.

However, to test the safety of the drugs and to develop new drug administration routes for translating the treatments to humans in the future, we would like to use the rabbit as it is a well-known and well-studied model of eye disease and is particularly important for its similarity to the human eye. Specifically, we will use New Zealand rabbits.

The majority of these animals used in this project will be young adults, however, a small number of ageing animals will be included to study ageing changes and treatment efficacy, such as transgenic Alzheimer's and Parkinson's mice.

Typically, what will be done to an animal used in your project?

Animals will undergo one procedure to make a disease model and will receive neuroprotective substances or vehicle via one or two administration routes, and will be assessed for retinal structural and/or functional changes and therapeutic efficacy. At the end of the experiment, animals will be killed by a Schedule 1 method or perfusion fixation.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects include corneal cloudy, some degree of vision loss, post-surgical pain, weight loss, and weakness. Because disease models will be induced in one eye and left the other eye intact, corneal

cloudy and vision loss will occur in one eye only, which would not affect overall animal welfare. Post-surgical pain may last less than 24 hours and topical and systemic analgesia will be administered. Weight loss and weakness may occur in some disease models, such as diabetic retinopathy and Parkinson's disease. To reduce the duration of these adverse effects, animals will be kept for a shorter period of time as possible, for example, diabetic animals for 4-24 weeks and
Parkinson's for 8 weeks. Animals will be monitored and scored daily for clinical signs, and any animal who has a weight loss of more than 15% will be killed by a Schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Although the severity of this project has been set up as moderate, the majority of animals will experience mild procedures. A small proportion of animals will be expected to experience moderate, such as surgically-induced glaucoma models and substance-induced diabetics. The proportion of animals who may have moderate severity in this project as a whole will be less than 25% in mice and rats, and 5% in the rabbits.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work relies on the assessment of processes in the living being – it is not possible to use cell culture or test-tube, as studying whole-body conditions is essential. There is no alternative to using live animals to answer our scientific questions.

Which non-animal alternatives did you consider for use in this project?

For partial replacement, cell culture methods are useful to assess drug safety, to screen drug candidates, and to optimise dosages before testing them in animals. This has been used in our previous PPLs and will be continually used in this project.

Why were they not suitable?

However, cell culture or test-tube methods do not allow us to directly apply to patients. It is not possible to reproduce the highly complex anatomical structure of the eye and brain in cell culture or test tube. Moreover, our studies are exploring the use of real-time retinal nerve cell death and apoptosis measurements and their correlation with disease and treatment. This cannot be done in tissue culture models where the environment can never be completely replicated.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our study is designed on the basis of pilot studies and previous research, to optimise the information gained with the minimal use of animals, with good scientific practice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have recently attended a course of the NC3R's Experimental Design Assistant (EDA). The useful online tools show how to design the randomisation and blinding of the experiment and sample size calculation, in order to produce robust and reproducible data with a minimum of animal use, such as randomised block experimental design. This accounts for the influence of variables and addresses sources of bias, appropriate controls, and efficient use of statistics to ensure that the data from every animal is utilised to its full potential.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A major advance in our laboratory research is our use of in vivo techniques for disease assessment e.g., cell death imaging and electrophysiology. This allows the collection of serial data so the same animal can be tracked over time, and recent research has enabled us to reduce the number of animals used compared with previous applications. Furthermore, the parallel cell culture studies will enhance the investigation of neuroprotective strategies, highlighting appropriate agents and dosages.

In addition, to optimise the number of animal use, we will breed animals efficiently to make sure not to breed more than we need. We will collaborate with other PPL holders, who have breeding protocols for genetically modified animals. We will continue to use pilot studies and computer modelling as well as share tissues with others. For example, we have recently obtained mouse eyes with multiple sclerosis by collaborating with another group.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and mice are the main species to be used in this project because the rodent is the lowest vertebrate group with many similarities to human tissues in structure and function. However, to test the safety of the neuroprotective agents and to develop novel drug delivery for translating the treatments to humans in the future, we would like to use the rabbit as it is a well-known and well-studied model of ocular disease and is particularly appreciated for its similarity to the human eye. Specifically, we will be studying drug delivery and islet cell transplantation in NZW rabbits. All models chosen in the new project are the most established and accepted models that involve animals with the lowest degree of neurophysiological sensitivity, cause the least pain, suffering, distress, or lasting harm, and are the most likely to produce satisfactory results. These models have either been established by us, and covered in previous PPLs, or are established by other experts in our university.

Why can't you use animals that are less sentient?

The animal models with retinal neurodegeneration are to mimic human diseases that occur in adulthood and mostly in ageing. So, it would not be suitable to use the immature life stage of animals. Rodent models of retinal disease have been well established and widely used worldwide. The majority of animals in the project will be studied over time to determine structural and functional changes and to assess therapeutic efficacy. However, some animals will be considered to be terminally anaesthetised where it is possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise stress, animals will be handled and trained before procedures, such as clicker training (https://www.jove.com/video/58511/using-clicker-training-social-observation-to-teach-rats-to) and tickling (https://www.jove.com/video/57190/tickling-a-technique-for-inducing-positive-affect-whenhandling-rats); less harmful models will be used, such as using Akita females instead of males; and less invasive methods will be used, such as use ear snips rather than tail tips for genotyping.

Beware of potential adverse effects of the procedures before being performed. To minimise any adverse effects, animals will be carefully monitored for any signs of distress and pains after procedures, with post-operative care and pain management.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure experiments are conducted in the most refined way, I will follow the best practice guidance, such as The PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) for experimental design, and The ARRIVE (Animal Research: Reporting of In Vivo Experiments) for publication of results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have registered and attended the course of the 3Rs, and will stay informed about advances in the 3Rs by visiting the NC3Rs website regularly and reading newsletters, and by attending national and international conferences.

NON-TECHNICAL SUMMARY

47.Early Diagnosis and Therapy through the Eye

Project duration

5 years 0 months

Project purpose

- (c) Basic research
- (d) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

retinal neurodegeneration, ocular surface disorder, disease models, imaging, therapy

Animal types	Life stages
Mice	adult
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterise disease models with retinal neurodegeneration or with dry eye in order to develop therapeutic strategies for the treatment of ocular diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Retinal neurodegeneration (RN) is the major cause of irreversible blindness worldwide. There is currently no early diagnosis and no cure. The retinal degenerative condition occurs not only in eye diseases, such as glaucoma and age-related macular degeneration (AMD) but also in neurodegenerative disorders, including Alzheimer's (AD) and Parkinson's (PD). Dry eye disease (DED) is a multifactorial ocular surface disease characterised by symptoms of discomfort, irritation, and visual disturbance. DED is a very common condition with a high prevalence among the elderly and has no cure. In monitoring the basic mechanisms of retinal neuronal loss in RN and ocular surface abnormality in DED, this work aims to shed light on poorly understood ocular diseases and characterise the ocular manifestation of systemic conditions. These approaches would allow us to develop new strategies for treating widespread diseases thus prevent or delay the onset of blindness. The wider implications would impact on any conditions associated with neuronal loss and ocular surface disorder, where our findings can help to enhance the clinical diagnosis and refine the therapeutic intervention.

What outputs do you think you will see at the end of this project?

- This work is expected to shed light on poorly understood ocular diseases and to identify and characterise the ocular manifestation of systemic diseases.
- Our findings are expected to potentially help to enhance the clinical diagnosis and refine the therapeutic intervention.
- The primary expected benefit is the publication of new therapeutic strategies for retinal neurodegenerative diseases and dry eye.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will provide a new understanding of the mechanisms behind retinal neuronal death and identify new strategies to reduce or halt neuronal loss in neurodegenerative diseases. We will also promote and publish any refinements or best practices we identify during this project. We will use post-mortem tissue to correlate ocular changes elsewhere

in the body to make maximum use of a single animal.

In the medium-term, the pharmaceutical industry will be interested in potential novel therapeutic targets we identify.

The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of neurodegenerative diseases, both in humans, benefitting patients and clinicians by contributing to the development of effective neuroprotective therapies, which will ultimately reduce the economic and health burden caused by the devastating conditions.

How will you look to maximise the outputs of this work?

We will collaborate with other researchers and share new data and knowledge as well as unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 3000
- Rats: 2000
- Rabbits: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice are the main species to be used in this project because the rodent is the lowest vertebrate group with many similarities to human tissues in structure and function. We now have a great experience with these models in imaging nerve cell death in the back of the eye and making different disease models.

We will only use transgenic rodent models that have been closely linked to human disease. Transgenic animals provide a chronic model of disease that is not easily achievable in surgically or substance induced models, such as mouse models of Alzheimer's and Parkinson's disease.

However, to test the safety of the drugs and to develop new drug administration routes for translating the treatments to humans in the future, we would like to use the rabbit as it is a well-known and well-studied model of eye disease and is particularly important for its similarity to the human eye. Specifically, we will use New Zealand rabbits.

The majority of these animals used in this project will be young adults, however, a small number of ageing animals will be included to study ageing changes and treatment efficacy, such as transgenic Alzheimer's and Parkinson's mice.

Typically, what will be done to an animal used in your project?

Animals will undergo one procedure to make a disease model and will receive neuroprotective substances or vehicle via one or two administration routes and will be assessed for retinal structural and/or functional changes and therapeutic efficacy. At the end of the experiment, animals will be killed by a Schedule 1 method or perfusion fixation.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected adverse effects include corneal cloudy, some degree of vision loss, post-surgical pain, weight loss, and weakness. Because disease models will be induced in one eye and left the other eye intact, corneal cloudy and vision loss will occur in one eye only, which would not affect overall animal welfare. Post-surgical pain may last less than 24 hours, and topical and systemic analgesia will be administered. Weight loss and weakness may occur in some disease models, such as diabetic retinopathy and Parkinson's disease. To reduce the duration of these adverse effects, animals will be kept for a shorter period of time as possible, for example, diabetic animals for 4-24 weeks and
Parkinson's for 8 weeks. Animals will be monitored and scored daily for clinical signs, and any animal who has a weight loss of more than 15% will be killed by a Schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Although the severity of this project has been set up as moderate, the majority of animals will experience mild procedures. A small proportion of animals will be expected to experience moderate, such as surgically-induced glaucoma models and substance-induced diabetics. The proportion of animals who may have moderate severity in this project as a whole will be less than 25% in mice and rats, and 5% in the rabbits.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work relies on the assessment of processes in the living being – it is not possible to use cell culture or test-tube, as studying whole-body conditions is essential. There is no alternative to using live animals to answer our scientific questions.

Which non-animal alternatives did you consider for use in this project?

NON-TECHNICAL SUMMARY

48. Ecotoxicity Studies with Amphibians

Project duration

5 years 0 months

Project purpose

- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Endocrine, Disruptor, Xenopus, XETA, Chemicals

Animal types	Life stages
Xenopus	adult, pregnant, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Reason for retrospective assessment

This may include reasons from previous versions of this licence.

- Contains severe procedures

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to assess the interactions of a range of chemical types (industrial chemicals, agrochemicals, pharmaceuticals, biocides and microbial pesticides) with the endocrine systems of Xenopus tadpoles, Eleutheroembryos or transgenic Eleutheroembryos, such that the hazardous properties of these substances with respect to their ecotoxicological properties can be assessed. These properties are a fundamental requirement of the risk assessment process for such substances.
A retrospective assessment of these aims will be due by 21 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The data obtained in these tests are submitted to regulatory authorities to inform decision-making processes and, where appropriate, satisfy the governmental regulatory requirements that are necessary to gain product registration or to assess the risk and impact posed to the natural environment or human health by the use of chemicals, agrochemicals or pharmaceuticals. Ecotoxicology studies in general are designed to assess the likely impact on populations of plants and animals, and to identify ecologically benign concentrations.

What outputs do you think you will see at the end of this project?

The assessment of the risk posed by new and existing chemicals and waste materials to the natural environment continues to be an important international issue for industry, governments and the public alike. Synthetic chemical substances will inevitably enter the natural environment as a result of their use and disposal in industrial and domestic environments. Ecotoxicology studies are designed to assess their likely impact on natural populations of plants and animals, and to identify ecologically benign concentrations.
The main aim of the studies conducted within this project is to identify substances that may interfere with the normal function of the hypothalamic-pituitary-thyroid (HPT) axis in amphibians, specifically *Xenopus laevis*. This is an important assay as amphibian metamorphosis is a thyroid dependent process, which is well studied and is the only assay that detects thyroid activity in an animal undergoing morphological development.

The studies are designed to evaluate a number of endpoints, including survival, developmental stage and associated morphological features, body wet weight and thyroid histology.
The use of Xenopus Eleutheroembryonic Thyroid Assay (XETA) will allow detection of potential modulations of thyroid activity induced by a range of test chemicals.

Who or what will benefit from these outputs, and how?

There are many concerns that environmental levels of specific chemicals interacting with the endocrine system (the oestrogen, androgen or thyroid hormone) may cause adverse effects in both humans and wildlife populations and have wider implications for both human and ecosystem health. Aquatic organisms have been identified as the most convincing examples of evidence for the impact that potential endocrine disrupting chemicals can have on animal health. These concerns have led to the revision and development of guidelines in order to facilitate screening and testing of these potential endocrine disruptors.
The data obtained in these tests are submitted to regulatory authorities to inform decision-making processes and, where appropriate, satisfy the governmental regulatory requirements that are necessary to gain product registration or to assess the risk and impact posed to the natural environment or human health by the use of chemicals, agrochemicals or pharmaceuticals. Ecotoxicology studies in general are designed to assess the likely

impact on populations of plants and animals, and to identify ecologically benign concentrations.

How will you look to maximise the outputs of this work?

All of the studies conducted in this facility with aquatic species are bound by confidentiality agreements and unless contracted to provide support through the registration process, the testing facility does not normally receive information regarding the progression of a substance through to marketing authorization. It is not possible therefore to identify the number of substances tested in the facility that have gained marketing authorization or product registrations. Success in this programme of work is not only associated with the successful registration of a substance but also the refinement of risk assessments, and the derivation of risk-reduction and toxicity mitigation strategies. Another important role of studies in this programme is the identification of substances with unacceptable effects or safety margins.

Species and numbers of animals expected to be used

- Xenopus: 50 (Adults), 13500 (tadpoles), 36,000(eleutheroembryos)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult *Xenopus laevis* are required in order to produce eggs for the acute and definitive tests for the 21 day metamorphosis assay.
For this assay to be assessed correctly it is essential that a life stage is used that is going through the process of metamorphosis so that developmental end points can be assessed. Amphibian metamorphosis is a thyroid dependent process and is the only assay that detects thyroid activity in an animal undergoing morphological development.

Adult Xenopus laevis may also be used in order to produce eggs/ Eleutheroembryos for the XETA range-finding assay. Eleutheroembryos or transgenic Eleutheroembryos at stage NF45 are used for the XETA range-finder or definitive test respectively as this assay requires embryos at a specific developmental stage in order for this assay to work successfully. The definitive test requires the use of transgenic Eleutheroembryos as the fluorescence of each organism needs to be quantified at the end of the test.

Typically, what will be done to an animal used in your project?

21 day metamorphosis assay:

In order to conduct the aquatic toxicity tests using tadpoles at a specific morphological stage (Stage 51), the production of eggs from breeding adult *Xenopus laevis* held in the laboratory must be induced. All tadpoles exposed in the metamorphosis study must originate from the same spawning event, and therefore sufficient numbers of eggs are required. Approximately 12 hours before the required egg collection, injections of hCG (human Chorionic Gonadotrophin) are given, and the breeding pairs are then allowed to perform natural mating and egg laying procedures.
In order to conduct the assay Animals will be transferred from holding tanks to test vessels, transfer to fresh test media (where applicable) in all animals.
The developmental stage of the animals is determined using a binocular dissection microscope to ensure that

stage 51 tadpoles are utilized during the test. A selection of animals (approximately 20) may also be measured and a mean whole body length for this group of animals determined, minimum and maximum limits for the whole body length of experimental animals can be set by allowing a range of the mean value ± 3 mm.
There is a minimum of three test concentrations and a clean water control (and vehicle control if necessary). Separate groups (typically 80 tadpoles over 4 replicates per concentration) of stage 51 Tadpoles will be exposed concurrently to varying concentrations of the test item for a period of up to 21 days under semi-static or continuous flow test conditions.
Animals are observed at least daily. Where signs of toxicity are seen, the frequency of observations will be increased. At each observation time, animals that are considered likely to die or are showing symptoms of exposure that represent a significant departure from the animal's normal state of health or well-being will be identified and humanely killed by an appropriate non-schedule 1 method at the designated establishment. The tadpoles will be given an overdose of anaesthetic (eg MS222) for a period of at least 2 hours. The absence of response to a physical stimulus will be confirmed followed by permanent removal from the aqueous environment prior to immersing them in a suitable fixative (Davidsons solution or a suitable alternative). All humane kills are recorded.
Food will provided throughout the test, the type and amount of feeding will be dependent on the life stage of the larvae, whilst minimising the surplus that will be removed throughout the study.
A selection of tadpoles will be humanely killed and sampled once during the study, this will be conducted (e.g. on Day 7) by a non-schedule 1 method at the designated establishment. The tadpoles will be given an overdose of anaesthetic (e.g. MS222) for a period of at least 2 hours. The absence of response to a physical stimulus will be confirmed followed by permanent removal from the aqueous environment prior to immersing them in a suitable fixative (Davidsons solution or a suitable alternative).
At the end of the exposure period (e.g. Day 21) surviving tadpoles will be humanely killed by a nonschedule 1 method at the designated establishment. The tadpoles will be given an overdose of anaesthetic (eg MS222) for a period of at least 2 hours. The absence of response to a physical stimulus will be confirmed followed by permanent removal from the aqueous environment prior to immersing them in a suitable fixative (Davidsons solution or a suitable alternative) and all appropriate end-points determined.

Xenopus Eleutheroembryonic Thyroid Assay (XETA):

In order to conduct the assay Eleutheroembryos will be transferred from holding tanks to test vessels and transferred to fresh test media (where applicable).
The developmental stage of the Eleutheroembryos is determined using a binocular dissection microscope to ensure that stage 45 Eleutheroembryos are utilized during the test.
Eleutheroembryos between developmental stages NF45 (beginning of the test) and NF47 (end of the test) are used for this test. They are not fed before or during the test as yolk is still present in the intestine from stage NF45 to stage NF47 and is used as the source of energy for the development of the eleutheroembryo (Nieuwkoop and Faber, 1994).
There is a minimum of three test concentrations (+/- triiodothyronine (T3) 3.25 µg/L)) plus relevant control groups (Test media, Triiodothyronine (T3) and Thyroxine (T4)) (and vehicle control if necessary). Separate groups (typically 20 Eleutheroembryos over 2 replicates per concentration) of stage 45 Eleutheroembryos will be exposed concurrently to varying concentrations of the test item for a period of approximately 72 hours under semi-static or continuous flow test conditions. Three runs will be conducted per test.
Eleutheroembryos are observed at least daily. Where signs of toxicity are seen, the frequency of observations will be increased. At each observation time, Eleutheroembryos that are considered likely to die or are showing symptoms of exposure that represent a significant departure from the normal state of health or well-being will be identified and humanely killed by an appropriate non-schedule 1 method at the designated establishment. When both the acute and XETA studies have been completed, all remaining Eleutheroembryos are humanely killed by a non-schedule 1 method at the designated establishment. The Eleutheroembryos will be given an overdose of anaesthetic (eg MS222) for a period of up to 45 minutes (as specified in the test guideline) followed by permanent removal from the aqueous environment. All Eleutheroembryos will then be frozen (-18˚C) prior to destruction by incineration. (AC).
The fluorescence of each organism is quantified after 72 ± 2 h of exposure.

What are the expected impacts and/or adverse effects for the animals during your project?

Transfer of animals from holding tanks and transfer to fresh test media (where applicable) will cause mild stress in all animals. The discomfort will be transient in the majority of animals (>90%) and no additional action will be required.

It is anticipated that only transient minor discomfort should occur in the adult animals during injection procedures. Reactions to the gonadotrophin injected are not expected.

Due to the inherent nature of LC_{50} testing deaths and adverse clinical signs (e.g. abnormal swimming behaviour, loss of orientation, lack of surfacing activity, muscular spasms or lethargy) will be noted in the tadpoles especially at higher test concentrations, no adverse effect are to be expected at the lower levels. It can be assumed that cumulative signs of toxicity may be seen as the study progresses.

It is not the intention of the definitive test protocols to cause mortality or significant signs of toxicity. However, typically, the highest concentration tested in the metamorphosis assay will be near the maximum tolerated test concentration, or may be approximately one-third of the LC_{50}, depending on the dose response. As such, at the higher concentrations being tested there may be accumulation of toxicity noted during the exposure period which may result in adverse clinical signs (e.g. abnormal swimming behaviour, loss of orientation, lack of surfacing activity, muscular spasms or lethargy) being apparent (but not to the same degree as in the acute protocol) for a period of time resulting in cumulative toxicity/severity.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

21 day metamorphosis assay:

All adult animals which are subject to gonadotrophin injections will feel mild discomfort at the site of injection for a short period of time.

In the acute toxicity protocol it is anticipated that approximately 50% of the individuals will suffer mortality or adverse effects such as abnormal swimming behaviour, loss of orientation, lack of surfacing activity, muscular spasms or lethargy.

It is anticipated that approximately 15% of the individuals may suffer moderate effects such as abnormal swimming behaviour, loss of orientation, lack of surfacing activity or lethargy. These effects/clinical signs should not be experienced by the tadpoles to the same degree as in the acute toxicity protocol but due to the length of time that they may persist, cumulative severity may result in a moderate classification. Malformations may also be seen on occasion which will be assessed for severity.

Typically, the concentration range in the definitive test will be based on the results of acute toxicity tests or metamorphosis assays, and therefore it is not the intention to cause mortality. It is anticipated that no adverse effect will be observed at the lower levels.

All animals at some point will require moving to fresh test media, this is considered to cause mild stress in all animals. The discomfort will be transient in the majority of animals (>90%) and no additional action will be required.

Xenopus Eleutheroembryonic Thyroid Assay (XETA):

In the acute toxicity protocol it is anticipated that approximately 50% of the individuals will suffer mortality or mild to moderate effects such as abnormal swimming behaviour, loss of orientation or lethargy. Due to the low neurophysiological sensitivity of the life-stage of the tadpoles being used, death is classed as a moderate effect.

Typically, the concentration range will be based on the results of acute toxicity tests and therefore it is not the intention to cause mortality. It is anticipated that no adverse effect will be observed at the lower levels.

All animals at some point will require moving to fresh test media, this is considered to cause mild stress in all

animals. The discomfort will be transient in the majority of animals (>90%) and no additional action will be required.

What will happen to animals at the end of this project?

- Kept alive
- Killed

A retrospective assessment of these predicted harms will be due by 21 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently there are no validated non-animal alternatives to replace the whole animal toxicity tests that are mandatory for the evaluation of new and existing chemicals to assess their safety and efficacy. To assess morphological development due to effects on the thyroid axis, the use of a live animal is a necessity. Xenopus laevis is proposed as the test organism as it is known to be widely available, obtainable throughout the year and relatively easy to maintain. It is representative of the more sensitive species and a large literature base is available to provide background information.

Which non-animal alternatives did you consider for use in this project?

Currently there are no validated non-animal alternatives to replace the whole animal toxicity tests that are mandatory for the evaluation of new and existing chemicals to assess their safety and efficacy.

Why were they not suitable?

Currently there are no validated non-animal alternatives to replace the whole animal toxicity tests that are mandatory for the evaluation of new and existing chemicals to assess their safety and efficacy.

A retrospective assessment of replacement will be due by 21 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Amphibian metamorphosis Assay:

Numbers have been calculated based on running six LC_{50} tests and six definitive tests per year over the five year duration of this project licence.

Xenopus Embryonic Thyroid Assay

Numbers have been calculated based on running twelve LC_{50} tests and twelve definitive tests per year over the five year duration of this project licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Regulatory guidelines dictate numbers of organisms exposed per concentration and the spacing factor employed for definitive stage testing. Statisticians are consulted to ensure studies are designed to maximise the strength of replication in order to use the minimum number of organisms per vessel.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The use of a range finding phase of testing where existing information of the toxicity of a chemical is not available reduces the risk for repetition of the full metamorphosis or Xenopus Embryonic Thyroid Assays using high numbers of tadpoles or eleutheroembryos respectively, as a suitable range will be identified which aims to ensure the study endpoints are achievable.
Whenever possible, the maximum spacing factor will be employed when setting concentration ranges.
The priming and induction procedures utilised during the production and collection of eggs, in preference to relying on natural mating procedures, ensure that the minimum number of adult Xenopus laevis are used (e.g. 3 tanks of 3 pairs per spawning event), in order to achieve the maximum fecundity levels.
It is aimed that approximately 5000 eggs will be produced from the spawning event, from which the tadpoles from the spawn with the highest hatching success are selected and a minimum number (approximately 800) of these individuals are raised to the independently feeding stage.
A retrospective assessment of reduction will be due by 21 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Adult frogs used to produce eggs will suffer mild pain at the site of injection for a very small amount of time. As eggs are required for these protocols there are no other options available other than using adult animals.

Amphibians represent vertebrates and one of the highest trophic levels in the aquatic ecosystem and are of particular importance in the testing scheme because of their developmental life-history and sensitivity to

chemical substances, making them important ecological indicators. The species and stage of tadpole development employed are considered to represent the most suitable model to identify effects of exposure in the environment. The objectives and protocols are aimed at assessing the impact of a substance on the survival and development of Xenopus tadpoles, and therefore on the potential for further effects on the ecosystem, using mandatory tests that follow internationally accepted test designs. Due to the low neurophysiological sensitivity of the life-stage used during XETA, death is classed as a

moderate effect and as such this life stage (tadpole) will be the one that suffers the least during this type of testing.

Why can't you use animals that are less sentient?

As eggs are required for these protocols there are no other options available other than using adult animals. As the objectives are aimed at assessing the impact of a substance on the survival and development of Xenopus tadpoles, it is essential that living animals are used such that the development of these animals can be assessed. These animals are considered to be the least sentient species at this life stage used in this project licence where a meaningful assessment can be made on their development. The life stages that are required to be used are specified in the relevant OECD test guidelines.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Any refinements identified during the conduct of tests under this licence, as experience with these species is gained, will be assessed and put into common practice where possible. Methods for handling and identification have been designed within the field of amphibian laboratory use in order to minimise the chance of causing stress and pain in the adult Xenopus.
Appropriate handling of the adult organisms will ensure restraint procedures are effective for injection purposes and therefore ensure time taken for completion of injection procedures is minimised.
When necessary, any identification of the adult stock animals will take place using non-invasive methods e.g. photographic records in preference to toe clipping, tagging or microchip implant. Tank labels will be used to identify groups of animals.
The minimisation of excessive stress and rapid changes to environmental conditions, especially during movement, cleaning of vessels and manipulation of larvae, has been identified as a key factor in the optimisation of using Xenopus laevis. Husbandry and exposure conditions, and the associated techniques, will be well defined to ensure noise, vibration and activity levels within the laboratory are kept to a minimum. Environmental conditions e.g. temperature, pH, dissolved oxygen, light levels and water flow rates will be controlled and maintained.
Regulatory systems that require specific test requirements may allow little discretion in the species used. However, the most appropriate species, particularly in terms of species sensitivity and availability of background data, as well as the species having the lowest neurophysiological sensitivity, are chosen. Thus the most appropriate species is chosen on scientific grounds rather than custom and practice.
All scientific procedures using animals are performed in accordance with UK Good Laboratory Practice regulations. Standard Operating Procedures define animal welfare practices and experimental procedures. Licencees are fully trained and competent in the appropriate procedures and are familiar with the signs of pain, discomfort or distress in the species with which they are working. Training records are maintained to document training levels, retraining and competence. Staff are encouraged to identify and encourage improved methods particularly with regard to procedural methods, housing and handling of animals.
Animal tests are designed and conducted in every case so that any actual or potential pain, discomfort, or distress to the animals is minimised or alleviated by choosing the earliest endpoint that is consistent with the scientific objectives. The term "endpoint" is defined as the point at which an experimental animal's pain and/or distress is terminated, minimised or reduced, by taking actions such as killing the animal humanely or giving treatment to relieve pain and/or distress.
The ultimate purpose of the application of humane endpoints to ecotoxicology studies is to be able to accurately predict severe pain, severe distress, suffering, or impending death, before the animal experiences these effects. However, the science of ecotoxicology is not yet at the point where such accurate predictions can be made prior to the onset of severe pain and distress. It is possible at this time to identify pain, distress and suffering, very early after their onset by careful observations of animals on test. This test facility is fully committed to the implementation of the recognition, assessment and use of clinical signs as humane endpoints for test animals.
Before starting a safety evaluation study, consideration is given to relevant background data or information supplied with the test material, together with databases for similar chemicals or substances or previous

experience with other sponsor products. Thus, the type and severity of the abnormal signs of toxicity, particularly in terms of time of occurrence in relation to time of dosing may be anticipated. Technical and animal welfare staff will be alerted to what signs to look for.
Studies likely to cause significant acute adverse effects are scheduled to start as early in the working day as possible. This ensures that the critical period for the animals occurs during normal working hours when the frequency of observations can be maximised or increased depending on the potential for increasing pain or distress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The proposed work will be conducted according to standardised test guidelines. These guidelines incorporate the scientific rationale for national regulatory requirements and are peer reviewed by scientific and industry experts to reflect current scientific knowledge and ethical standards in animal experimentation. Completed studies are peer reviewed by Competent Authorities, the company Registration Department and Sponsor representatives, and the comments received from post study peer reviews are used to further refine subsequent testing. Animal studies are not initiated until written confirmation is received from the sponsoring Company that they are needed to satisfy a regulatory authority and that funding to cover the full cost of the studies will be provided. The company Project Management Department (PMD) co-ordinates major notification projects and liaises with the Study Directors in charge of each study to ensure that unavoidable animal studies do not commence until the results of related non-animal studies are known.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

All staff involved in animal testing at maintain an up to date outlook on animal welfare considerations via the attendance of relevant meetings, review of publications in journals and other sources, and face to-face meetings with other individuals working in the area of ecotoxicology or aquatic husbandry. This ongoing knowledge building allows for any refinements that are identified to be introduced into standard procedures.
A retrospective assessment of refinement will be due by 21 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

49. Effects of neurotransmitters on metabotropic receptors in hippocampal neurons

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

neurobiology, receptors, ion channels

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The principle aim of this project is to understand how naturally occurring chemicals known as neurotransmitters exert their effects on the activity of brain cells, neurons, by binding to specific proteins on their surface that are called metabotropic receptors. In particular, we will be investigating the effects of neurotransmitters on adult mature and newly-generated granule neurons found in a key area of the brain, the hippocampus, which plays a central role in many brain functions including learning and memory.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Neurotransmitters play an important role in regulating the activity of neurons. These are released often in response to changes in behaviour. Certainly, alterations in their levels in the brain have been associated with many disorders including cognitive dysfunction and neuropsychiatric diseases such as anxiety and depression. It is, therefore, important to understand how these exert their effects on neurons.

We will be investigating the role of two particular neurotransmitters, acetylcholine and glutamate, acting on specific receptors on hippocampal adult mature granule neurons. These neurotransmitters play a key role in many brain functions such as learning and memory and medicines that bind to their specific receptors are currently in clinical development for the treatment of many disorders including dementia and neuropsychiatric disorders. Moreover, altered hippocampal granule neuron activity influences processes such as memory acquisition and consolidation and stress resilience. Despite this, we know very little about how acetylcholine and glutamate exert their effects on these neurons and the functional consequences of this. In this project, we will investigate this. The information generated will significantly advance our understanding of the mechanisms underpinning physiological processes such as learning and memory. It might also be beneficial in identifying new forms of treatment for disorders such as dementia and Alzheimer's disease.

The dentate gyrus is also one of two areas in the adult brain that can generate new neurons. These so called 'adult new-born neurons' have been suggested to significantly influence learning and memory during their development. Indeed, a reduction in the number of these neurons has been associated with cognitive deficits in Alzheimer's disease patients. The work proposed will substantially enhance our understanding of how acetylcholine and glutamate influence adult new-born neuron development and will be beneficial in designing new therapies for the treatment of disorders such as Alzheimer's disease.

What outputs do you think you will see at the end of this project?

We expect to generate novel information on how neurotransmitters regulate information processing in adult hippocampal neurons, which play a critical role in affecting normal processes such as learning and memory formation. In particular, the information will, for the first time, shed light on how two neurotransmitters, acetylcholine and glutamate, affect hippocampal neuronal activity when they activate receptors that are localised to a specialised part of neurons, the axon. This is important as digital, all or none signals known as action potentials are generated in axons. Action potentials play an essential role in determining a neuron's activity. Changes in hippocampal neuronal activity will affect our ability to learn as well as other forms of behaviour such as our levels of stress. Hence, this work will yield important information on the mechanisms underpinning these processes. It is anticipated that we will present this work at scientific meetings either in the form of posters or as PowerPoint presentations. Moreover, final datasets will be published in highly respected peer-reviewed neuroscience journals as we have previously done.

In addition to the above, the hippocampus is one of two brain regions where it has been determined that new neurons are generated. At present, we have very little knowledge about how neurotransmitters affect the development of these neurons. It is anticipated that this new knowledge will significantly advance our understanding of their development and will be of considerable interest to academic and industrial scientists. We will, thus, make every effort to widely disseminate this information by presenting complete datasets at scientific meetings and publishing final datasets in peer-reviewed journals that are fully open access.

Who or what will benefit from these outputs, and how?

In the short term, the findings will mostly advance our knowledge of how hippocampal neurons function and thus will be of immediate interest to academic scientists.
Since acetylcholine and glutamate metabotropic receptor stimulators are currently in clinical development for the treatment of multiple disorders including dementia, Alzheimer's disease and neuropsychiatric disorders, we anticipate that the information generated will be useful for those scientists working in industry who are interested in developing more targeted drugs with an improved side-effect profile for these disorders. This is expected to be a medium- long term impact of the findings.

How will you look to maximise the outputs of this work?

We already collaborate with many scientists in the UK, Europe and USA and will share datasets with them as appropriate as soon as we can.
Moreover, we will be presenting data at scientific meetings attended by academic and industrial scientists and medical staff, thereby ensuring that we will be disseminating the information as widely as possible.
We will publish all final datasets, regardless of whether the approaches are successful or not, thereby ensuring that the information is in the public domain.
Finally, we will take part in public engagement events such as the Royal Society Summer Scientific Fair to convey our findings to the public.

Species and numbers of animals expected to be used

- Mice: 6400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using juvenile and adult mice for our work. We have selected mice for our work as these breed well in house and mice with specific genetic modifications that would be particularly useful for addressing our question are readily available. Hence, the tissue from these animals is readily available for our experiments and will provide a reliable and consistent source for generating data.
We will be using adult mice as we are interested in understanding how neurotransmitters affect adult neuron function.

Typically, what will be done to an animal used in your project?

Typically in most experiments, mice with particular genetic modifications (transgenic mice) will be bred. The offspring will be genotyped to identify wildtype and genetically modified mice. When these mice are adult (5-8 weeks old), we will be terminally anaesthetise them and obtain brain sections from them to analyse the effects of neurotransmitters on particular metabotropic receptors in the hippocampus.
In a subset of experiments, particularly if transgenic mice are not available, we will surgically inject viral vectors that have been proven to be safe, into the hippocampus of adult mice to specifically modify the expression of particular proteins in the neurons that we wish to study. 2-3 weeks after this procedure, when the animals have recovered from this procedure and there is maximal expression of the viral vectors, we will terminally

anaesthetise the animals and obtain the brain sections to analyse the function of neurons when specific metabotropic receptors are activated.
In the event that transgenic mice or viral vectors for genetically modifying the expression of particular proteins are not available, then we will consider the use of chronically treating wildtype adult mice with particular pharmacological agents that modify the activity of particular proteins. If these are available and have been proven to be safe and harmless, then these agents will be continually administered via a device known as an osmotic mini-pump which is surgically implanted into mice. After a suitable period of treatment, animals will be terminally anaesthetised and brain sections obtained to study the effects of neurotransmitters on specific metabotropic neurons in adult mice.

What are the expected impacts and/or adverse effects for the animals during your project?

The transgenic mice that we wish to use are not expected to exhibit any abnormal behaviour or show signs of distress. These mice breed normally and develop normally too. Further, terminally anaesthetising mice to obtain the brain tissue is expected to cause minimal distress.
Mice will have to undergo surgery for the injection of injecting AAV or lentivirus viral vectors into specific areas of the hippocampus or implantation of osmotic mini-pumps for chronic pharmacological treatment (Protocol 2). Surgery is associated with several adverse effects including non-recovery from anaesthesia, wound infection and post-surgery pain. We, however, have adapted this procedure so that more than 95 % animals recover fully from anaesthesia and no animals suffer from either wound infection or post-surgery pain.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding of transgenic mice and obtaining brain sections from mice is likely to cause minimal distress and is therefore likely to be at most of mild severity. This will apply to approximately 94 % of the animals that we will use.
We estimate that a very small proportion (6 %) will undergo surgery. This is categorised as moderate as it might result cause some temporary discomfort to animals.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently, we know very little about how neurotransmitters acting on metabotropic receptors exert their effects on neuron activity in real time. To study this, we need to obtain living, healthy brain tissue in which neuron function is intact. Thus, to understand how the function of individual neurons is affected by metabotropic receptors, it is essential to use animal tissue.

Which non-animal alternatives did you consider for use in this project?

Non-animal alternatives include
1) in silico advanced computer models.

2) human and stem cells that can be maintained in a dish.

3) human tissue.

Why were they not suitable?

In silico advance computer models: Whilst we have collaborated with scientists that are specialised in generating computer models, at present we have very little information available on how particular neurotransmitters acting on their specific metabotropic receptors affect neuron function. Thus, we cannot make these models or use existing models for this work.
Human and stem cells: Metabotropic receptors can be expressed in human cells that are maintained in a dish. However, human cells maintained in a dish do not express many of the naturally occurring signalling molecules that metabotropic receptors couple to when exerting their function. Indeed, our preliminary data show that there are significant discrepancies between how metabotropic receptors function in neurons present in living brain tissue and data obtained from human cells expressing metabotropic receptors. It is, therefore, important to use animal tissue to understand how native metabotropic receptors function and exert their effects in the brain. Stem cells can be used to generate neurons in a dish. However, this process is challenging and the properties of neurons derived from stem cells differ from those that are naturally occurring in the brain. For this reason, we cannot use stem cells for our work.

Human tissue: Postmortem human tissue is not suitable for our studies as we need to determine the effects of these neurotransmitters on living neurons in real time. The availability of healthy human living tissue obtained using surgical methods is limited and therefore, this method is not ideal for our work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on our experience and our data of the minimal numbers required to determine how neuron function is affected by neurotransmitters acting on specific receptors.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To estimate the animal numbers required for experiments involving surgical injection of viral vectors and implantation of osmotic mini-pumps for chronic pharmacological treatment, we performed power calculations using programmes such as G*Power. We estimated the number of neurons from which electrophysiological recordings or anatomical data would be required. Since we know that we can obtain at least one good electrophysiological recording from a neuron in slices obtained from one animal, we estimate that the number of neurons required to produce the required data is equivalent to the number of animals required.

Most experiments, though, involve breeding transgenic mice. These are heterozygotes to generate a mixture of wildtypes, genetically modified mice and heterozygotes. We use wildtypes and genetically modified mice for our experiments. However, we cannot determine the numbers of these generated by a given breeding pair. From our experience, we need to keep at least 4 breeding pairs per colony to allow generation of the required numbers of animals for all our experiments and for the colony to be maintained. Hence, the number of mice estimated for breeding is based on our current experience of the number of mice produced using 4 breeding pairs per mouse colony.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have optimised breeding by using animals between one month to 7 months for this purpose. The animals are housed in environmental enriched cages. This allows us to keep 4 breeding pairs at any one time and produces the required animals to complete our experiments.
Animals used for experiments are also group housed in enriched environments. This allows animals to be relatively relaxed, thereby ensuring that we get good quality brain tissue from them and obtain the maximum amount of data from each animal.

A small number of animals will undergo surgery. We have optimised the conditions required for surgery to ensure that more than 95 % animals undergoing this procedure have little post-operative pain or distress. Moreover, wherever possible, animals are group housed in environmentally enriched cages. Further, the viral vectors that will be used are those that have been shown to be safe. The genetic modifications induced by these vectors are not predicted to cause any harm.
For vectors and pharmacological agents that we have not used previously and for which there is no publicly available data, we will carry out pilot experiments to optimise these experiments.
We often share our data and materials with other scientists, particularly those involved in computational modelling, thereby enabling maximal use of the data that we generate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using genetically modified mouse models for the majority of our work. These mouse models are commercially available. The genetic modifications have been shown to have little impact on breeding and the animals have a normal life-span and are able to eat and drink normally. Mice will be identified using genotyping and may be administered substances to induce gene expression.
For some experiments, we will be performing surgery to administer substances to alter gene expression or to manipulate receptor activity. The substances that will be used are those that have been proven to be safe to animals and humans and not predicted to cause distress or lasting harm to animals. Surgery itself is associated with pain and distress. To minimise this, we have optimised this procedure by using appropriate anaesthesia, aseptic techniques, monitoring body temperature and breathing, administering peri-operative analgesics and treating wounds with iodine to reduce infection. We find that using these conditions, animals are not distressed.
To quantify the effects of genetic modifications or changes in receptor activity, we will obtain brain tissue from animals. To obtain good quality tissue, we will terminally anaesthetise animals before embarking on this procedure. This will ensure that the animals experience little distress during this process.

Why can’t you use animals that are less sentient?

We will be investigating how neurotransmitters exert their effects on adult neurons as there is very little information available on this. For this, we need to use adult animals and obtain brain tissue from them that contains the neurons that we are interested. For most experiments, we will terminally anaesthetise animals to obtain the brain tissue required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Biological Services unit staff and/or research staff monitor animals housed in the Biological Service unit at least three times a week. If animals are observed to be experiencing distress, we will monitor these more regularly at least twice a day and consult the NACWO and/or NVS on best practice.
For 5 days post-surgery, animals will be regularly monitored twice a day for signs of distress. Moreover, they will be weighed once daily to ensure that they are feeding and developing normally. They will be group housed in environmentally enriched cages.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will following ARRIVE guidelines which have been published and are available on the NC3Rs website.
In addition, we will following the published AWERB guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend seminars run by NC3Rs which are run by an NC3Rs representatives. Moreover, we will regularly visit the NC3Rs website a to be informed of these matters. Further, we are in regular contact with the NACWO and NVS who will also provide advice on how to implement advances in 3Rs during the during of the project.

Home Office

NON-TECHNICAL SUMMARY

50. Efficacy evaluation of products to support the health and welfare of farmed fish

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b) **Key words**

aquaculture, product development, vaccine efficacy, therapeutic efficacy, feed additives

Animal types	Life stages
Atlantic salmon (Salmo salar)	juvenile, embryo, neonate, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to evaluate the efficacy of products, including veterinary vaccines, therapeutics, feed materials, feed additives and biocides, intended for use in the production of farmed fish. The project will provide a service to commercial clients and research providers seeking to develop products for fish. The principal objectives are to provide data on the effectiveness of the products in relation to prevention and treatment of infectious disease and other pathologies, and impacts on performance and welfare.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

These studies are necessary to enable assessments of the effectiveness of the products for use in farmed fish, including regulatory assessment for the purposes of product licensing, to identify the preferred treatment procedure and to understand the modes of action of the products so that the products can be used safely and effectively.

What outputs do you think you will see at the end of this project?

The expected benefits of this project will be to:

1. Establish a platform which clients can access to develop products for aquaculture. A shortage of capacity at present is restricting the availability of new products for farmed fish.

2. Support the evaluation, development and licensing of new products to improve the health and welfare and performance of farmed fish. These products will be used by salmon farmers to reduce losses due to salmon lice and other diseases and to improve production efficiency.

3. Generate high quality data to ensure that new licensed products are demonstrably effective. These data will be produced to the internationally recognised quality standards required by relevant regulatory authorities.

4. Support the production of fish as food that is safe, healthy and nutritious, economically sustainable, environmentally acceptable and produced to the highest animal welfare standards.

5. Tackle biological challenges which threaten the sustainability of an industry which supports jobs and economic activity in remote areas.

Who or what will benefit from these outputs, and how?

The benefits will be realised by:

1. Farmed fish which will benefit from improvements in health and welfare.

2. Husbandry and veterinary staff who will benefit from access to new tools to maintain and improve the health and welfare of animals in their care.

3. Aquaculture producers, processing companies and retailers who can expect marketing and price advantages based on reduced losses and more efficient production of fish with higher health and welfare standards.

4. Supply chain companies who will benefit from opportunities to develop new products and services.

5. The consumer who will benefit from access to food produced using products which have been developed according to established and assured safety and welfare standards.

How will you look to maximise the outputs of this work?

We will advertise our capabilities and expertise within our target market so that a wide range of clients can take advantage of these.
We will encourage our sponsors to publish study findings, including negative findings, where appropriate.
We will offer experimental models to research groups for testing novel products. Knowledge of these models will be shared and may be published.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The fish species and life stages used in this project are representative of the farmed fish species and life stages for which the products are being developed.
The developers of the products and Licensing Authorities responsible for approval of new products require data from these 'target' species for decision-making and formal regulatory assessment.

Typically, what will be done to an animal used in your project?

A test product may be administered to experimental fish, for example by voluntary feeding daily for up to 12 weeks or by immersion or by intra-peritoneal or intra-muscular injection under temporary anaesthesia, at a dose which has previously been shown to be safe.
In studies to determine the efficacy of the product against pathogen challenge, fish may be challenged with a pathogen under controlled conditions. Pathogen challenge may be before or after administration of a test product. Fish will be held in tanks and may be anaesthetised or euthanased and sampled during the study. Samples will typically collected in order to assess infection status, for example to count the number of attached sea lice at a certain time point.
In fish performance studies, fish will be held in tanks and may be anaesthetised or euthanased and sampled in

order to evaluate key performance indicators including growth and feed conversion rate, nutrient retention and physiological function.

What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts are those associated with disturbance and handling of animals for dosing and controlled infection with the pathogen of interest. Short term effects are expected to include increased ventilation rate, skin darkening and inappetence with full recovery within 24 h.
In the case of sea lice challenge and sea lice product efficacy studies, sea lice infestation may cause irritation leading to increased jumping behaviour and inflammation of the skin in approximately 20% of fish which will resolve within a few days. The other 80% of fish are expected to experience no adverse effects.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of fish in sea lice challenge and sea lice product efficacy studies will experience Mild severity.
Approximately 20% of fish in each study are expected to experience Moderate severity.
All animals used in fish performance studies are expected to experience Mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project will test the effectiveness of products administered to the intended target species which will be a species of farmed fish. Due to the complex nature of the interaction between a product and the animal (and pathogen where used) the effectiveness of the products cannot be evaluated adequately using non-animal alternatives.

In studies conducted for regulatory purposes, the use of relevant animal models is a requirement of the regulatory authorities in order to properly assess the product.

Which non-animal alternatives did you consider for use in this project?

Computer simulation models. *In vitro* bioassays.

Why were they not suitable?

These non-animal models are either not available or not well-enough developed to provide the required high level of confidence in the results.
In vitro bioassays will be used for initial product screening.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For each type of study, fish numbers are based on the typical study design requirements (based on regulatory guidelines) and on published data and/or past experience of appropriate sample sizes.
The estimated total number of animals is based on expected demand and capacity for approximately 32 studies using standard study designs.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The study designs use prior data to estimate the likely magnitude of variation in response due to random effects and the level of treatment effect which is practically valuable. The discrimination of the study design (i.e. its ability to distinguish treatment effects from random variation) is maximised by minimising the effects of random variation by the practice of using fish of similar age, source, size range and history, similar experimental tanks and consistent environmental conditions across each study.
When designing new challenge models, guidance on study design will be sought from a biostatistician. Study designs for indivdual experiments will be evaluated by a biostatistician as part of the experimental and ethical review procedure.

Group sizes for voluntary feeding studies are restricted by the requirement for fish to show a uniform feeding response. A minimum group size of 20 fish is used in these studies since this is considered to be the minimum necessary to overcome social hierarchy effects and provide an acceptable feeding response in the majority of individuals in the population.
Smaller numbers of fish may be used where dosing is by immersion, oral gavage, injection or topical administration.
In time series studies, for example to determine the duration of efficacy, where a group of fish may be treated with an experimental product and sub-sets challenged and sampled at intervals, numbers of fish reflect the number of sample points and the number of individuals required for sampling at each point. In studies which are required to generate quantitative data, numbers of fish used at each point are those necessary to provide an accurate and precise measure of the magnitude of response. This is determined separately for each study using sample size calculation methodology but is typically in the order of 10-20 fish per time point.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies may be used to determine the magnitude of effect of treatment and thereby the number of animals/samples necessary in pivotal regulatory studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques

during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The sea lice challenge procedure uses the number of fish necessary to support the required numbers of parasites without over-infestation of fish and without the use of too many fish. Individual animals may be used for a series of challenges when the harm caused by the additional challenge is less than the harm caused by acclimatising, challenging and habituating new fish to attachment of the parasites. The experimental challenge procedure is well established and refined so that settlement rates are predictable.
A sea lice product efficacy test aims to minimise random variation (noise) in sea lice data so that it is possible to detect effects due to the test product, statistically, with use of the minimum number of fish.
A fish performance study aims to evaluate the performance of fish receiving the product under practical conditions of use. High welfare standards are necessary to achieve commercially realistic growth and feed conversion rates and experimental procedures are minimal in order to limit any risk to welfare and reduction in performance.
Products used in these studies will be used at dose rates or inclusion levels which have been shown elsewhere to be within the safe range.

Why can’t you use animals that are less sentient?

The species and life stages used are those for which the products are being developed. Reliable data is important to ensure the safety of farmed fish and the consumer. Less sentient animals have not been shown to provide data which can be reliably extrapolated to the target animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Frequent monitoring for adverse effects using established criteria as described in the relevant protocols. Refinement of the procedure used for identifying, describing and recording clinical signs, for example identification and specific focus on relevant new operational welfare indicators identified in future publications, increased use of video monitoring to avoid disturbing fish and refinement of terminology used to describe clinical signs.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NON-TECHNICAL SUMMARY

51. Embryogenesis, stem cells and cell fate decisions

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how cells choose and maintain specific fates during development of the mammalian embryo and in the adult animal, how this leads to disease when the processes go wrong.
A retrospective assessment of these aims will be due by 22 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

During the development of an animal, cells have to undergo decisions of cell fate, choosing which path to follow. Similar decisions are made throughout life by stem cells and progenitors in many tissues. These decisions rely on intrinsic factors, such as transcription factors, and extrinsic signals, which together establish gene regulatory networks that define specific cell states. These have to be coordinated in time and space to generate functional tissues, organs and the animal, where little in the latter is static: cells are constantly having to be replaced due to normal wear and tear and to cope with changing physiological states, trauma, and disease. The main purpose of the work to be conducted under this Project Licence is to provide fundamental knowledge on cell fate decisions in specific biological systems, notably the gonads, CNS, pituitary, gut, and sensory systems, which is relevant to how these develop, mature, and age normally. However, there are many situations where decisions of cell fate are aberrant or discordant. This can lead to infertility or embryo failure, to congenital disorders, disorders affecting maturation, health span or aging, or to cancer. There can also be aberrant responses to environmental factors. Improved understanding of underlying mechanisms can lead to improved diagnosis and/or novel forms of treatment.

What outputs do you think you will see at the end of this project?

1. Improved understanding of gene regulatory networks in the early gonad will not only inform clinical cases of Disorders of Sex Differentiation (DSDs), but be of broad significance in studies of organ formation.

2. Improved understanding of gene regulation during gonadal development will also inform clinical cases of Disorders of Sex Differentiation (DSDs), as it is become apparent that many are due to regulatory mutations. We also anticipate that this work will provide general insights into both temporal and spatial control of gene activity, especially for genes such as *Sox9* which are active and have critical roles in many tissues.

3. Improved understanding of gonadal sex maintenance and reversal will lead to new insights into cellfate reprogramming and organogenesis, both of which could be of potential importance for regenerative medicine. More directly, this could be of clinical benefit for some cases of DSDs, giving new options for treating patients, such as in cases where ovotestes are present it may be possible to turn the whole gonad into a testis or ovary, or to convert the entire gonad, either to match chromosomal sex or, perhaps, gender identity.

4. Improved understanding of female reproductive function, fertility and premature ovarian failure, could help inform new strategies to manage or maintain fertility in women.

5. Developing methods to obtain gonadogenesis and gametogenesis in vitro, could provide information relevant to DSDs and to causes and potential treatments for infertility. It is very difficult to study the etiology of DSDs given that the phenotypes develop in the embryo in utero, and they are generally recognised at birth or, often, at puberty. The only alternative at present is to make and study an animal model, which, while useful, may not always accurately reflect the human situation. (N.B. Our work deriving Sertoli-like cells in vitro from pluripotent stem cells has already contributed to one study (yet to be published), where patient derived cells were unable to give rise to Sertoli cells, unlike controls, showing that the defect was in primary sex determination). Current efforts to derive sperm or eggs in vitro from pluripotent stem cells reveal that co-culture with somatic cell types from the gonad is essential for primordial germ cell-like cells to progress into later stages of spermatogenesis or oogenesis. Our culture systems, if validated in animal studies, will help these endeavours, which are important both to allow detailed study of human germ cell development and, in the long term, to provide ways to treat infertility or even as a route to correcting deleterious gene variants in subsequent generations.

6. The use of animal models to provide improved understanding of the mechanisms underlying sex bias in human diseases will be of clinical benefit in terms of improved diagnosis and perhaps options for treatments. Our current work on Hirschsprung's Disease provides an example, where two mechanisms that could contribute to the distinct sex bias have been identified. Work on sex differences in the biology of neural stem cells is of potential relevance to understanding and perhaps eventually treatment of a range of CNS disorders that affect one sex more than the other, such as depression.

7. In addition to providing novel fundamental insights, our studies on intrinsic versus extrinsic control of CNS development and disease could be of benefit in providing new options for avoiding or treating diseases that have previously thought to have their origins within the CNS.

8. Our work on the role of SoxB1 and SoxE genes in development, from the early embryo to neural stem cells in the adult, has already led both to new fundamental knowledge and to clinically relevant findings. These range from Sox2 being recognised as a gene essential for pluripotency and hence to the development of iPS cells, to studies on the decline of neural stem cell populations in ageing. We expect our further studies on these genes to continue to give new knowledge.

9. Improved understanding of neural stem cell niches will contribute to basic knowledge, but also potentially to the development of new clinical options for treatments of CNS defects and trauma. Neural stem cells have already been used in attempts to treat a range of diseases as well as conditions such as stroke, but with limited effectiveness. Providing other niche components, whether factors produced by cells or the cells themselves, may be beneficial.

10. Gliomas and glioblastomas have proved to be very hard to treat. Our work on this topic is designed to reveal more about the origins of these aggressive tumours, and the knowledge gained will potentially provide new ideas for treatment options.

11. Our work on the pituitary and hypothalamus, and stem and progenitor cells in both, has already led to new insights. Ultimately, we hope this work will lead to better, more physiological options to treat a range of clinical disorders that involve deficiencies in pituitary hormones and/or in hypothalamic function. These can be congenital or occur after trauma, disease (including cancer), or may be due to current treatment regimes.

12. Pituitary tumours are relatively common, but not well understood. Our work may provide new treatment options, especially as surgery on the organ, which is centrally located below the brain and highly vascularised, is often very challenging. For example, via the use of drugs to disrupt specific cell signalling molecules that our current work suggests are required for tumour growth or that might reduce *Sox2* expression, which is also associated with tumour growth.

13. Our work on the development and function of endocrine organs and sensory systems is mostly to provide fundamental knowledge of the role of specific genes. However, this knowledge will be relevant to diagnosis and management of patients and may eventually provide new treatment options.

We will publish all of our findings in open access journals, with data in a reusable form. Moreover, any genetically altered mice produced as part of this PPL, which should be of benefit to other researchers, will be made freely available, as we have done so in the past.

Who or what will benefit from these outputs, and how?

There are likely to be multiple beneficiaries from the outputs above. These will first include other scientists and clinicians involved in similar studies or who are interested in the systems we are exploring. Benefits to patients may come within a few years, perhaps some within the time frame of this PPL, from improved diagnosis and from better management of disorders or trauma. In the longer term, perhaps in 5 to 15 years, we would expect our work to lead to new treatment options.

How will you look to maximise the outputs of this work?

Alongside the publication of primary research papers in open access journals, we will present our work at meetings, ranging from small focussed workshops to large international conferences. Critically, we will communicate negative results and approaches as well as those that are positive.

We collaborate widely, both internally within the host establishment, and externally with scientists and clinicians based in the UK and in several other countries (including currently France, Spain, Israel, the USA and Canada, and Australia). We share details of approaches and data generated with our collaborators, which allows for improved development of methods and better synthesis of findings.

Where we develop new transformative methods, we will publish the protocols as papers and post them on bioRxiv.

Species and numbers of animals expected to be used

- Mice: 95,700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice for all the projects covered in this PPL. Mice are chosen because of the powerful techniques and knowledge available for this species in terms of genetics, cell biology, embryology, physiology, reproductive biology, and behaviour, but also as they have relevance to the human situation.

Evolutionary comparisons can be very informative. A separate PPL will cover our work with the chick. In addition, our mouse work will include a small number of chimeric animals that will be generated by admixing mouse embryos with cells (such as embryonic stem cells) from another mouse or small mammal, such as the rat. We will use this strategy to replace the elements of, for example, the developing brain and spinal cord so we can observe some aspects of how these systems develop, and how much is determined by the cells of the system and how much by the surrounding tissues. This approach can be used to study aspects of physiology or disease that affect other mammals where it would be difficult to conduct the experiments in these mammals. This could include humans, although this is not part of our current programme of work.

With respect to life stages, our work ranges from preimplantation embryos all the way to ageing adults. This range reflects, in part, the focus of the lab on certain genes, for example *Sox2*, that function in cell fate decisions throughout many or all these stages, but also the importance of understanding the changes that take place during organ development and maturation and altered physiological circumstances, including ageing.

Typically, what will be done to an animal used in your project?

Because we often use genetic approaches, much of our work involves breeding, including GA animals, and harvesting embryos or tissues from postnatal animals after they have been killed (using a schedule 1 procedure or fixation/perfusion) for detailed analysis of phenotypes. We will use hormone injections to control aspects of reproduction, e.g. superovulation when making genetically altered animals. Quite often we make use of substances, such as tamoxifen, to induce a genetic alteration, e.g. a conditional loss- or gain-of-function of a specific gene, as well as to follow cell fates or isolate specific cell types (e.g. by activation of a fluorescent reporter gene).

For a smaller number of animals, we will use some surgical techniques, always employing appropriate anaesthesia and analgesia, and in consultation with the NVS. These include methods associated with the production of genetically altered mice, including chimeras, and studies on reproductive biology, such as embryo transfer, vasectomy, ovariectomy and orchidectomy. Some of these methods are also used for routine maintenance or preservation, as frozen embryos or sperm, of specific genetically altered mouse lines. We also use surgery in a small number of animals to explore the consequences of removing target organs (such as the adrenal gland) of the pituitary on the hypothalamic-pituitary axis.
Our work has shown that this leads to activation and differentiation of stem cells within the pituitary. Occasionally more than one organ will be removed (e.g. adrenals and testes) for the same reason, and to explore if the

effects are additive or affect distinct cell populations. As part of this PPL, due to having derived a new genetically altered mouse line that permits cell fate mapping without the use of tamoxifen (which disturbs reproductive function and the hypothalamic-pituitary axis) we will investigate the effects of changing physiology, such as puberty, pregnancy, lactation, on the pituitary stem cells. This will not necessarily involve surgery, but may involve additional injection of relevant substances including into pregnant mice, where the main object is to study the mothers rather than the embryos.

We will also use substances, such as EdU or BrdU, to look at cell proliferation in tissues after harvesting. These substances are introduced by injection or gavage, into pregnant females or live-born animals, and may be carried out multiple times over a few days, followed by a variable period prior to the animal being killed and the tissues analysed. This can be to follow cell fates over this period, or to examine the consequences of an induced mutation at different life stages, or to carry out specific assays, such as a ‘label-retaining’ assay, often used to identify quiescent stem cells.

Some projects, involving few animals, make use of conditional or inducible genetic systems or drugs to deliberately kill specific cell types. This can be to study the consequences of their loss on the organ system under study, such as the pituitary or stem cell niches in the brain. And a new project will explore the effects of radiation or anti-mitotic chemicals on the hypothalamic-pituitary axis, which is known to be compromised after radiotherapy or chemotherapy. Most of these experiments are short term, lasting days to a few weeks, before the consequences are analysed. Alternatively, these methods may be for studies using blastocyst complementation, when specific cells, such as neurectoderm progenitors, are deleted in the developing host embryo, but replaced by cells differentiating from pluripotent stem cells introduced at blastocyst stages. In this case, the effects are assessed in a stepwise manner, looking at embryos less than two thirds through gestation, then at embryos shortly before term, before allowing any chimeras to be born. If these are viable, the animals will be kept longer for subsequent phenotype analysis, but with careful monitoring.

For some projects, but again involving small numbers of mice, we need to introduce substances and/or cells into the brain, which will also involve surgical procedures, including implantation of canulae and osmotic minipumps, injection needles, and, electrophysiology. Substances and/or cells may also be introduced into the developing brains of embryos in utero, which also requires procedures to be performed on the pregnant female. Imaging methods, such as ultrasound, may be used to guide positioning of needles. For monitoring changes in physiology or hormone levels, we may implant a cannula into a blood vessel to sample blood.

A small number of control and genetically altered mice, some after surgery, may be subject to (mild) learning and memory or other behavioural tests.

Some projects are also concerned with cancer and/or ageing. In the majority of cases, those mice expected to develop tumours will do so as a result of a particular breeding protocol involving certain genetically altered strains, such as with null or conditional mutations in *p27*. In other situations, the tumours will develop through injection of cells that are known to lead to tumours, either from an original tumour, such as a gliobastoma, or from pluripotent stem cells that can give rise to teratomas or teratocarcinomas. In all these cases we monitor tumour development, using imaging methods where possible, as detailed in the relevant protocol. Extensive

post-mortem tissue analysis will be performed to maximise the information obtained from each animal. For certain types of tumours, such as those developing in the pituitary due to mutations in *p27*, these generally only become apparent in older animals. The effects of ageing on stem and progenitor cells in the CNS and pituitary, and on gonadal sex reversal, also require some animals to be kept for more than a year.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of our experiments, wild type and genetically altered liveborn mice should experience no more than mild effects. For strains that carry harmful mutations, the lines are maintained as heterozygotes, which themselves tend to have mild or no apparent phenotypes. However, animals may be crossed to generate homozygotes or compound mutations, where stronger phenotypes occur, including embryonic or postnatal lethality, or reduced lifespan. It will be necessary to study embryonic stages and to keep some animals with harmful mutations until the phenotypes develop, in order to study how they arise. We will kill animals before end points for the relevant severity band are reached.

The types of phenotype range, according to the specific gene being altered and the type of alteration, from complete or partial sex reversal and/or infertility, craniofacial defects, loss of hearing or vision, CNS defects, abnormal behaviour and/or defects in learning and memory, epilepsy (although this can be managed by careful handling), hypopituitarism, tumours, to shortened healthspan or lifespan. With mutations affecting some genes, there may be phenotypes outside the tissues we study, which can lead to lethality. An example would be kidney defects in addition to sex reversal with mutations in *Wt1* or in addition to enteric nervous system defects with mutations in *Ret*. In these cases, the animals are killed prior to the kidney defects becoming deleterious shortly after birth. In other cases, we are interested in the origins of a deleterious phenotype, such as the failure of the enteric nervous system to colonise the distal gut in mouse models of Hirschsprung's disease, and not the problems this leads to. We therefore kill any newborn animals with the relevant genotype before symptoms of the disease, such as 'megacolon', become evident.

The frequency, type and severity of any adverse event depends on the procedures being used, together sometimes with genetic status, including the genetic background of the strain. We endeavour to minimise the chances of these occurring, but the cause is sometimes unknown, such as the occasional death after administering tamoxifen. Depending on its severity, the duration of an impact or adverse effect may range from a small number of days to a small number of weeks, or even for much longer if fertility or behaviour are affected, with the animal being killed prior to it reaching the relevant end points as defined in the protocols.

For animals undergoing surgical procedures, most should only experience transient discomfort with pain being managed by anaesthesia and analgesia. They would be expected to recover fully within a few days. For some, the outcome may be more severe, notably after adrenalectomies there can be significant weight loss associated with 'salt wasting'. This can be managed by adding salt to their drinking water, but this fails to rescue the mice after 4-8 weeks. We therefore kill all such mice at a maximum of 3 weeks post adrenalectomy. If combined with tamoxifen treatment, animals that have been subject to adrenalectomy have a significantly increased risk of death about three days afterwards, which can be up to 50% (with no clear reason). For this reason, animals treated under this combined protocol (No. 11), which is used for a small number of animals, are maintained for no more than 7 days, and the protocol is classified as severe.

With aged animals, the chance of an adverse event, including unexplained death, is also increased. Such animals are therefore also maintained under a severe protocol (No. 9), although the majority do not exhibit severe effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities for the mouse experiments are:
Mild; about 75% of the animals.
Moderate; about 23% of the animals.
Severe; less than 2% of the animals

What will happen to animals at the end of this project?

- Used in other projects

A retrospective assessment of these predicted harms will be due by 22 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our work is very much embedded in mouse genetics, and this requires breeding animals. Furthermore, most, if not all cell fate decisions in the embryo and adult animal take place within a complex environment, where events intrinsic to the cells are influenced by a variety of extrinsic signals, whether these are from neighbouring cells, involve molecules, such as growth factors, cytokines and hormones (which can act over considerable distances), are commensal with the animal, such as gut microbiota, or are part of the environment, i.e. are external to the organism. Moreover, most tissues develop in a complex way in three dimensions over time in a carefully orchestrated manner. Therefore, although some aspects of certain cell fate decisions can be studied *in vitro*, and we both use and develop such approaches, it is generally essential to study them *in vivo* (as a minimum to judge the suitability of *in vitro* systems to give meaningful information). This is best illustrated with a few examples relating to our work:

(i). Several distinct cell lineages give rise to the developing gonads and their continued interactions are required for appropriate gene activity leading to the development of either testes or ovaries. For example, in the mouse, the supporting cells arise from the coelomic epithelium overlying the genital ridge, the steroidogenic cells arise from mesonephric mesenchyme at early stages, and the germ cells are specified amongst extraembryonic mesoderm in the base of the allantois during gastrulation and then migrate back into the embryo and eventually to the gonad. Some connective tissue cells arise from unspecified mesenchyme in the early gonad, whereas endothelial cells that are critical to establish an arterial blood flow in the testis migrate from the mesonephros after Sry activity has triggered Sertoli cell differentiation. Early Sertoli cells also influence germ cells to enter mitotic arrest, and actively prevent them from early entry into meiosis, which is typical of the ovary. It is currently not possible to mimic all of these cell-cell interactions using cells maintained *in vitro*. We can culture the intact early gonad for periods of two to three days, which does allow us to follow some events in real time (and reduce animal numbers), but this still requires breeding to produce the animals.
(ii). To study postnatal gonadal sex reversal, such as when *Foxl2* is conditionally deleted, cannot meaningfully be studied in any in current *in vitro* system. While it is possible to culture isolated granulosa cells for a limited time, they tend to lose expression of critical genes and their normal phenotype. The same is true of Sertoli cells. Without a robust and reliable culture system that could maintain both of these cellular phenotypes, it would be impossible to address the consequences of deleting *Foxl2* in meaningful way. Moreover, it would not be possible to investigate how other testicular cell types differentiate, nor the morphological changes that accompany the changes from ovary to testicular-like structures.
(iii). The pituitary develops through a complex series of reciprocal inductive events between the oral ectoderm and the overlying ventral diencephalon. Some progress appeared to have been made several year ago to mimic aspects of this *in vitro*, beginning with ES or iPS cells; however, the structures reported failed to reflect the cellular organisation of the pituitary, or appropriate production of hormones. Moreover, these experiments have proved difficult to replicate. We can also grow stem cells from the pituitary for a limited time *in vitro* and, by changing conditions they can differentiate into each of the hormone producing cell types typical of the anterior lobe and we use this *in vitro* model to ask some questions about factors influencing stem cell self-renewal and differentiation. However, it has not been possible to reintroduce these to the pituitary *in vivo* to test if they retain relevant functional properties. Nor are these ‘pituispheres’ likely to have sufficient complexity to model the real organ or to be useful to address issues of the interactions of the pituitary with the hypothalamus and its target organs, which requires whole animal studies.
Over the last few years we have determined that the pituitary stem cells respond to changing physiological conditions. For example, the stem cell population is mobilised by estrogen treatment of males or by gonadectomy or adrenalectomy, but it is not known how a systemic signal affects the stem cells, whether this is via other cell types in the pituitary, or the hypothalamus, etc. We have also recently discovered that the stem cell population is itself complex. To answer these questions requires *in vivo* experiments. Moreover, as we move to explore how the stem cells respond to normal life events such as puberty, pregnancy, lactation, etc, these again have to be carried out *in vivo*.
(iv). To explore the role of specific *Sox* genes in CNS development and their association with the origin of specific tumour types or with ageing, similarly cannot be adequately replicated *in vitro*. For example, there is no *in vitro* model of hippocampus development. Addressing the consequences of abnormal CNS development on behaviour or learning and memory also requires *in vivo* experiments.
(v). There is now increasing evidence that many aspects of anatomy, physiology, behaviour, pathologies, and responses to treatment, differ between the sexes; and even when these appear similar, the underlying mechanisms may be different. These differences are likely to be due to direct effects of X and Y linked genes, to sex hormones made by ovaries or testes, or both. Moreover, these effects can be organisational (i.e. they are established during development, perhaps prior to any obvious difference), or activational (require constant input). Experiments to understand the mechanisms involved, the importance of which have been widely recognised in recent years, cannot be conducted *in vitro*.

Which non-animal alternatives did you consider for use in this project?

We complement our *in vivo* analyses with tissue culture models and organoids. These include the pituispheres mentioned above, as well as neurospheres and NS (neural stem) cell cultures for the CNS. We also make use of cell types obtained from mouse or human pluripotent stem cells (ES or iPS cells) via processes of directed differentiation *in vitro*. These can give rise to cell types typical of the CNS and, from our work, to the early gonad. We have also, with collaborators, attempted to use tissue engineering to construct 3-D models of neural stem cell niches, and plan to use similar methods to assemble gonad-like structures.

Why were they not suitable?

We can gain a certain amount of information from these *in vitro* systems, but there are serious limitations. It is not currently possible to replicate the complexity of mammalian tissue structures in culture models. In addition, while some molecular assays (e.g. RNAseq), suggest that the various cell types we have derived from pluripotent stem cells are similar to the endogenous cell types we wish to study, they are not identical. Moreover, the proof that we can derive and propagate relevant cell types, will depend on their ability to function when reintroduced into the relevant organ *in vivo*, which can be challenging and still requires animals. Finally, such cell or organoid cultures cannot permit research on aspects of biology such as reproduction, brain function, or physiology.

A retrospective assessment of replacement will be due by 22 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based on several factors. It is based on our past experience, particularly over the past 5 years. We have also taken into account the number of researchers within the group who perform mouse experiments (currently 10, and it is likely to remain around this number over the next five years, with MSc students usually boosting this (currently two) for 3 to 6 months during each spring/early summer). We also continually re-evaluate the numbers of mice required for each experiment using power calculations. For this we access help from an in-house statistician when necessary. This will allow us to determine the number of animals required per experiment to give statistically valid results. Numbers of mice used for breeding are based on best practice, experience with each strain or combination of strains, and factoring in the likely proportion of the desired genotypes, including controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing specific experiments within the overall project we estimate the minimum number of animals required to give robust answers. Most often this can be based on our prior experience or on published data. Often it is not necessary to use statistics (e.g. three transgenic lines giving the same pattern of expression

shows that this is correct), however, we perform statistical analysis whenever necessary. Where experiments involve physiological manipulation, or result in phenotypic and/or physiological consequences, for which we have little or no prior information, usually around 5 or 6 animals per treatment group (which will include sex as a variable when relevant and possible) are sufficient to obtain robust results. The design of quantitative experiments generally follows the ARRIVE guidelines and sample sizes may be set using power analysis. Any exceptions are where there is a degree of variability beyond our control (for example, where minor fluctuations in conditions together with threshold effects require more animals to be examined in order to have statistically significant results). We generally use a significance level of 5% and a power of 80%, estimating standard deviation from pilot experiments. We include advice taken from local statisticians as well as make use of online tools, such as the NC3Rs' Experimental Design Assistant.
For some important questions that we wish to address there can be a choice between using a mild procedure but many animals because the measurable effect is weak, or a moderately severe procedure with few animals because the effect is robust. Our choice will depend on the specific question and available resources, but it will most often be to use fewer animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We try to keep as few mice as possible by careful monitoring our mouse colony and good practice. Whenever possible and when there are no harmful phenotypes (or infertility) we maintain genetically altered mouse lines as homozygotes to reduce the numbers of animals required and to reduce the need to genotype. These may be crossed to another genetically altered strain or to wild type mice prior to beginning an experiment followed by intercrossing the heterozygote offspring when wild type and/or heterozygous animals are required as controls for the homozygotes. We also make use of fluorescence reporters that can also (in some circumstances) avoid the need for biopsies, especially for genotyping. To minimise breeding, lines under sporadic use are maintained at lower levels. We also use cryopreservation, such as of embryos and sperm, whenever a strain of mice is not in current use, to preserve unique alleles or allele combinations, and also to permit efficient export or rederivation of animals.

Whenever possible, we prescreen substances (including molecules to induce gene expression, cell death, mutagens, etc) and agents such as viruses *in vitro* to determine approximate doses required *in vivo*. When possible, we also test genome editing components *in vitro* (e.g. with ES cells), prior to the generation of genetically altered animals.
To maximise information gained from single animals, we use *in vivo* imaging when feasible, obtain data on as many tests of behaviour and learning and memory as possible on single animals, and obtain relevant tissue samples from multiple sites after killing. Where more than one project involves the study of an animal with a particular genotype, for example *Sox9* is relevant to studies on the CNS, pituitary and gonads, we often collect multiple tissues from single animals. Similarly, when designing new genetic tools, and maintaining animals derived with these, we will, wherever possible, do so in a way to allow them to be shared amongst as many people as possible, including making use of the host establishment sharing platform. This efficient use of animals minimizes the number used.

A retrospective assessment of reduction will be due by 22 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn

from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We choose well-established protocols, known to have minimal harmful effects, whenever possible.
Although it is not always possible to predict the nature or severity of any defect that arises from a newlygenerated genetic alteration, we take steps to minimise unwanted phenotypes and/or the number of animals exhibiting these. For example, we make use of tissue-specific regulatory elements and whenever practical, we prefer to make genetic alterations that are inducible, so that the animals do not show a phenotype until expression of the candidate gene or a deletion is induced. Animals exhibiting unexpected or detrimental phenotypes will be killed by a Schedule 1 method, or in the case of new lines or individual animals with phenotypes that may be of particular scientific interest advice will be sought from the Home Office Inspector.

When the experiment is predicted to lead to harmful effects outside the body system under study, we will provide treatments designed to alleviate these – for example, high salt will be given after adrenalectomy, and calcium lactate will be after removal of thyroid and parathyroid organs, or if tumour formation is not a desired outcome, then it may be possible to give anticancer agents (or growth inhibitors). By introducing substances, including viruses and cells, into specific tissues or cavities (such as the lateral ventricles of the brain) we minimise suffering because other body systems are not affected.
To minimise stress during breeding and maintenance we follow best practice guidelines, institute refinements and, for some strains, our own specific procedures of husbandry. These include cage enrichment, sufficient nesting material, and, for particularly sensitive strains and animals subject to specific procedures, minimum disturbance. In the case of any new strain of animal or application of any new procedure or refinement we pay special attention by increased observation and monitoring until we have become familiar with the phenotype and/or the consequences. If welfare implications are identified they will be acted upon and refinements considered in consultation with the NVS, NACWO and animal technicians.

Why can’t you use animals that are less sentient?

A significant fraction of our research involves studies on mouse embryos prior to two-thirds through gestation. We also make of chick embryos (covered under a separate PPL), for some projects. This is partly for evolutionary comparisons, and in some respects the chick and human may be closer than the mouse is to human (in morphology of the foetal ovary or as a model for the craniofacial abnormalities associated with mutations in *Foxl2*), and partly because certain embryological techniques are feasible *in ovo*, but not in utero. However, in most cases the mouse is a better model for the human situation, and the wide range of methods and tools that have been developed for the mouse makes this a more tractable model to study. In addition, many of the systems we study including sex determination, reproductive biology, the pituitary, and the CNS have aspects that are specific to mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all manipulations, we will adhere to the relevant guidelines that aim to minimize suffering. We examine the animals for signs of pain and discomfort (such as grimacing), providing additional analgesia if appropriate, and monitor body condition, killing the animals if the distress is likely to be more than temporary. Many of the genetic and physiological manipulations, as well as the administration of substances, including gene inducers and repressors, viruses, cells and grafting of tissues, are standard and previous refinements from the literature will be used and added to if possible. For novel types of manipulation, or where insufficient information is available, small-scale pilot experiments are conducted in order to determine the best conditions to obtain a sufficiently robust and meaningful response from the minimum dose, exposure time or treatment. These pilot experiments help to minimize any potential suffering.
In all surgery, analgesia will be provided according to best current practice and with advice from the NVS/NACWO. Appropriate aseptic surgical techniques, heat, and fluid therapy, will be applied as necessary. For studies involving tumours, we will check the animals every day and kill any that exhibit signs of significant illness. Where possible, we will also use imaging methods to monitor the growth of tumours.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

These will include publications from the NC3Rs and the Institute for Animal Technology, but also relevant articles in scientific journals. In the case of cancer models, we will follow the guidelines in Workman et al, British Journal of Cancer (2010), 102, 1555-1577 (PMID: 20502460); or any subsequent updates as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay up to date via regularly communication with animal facility staff at the host establishment, other scientists in our fields, via e-mail and other updates and publications from, and occasional attendance at meetings held by, the NC3Rs, the Institute for Animal Technology, and the International Society for Transgenic Technology, and through regular visits to their websites: https://www.nc3rs.org.uk/3rs-resources https://www.transtechsociety.org/ https://www.iat.org.uk/

A retrospective assessment of refinement will be due by 22 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

52. Energetics and homoarginine in heart & metabolic diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Heart failure, Ischaemia, Diabetes, Metabolism, Therapy

Animal types Life stages

Mice	adult, neonate, juvenile, pregnant, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to further our understanding of energetic pathways and the interplay between creatine and homoarginine in the heart and other metabolic tissues. This includes generating proof-of-principle evidence in rodent models in support of new therapeutic approaches for ischaemia and chronic heart failure.
A retrospective assessment of these aims will be due by 26 February 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the UK alone there are ~100,000 heart attacks per year and 800,000 individuals living with heart failure. Even with optimal treatment, 59% of men and 45% of women diagnosed with heart failure will be dead within 5 years, a clear indication that new and better treatments are urgently needed.

What outputs do you think you will see at the end of this project?

The major output of this programme of work will be the generation of new information that will advance scientific knowledge, in particular, how creatine and homoarginine interact and affect whole body metabolism, ischaemic disease, diabetic cardiomyopathy, and chronic heart failure (Objective 1). We will also provide proof-of-principle evidence for therapeutic potential using appropriate disease models, with the aim of moving closer towards clinical translation to humans (Objective 2).
The outputs will be evidenced by publication in international peer-reviewed scientific journals and by presentation at scientific conferences. Other outputs may include the characterisation of drug-like molecules that we would consider patenting and could be used by others as a starting point for the development of new medicines.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries will be the scientific community, who within the time-frame of this PPL, will gain new information that can be used to guide future work and will lead to the gradual accumulation of scientific knowledge in this area. This knowledge is also likely to be useful to the medical community and pharmaceutical industry since our research aims to answer key scientific unknowns that will bring us closer towards clinical translation to humans. By way of example: -
Our finding that homoarginine preserves contractile reserve in mice with heart failure already has potential for direct translation to benefit patients, particularly since hArg is cheap, can be taken orally and is safe in humans. Within the next few years we will seek funding for a clinical trial in heart failure patients. However, the work in this PPL will remove barriers to translation by addressing unknowns such as optimal dosing and a detailed understanding of mechanism in the heart and other organs, thereby paving the way for these trials. In the long-term (7-10 years), as an add-on to standard therapy, homoarginine has the potential to improve the quality of life for patients with chronic heart failure.

We have identified augmentation of creatine kinase activity or myocardial creatine levels via activation of the creatine transporter as a potentially beneficial strategy in diseases of ischaemic origin. The largest obstacle to translation is a lack of pharmacological tools to test this strategy in other disease models and as lead compounds for drug development, hence we are currently collaborating with the pharmaceutical industry to remedy this. By testing new compounds, or equivalent genetic modifications, in relevant disease models we will provide proof-of-principle evidence for future translational studies. By including co-morbid models of diabetes, we will ensure these benefits are also realised in the diabetic heart. In the longer term (10 years), this will move us towards the realisation of clinical benefit, e.g. for cardiac protection during heart surgery, treatment of angina and peripheral vascular disease, and diabetic cardiomyopathy.

How will you look to maximise the outputs of this work?

We aim to disseminate our findings as widely as possible to the scientific and medical communities via publication and presentation at conferences. Outputs are maximised by ensuring our research is conducted and reported with openness and rigour, with the aim of creating a legacy of trusted and reproducible new knowledge. This includes the publication of unsuccessful approaches, so that others can learn and concentrate resources on what works best without unnecessary duplication. We will actively engage in informed debate by authoring review articles, by giving seminars, and by public engagement.
We will seek opportunities to collaborate with other scientists and medical professionals in order to identify areas of synergy that will further our objectives, expand our findings into new therapeutic areas, or open new areas for investigation. For example, collaboration with colleagues that are expert in the design of clinical trials or drug development will be necessary to realise the long-term benefits of this project.

Species and numbers of animals expected to be used

- Mice: 16400
- Rats: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice will be used for the vast majority of this project because this species provides a unique combination of easy genetic manipulation with a cardiovascular system and disease models sufficiently similar to humans. Occasionally we will use rats, for example, because it is possible to induce coronary vasospasm under terminal anaesthesia as a refined model of angina in this species, or where a larger heart is required to make scientific measurements. We may also use rats to demonstrate that a new drug works the same way in different species, which would be necessary to justify more complex experiments in larger species such as pigs.

Typically, what will be done to an animal used in your project?

We will use surgical models that mimic the major causes of human heart failure since these are the most translational and therefore considered the gold standard in our field. A typical experiment might compare whether mice with a specific genetic alteration in the heart are better than control mice at responding to a heart attack. To do this, we perform surgery under general anaesthesia to stop blood flow in a coronary artery, thereby inducing a heart attack. The animal is given painkillers during recovery and we follow how the heart responds over the course of 6-8 weeks. This involves similar techniques to those found in a cardiology clinic, for example,

ultrasound or MRI imaging on one or two occasions to measure heart function and structure, and placing a catheter in the heart to directly measure pressure generation. All of these are performed under general anaesthesia and to control cumulative suffering the maximum number of anaesthetics in a lifetime is limited to 8. At the end of the experiment the mice are killed humanely and the heart removed to study the molecular and cellular changes.
Other variations of this experiment may use mice or rats that are being treated with a novel drug that we hope will be beneficial in heart failure. In this case we will give the drug by the oral route whenever possible, but if not, this may require daily injections. We will perform similar experiments using other models of heart failure, e.g. due to narrowing of the aorta or secondary to diabetes.
Mice will be made diabetic by one of the following methods: daily injections for 5 days with a compound that disrupts insulin secretion; feeding a Western-style diet to make them obese; or they will harbour genetic mutations that lead to diabetes. Experiments will last several months to allow for development of diabetes and cardiac complications during which time they will have urine and blood samples taken regularly to monitor glucose levels. At the end of the experiment we will measure heart function by ultrasound and cannulation for pressure measurements. Some of these animals will be given a heart attack under general anaesthesia as a final step, after which they will be killed humanely.
Approaches that are beneficial in the heart will also be tried in a model of skeletal muscle ischaemia, where blood flow to one of the legs is restricted to mimic peripheral vascular disease in humans. This involves surgery to occlude one of the main arteries supplying a hind-limb (the other limb acts as a normal control). An experiment may last up to 3 weeks post-surgery during which mice may receive test compounds and housed singly with access to a voluntary running wheel to measure exercise capacity. They will be anaesthetised on 1 or 2 occasions to non-invasively measure blood flow in both legs before being killed humanely to collect tissues for further analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

We will use surgical models of heart failure and many of the adverse effects are related to recovery from the surgical procedures used to create the disease models, e.g. pain, weight loss, poor body condition. However, these can mostly be controlled via good practice, for example, surgery takes place using aseptic technique within a clean air environment, animals are closely monitored during recovery and provided with pain killers, fluids, heat support and access to softened food. Most recover well within a couple of days and will remain free of adverse effects for the duration of the protocol. However, over subsequent weeks, approximately 10% may develop shortness of breath or laboured breathing, which is indicative of congestive heart failure. We monitor mice frequently to identify these symptoms and humanely kill affected animals at the earliest opportunity. Nevertheless, some animals will die of heart failure since these symptoms can develop rapidly.
In some models of diabetes the mice will lose weight, while in others the diabetes is secondary to obesity. In both cases, the mice may show poor body condition, will feel thirsty, and urinate more. Absorbent bedding, extra water and cage changes are utilised to prevent the potential for developing skin sores.
Although mice will develop measurable heart disease, this will not be severe enough to cause clinical symptoms.
The model of peripheral vascular disease utilises the same good surgical practice outlined above. Mice are given painkillers during recovery and will typically limp for a few days while their leg adapts. They will always have one good leg and are therefore still mobile and able to feed for themselves. Strength will progressively return to the affected limb over the course of the experiment. Use of a running wheel necessitates single housing, which may be stressful to the mouse, however it is partly mitigated since mice enjoy running on a wheel.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice will not experience adverse effects because they will be used for breeding purposes in order to establish and maintain animals with specific genetic alterations. Approximately 15% of these lines may have a harmful phenotype of moderate severity, e.g. they will be underweight with muscle weakness or obese with early signs of diabetes. Animals that have surgery but otherwise recover well are also considered moderate severity, since the adverse effects are well controlled and of short duration. However, the <10% of animals that develop congestive heart failure might have a severe experience, since they may have difficulty breathing for several hours before being found dead or euthanased. There is also potential for cumulative suffering leading to a severe severity, e.g. where the same animal receives multiple procedures as part of a single protocol. To mitigate against this, animals are allowed to fully recover before the next step in a protocol and we have limits on the total number of general anaesthetics administered in a lifetime.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 26 February 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying complex diseases such as chronic heart failure, which is a progressive disease that develops over many weeks. This represents a level of complexity that can only be fully represented by the intact animal since there is dynamic interplay between mechanical stress, haemodynamic loading, and the nervous, vascular, endocrine and inflammatory systems.

Which non-animal alternatives did you consider for use in this project?

We use non-animal alternatives whenever possible and consider these as complementary to the animal work, i.e. they may reduce the number of animals required, but do not completely replace the need for subsequent animal work. For example, we are running an *in vitro* screen to discover new drugs using a cell culture assay, however, any positive hits from this will ultimately need to be tested *in vivo*. We routinely perform many *in vitro* experiments using cell culture, since these are particularly useful in determining the consequences of altering gene expression at a molecular and cellular level.
We have an active collaboration with clinical colleagues to study energy metabolism in human heart disease. This includes access to small amounts of human myocardial samples and we also have access to a biobank of human adipose tissue that will allow us to validate our findings and show that they are relevant to human disease.

Why were they not suitable?

Human tissue is a valuable and useful resource, but the quantities obtained are very small, the samples exhibit a lot of variability, and it represents a snap-shot of disease. Taken together this greatly limits the types of experiment it can be used for.

We have previously used computer modelling for certain aspects of our research. However, when we tried modelling the effect of altered creatine levels on heart metabolism, we found that the computer model could not predict the widespread and varied metabolic response we have observed in animal experiments.
Homoarginine is our other metabolite of interest, but it has not yet been incorporated into any computer models, since it is unknown what proteins and pathways it interacts with. This project aims to address this gap in our scientific knowledge.
A retrospective assessment of replacement will be due by 26 February 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Breeding will make use of the majority of animals in this project and we have based our numbers on usage over the previous 5 years, since we anticipate the overall workload to be similar. We also know from experience that a fully controlled study in our heart failure models requires ~100 mice and will take ~1 year to complete, so 500 mice over a 5 year period is the maximum we anticipate using. In practice, the protocols we use will be guided by our scientific findings, so it is highly unlikely that we will use the maximum numbers across all protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We routinely use power calculations to guide our experimental design. This is a statistical technique that provides an estimate of how many animals are required in each experimental group based on the anticipated effect size and the variability observed in previous experiments.
We plan to make good use of non-invasive imaging techniques, such as ultrasound and MRI, which allow repeated measurements to be made in the same mouse at multiple time-points. This significantly reduces the number of mice required for longitudinal studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

By careful advance planning, we aim to closely match our experimental requirements with breeding output, and thereby avoid wastage. Our institution has a dedicated mouse colony expert who provides advice on efficient breeding. We freeze embryos or sperm from mouse lines that are not in routine use, since this avoids the need to breed mice simply to maintain a live colony. Wherever possible we will share spare tissue with other groups that can use it. For example, we do not study the brain, but our collaborators in Germany do, so we freeze organs from our experiments that may be of use to others.
We make use of pilot studies when working with new drugs or a new mouse line. Initial study in a small number of animals provides information on adverse effects and the natural progression in our disease models. We can then adjust the monitoring, experimental and humane end-points accordingly.
A retrospective assessment of reduction will be due by 26 February 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mostly mice for this project because of the ease of genetic manipulation and the similarity of the cardiovascular system to humans. We will use surgical models of heart failure, because these recapitulate the complexity of human disease and the discomfort associated with surgery can be mitigated (as detailed below). Alternatives include infusing drugs to cause heart failure, but the overstimulation of a single pathway does not reflect any common cause in patients, and mice are still at risk of developing congestive heart failure, which is the single biggest welfare concern. We therefore believe that the heart failure models used in this project are the most clinically relevant that also cause the least suffering to the animals.
We will use mouse models of diabetes in order to study diabetic cardiomyopathy and the early response to heart attack. These include injection of streptozotocin or high-fat diet or genetic models of obesity to reflect different types of diabetes. We need these models to develop heart dysfunction when measured by ultrasound, but they are less likely to develop clinical symptoms of shortness of breath compared to the surgical models of congestive heart failure. The major clinical symptoms are therefore related to changes in body weight and elevated blood glucose
We will generate a model of peripheral artery disease (hind limb ischaemia) by surgically tying-off an artery in one leg. The other leg is left unaffected, so although mobility is impaired in the first few days, animals will always be able to move around the cage and feed normally. The alternative model removes the entire artery and surrounding vessels and is associated with a high level of foot necrosis (up to 25% compared).
We will use a range of non-invasive methods to measure the effect on the heart and other organs, e.g. electrocardiogram, ultrasound, MRI, laser Doppler, relaxometry (body composition), blood sampling, and voluntary wheel running. These are all particularly benign and produce a wealth of scientific data without causing distress or lasting harm to the animals.

Why can’t you use animals that are less sentient?

We are studying how the heart responds over time to injury and the complex interplay of haemodynamic forces, energy requirements and regulatory systems. The human heart, in common with other mammals, has four chambers and generates normal pressures of 100-120 mmHg. Fish can be used to study acute heart injury and healing, but they only have two chambers and generate 2-3 mmHg in pressure, while frogs have a 3-chamber heart and generate 30 mmHg. Mice are therefore the least sentient species that have a cardiovascular system and response to disease that is sufficiently similar to humans. We need to use adults, because most heart disease affects adults.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When genetically-altered mice exhibit a harmful phenotype it is usually possible to conclude our experiments at an earlier time-point in order to minimise potential suffering or distress.

We will use disease models that have direct correlates to the major causes of human heart failure, e.g. ischaemic (following a heart attack), pressure overload (aortic stenosis), and diabetic cardiomyopathy. The first two of these are surgical models with the potential to cause pain and suffering during recovery, however, this will be mitigated by using aseptic technique and giving pain killers, fluids, softened food, and heat support during the recovery period. The majority of mice make a full recovery within days and will not experience further adverse effects. In the ischaemic model there is a risk of sudden death due to scar tissue rupturing, but this affects mostly males, so we typically use females for these experiments. Around 10% of mice will develop shortness of breath or laboured breathing during the following 6 weeks, which is indicative of congestive heart failure. Suffering is minimised by increased monitoring and using this as an immediate humane end-point.
For diabetic mice, we will regularly monitor blood glucose levels and humanely kill animals if they become dangerously high. We expect the mice to be thirsty and urinate more, so we will make use of absorbent bedding and keep fewer mice in each cage.
For mice with hind limb ischaemia, the same controls as above will mitigate against pain and discomfort caused by the surgery, and after a brief spell of reduced mobility, mice usually recover well.
Regular monitoring will identify animals that do not recover mobility or that develop early signs (e.g. skin discolouration or nail injury) and these will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office guidance on the “Code of practice for the housing and care of animals bred, supplied or used for scientific purposes”. Guidance for aseptic surgery will be taken from “Guiding Principles for Preparing for and Undertaking Aseptic Surgery” (LASA 2017). At the experimental planning stage we will refer to the PREPARE guidelines checklist (“Planning Research and Experimental Procedures on Animals: Recommendations for Excellence”) and to ensure our experiments are reported effectively we will adhere to the ARRIVE guidelines (“Animal Research: Reporting of *In Vivo* Experiments”).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

At the start of each experiment we will check 3Rs websites such as NC3Rs (https://www.nc3rs.org.uk/3rs-resources) and Norecopa (https://norecopa.no/3r-guide). We also receive regular newsletters from these and other organisations, our department holds animal welfare meetings three times a year where progress on the 3Rs is discussed, and there is a regular institution-wide newsletter on the 3Rs.
To keep abreast of new applications we actively scan the scientific literature for alternatives and talk to other researchers that are performing similar techniques to establish best practice. Hands-on advice from the vet is always available in implementing advances effectively.
A retrospective assessment of refinement will be due by 26 February 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

53. Environmental influences on immunity and tissue biology

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

mucosal immune system, intestinal stem cells, environmental signals, cancer, infection

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To study how environmental triggers transmitted via the aryl hydrocarbon receptor affect immunity and tissue biology

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

While it is known that genetic traits contribute substantially to how the immune system works to protect against pathogens and tissue damage, it is equally clear that environmental factors strongly impact such responses. Our studies have identified a protein which acts as an environmental sensor, the aryl hydrocarbon receptor (AHR). AHR functions as a molecular entry point for environmental factors that can be man-made pollutants (xenobiotics) or can be derived from the diet or the microbiota. Stimulation of AHR with dietary ligands helps to maintain the integrity of the intestinal barrier, through effects on different immune cell types as well as tissue cells such as epithelial and endothelial cells (which are the cells lining the gut or the vessels). We are working on the underlying mechanisms to understand why dietary AHR ligands are beneficial whereas pollutants have detrimental effects on health.

What outputs do you think you will see at the end of this project?

At the end of the project we anticipate to have a greater understanding of how environmental factors transmitted via the AHR influence the immune system and tissues in steady state as well as after challenges such as infections, tissue damage or the growth of tumours. We will disseminate our results in conferences and publications as well as in public engagement events.

Who or what will benefit from these outputs, and how?

Since many of the natural AHR ligands are derived from the diet, it is possible that dietary supplementation can be used for preventative purposes or for alleviation of inflammatory reactions particularly in the gut. In the long term this might be applicable to humans with intestinal disorders or the genetic predisposition to develop such disorders.

How will you look to maximise the outputs of this work?

We are collaborating with toxicologists who focus on the detrimental effects of pollutant AHR ligands to understand the underlying reasons for the different outcomes following exposures to these compared with dietary AHR ligands. We also have collaborations with groups that work on infection of the lung as AHR seems to play a role in tissue repair following infection. We have written several comprehensive reviews on the role of AHR in the intestine and other tissues and I am frequently asked to give seminars or conference presentations on our research.

Species and numbers of animals expected to be used

- Mice: 30000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice genetically modified to have deficiencies in the AHR pathway in different cell types using gene editing methods in order to evaluate where AHR is needed to protect against infection, inflammation and tumorigenesis. In most of our mice AHR is deleted or altered genetically so that the mice express these altered genes from birth. However, we also will use methods to be able to induce deletion or alteration at certain life stages. This is particularly important for assessment of AHR in cells lining vessels (endothelial cells) as the existing literature suggests that AHR is influencing vessel development very early in life. For this reason, we will need to use some neonates and juvenile mice to evaluate the consequences of AHR deletion early in their life, compared with deletion in adult stage. We anticipate that AHR roles early in life may be recapitulated in adult mice upon injury which requires restoration of vessels.

Typically, what will be done to an animal used in your project?

In a typical scenario animals might be subjected to administration of substances to induce gene deletion and/or activate or inhibit AHR. They might then be infected with a pathogen . Following such treatment the mice might be subjected to imaging under anaesthesia, they might have blood taken for analysis (and will finally be killed typically about 4 weeks after Step 1, which may involve perfusion or exsanguination under terminal anaesthesia. A minority of animals (<10%) might in addition experience irradiation followed by bone marrow reconstitution or transfer of immune cells as well as treatment with antibiotics. Protocol 5 (Induction of colon tumorigenesis) will follow mice over 12-16 weeks as induction of tumorigenesis, especially in wildtype mice is a slow process.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may experience pain, weight loss and tumours for a short period of time

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Immunocompromised mice and those lacking AHR might be more susceptible to the procedures and reach the moderate severity limit of the protocols.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While it is possible to generate information regarding regulation of some aspects of the immune response in cell culture it is not possible to mimic the response to infection or intestinal disease in vitro, since immune cells are highly connected with cells of the tissue lining and crosstalk between different cell types is an essential feature of inflammatory responses.

Which non-animal alternatives did you consider for use in this project?

We will where possible, collect and generate as much data as possible using culture methods for immunological tests. For instance, the state of intestinal epithelial cells in genetically modified mice may be investigated using organoid cultures which are often termed mini guts.

Why were they not suitable?

In vitro systems, while useful, do not fully replicate the complexity of immune interactions or disease pathogenesis in vivo and it is essential to use appropriate and robust animal models to dissect these processes. Furthermore to develop therapeutic approaches with potential to alleviate human disease it is necessary to establish parameters influencing efficacy in an animal model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For the design of most of the quantitative experiments, sample sizes will be set using power analysis, generally using a significance level of 5%, a power of 80% and at least practicable difference between groups of 20%. Otherwise, we will use the minimum number of animals to provide an adequate description, generally on the basis of previous experience (our own or from the literature). Wherever possible, factorial design will be employed to maximise information using the minimum mouse number. Statistics expertise will be sought within the institute, and active statistical discussion with bioinformaticians. Pilot experiments will use between 5-8 mice per group, which should be sufficient if a significant result is obtained. Experiment will be repeated to obtain further significance if there are only small differences; in this case it may have to be repeated with larger numbers of mice and/or modifications.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Measurements over time, in particular non-invasive ones, such as weight loss, clinical scores and non-invasive imaging, allow gaining a wealth of information on disease course over time with minimum number of mice used. Freezing of mouse embryos, tissues and cells is routine at the establishment and will ensure that the minimum number of mice is bred, and measures are in place to maximise efficiency of breeding schemes with minimum surplus. Reporting will be based on ARRIVE guidelines. Imaging technology will allow following a cohort of mice over time rather than setting up several experimental groups to monitor the consequences of an infectious stimulus. Furthermore, colonoscopy with an endoscope will be a monitoring method for the colitis and tumorigenesis protocols to allow us to detect inflammation and tumorigenesis earlier and without the use of large cohorts of mice. We will remain alert to any advances, which will enable the replacement of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The efficiency of animal usage is maximised in consultation with animal technicians, by careful control of breeding to meet research needs with respect to numbers, the reproducibility of their responses and health. This has been greatly facilitated by a mouse database in which every breeding pair and every mouse born are recorded and through which we can readily monitor the numbers of mice we hold. Littermates which do not express the modified genes, i.e. are wild type for the respective gene(s) from the breeding protocol will be used as appropriate age and gender matched controls. This allows optimal use of mouse numbers generated and is best scientific practice for the study of genetic alterations.

For experiments on tissue inflammation or the development of cancer in response to infection we will wherever possible make use of imaging to follow a cohort of mice over time, which will substantially reduce the number of mice involved. Lastly, this programme of work will make optimal use of several tissues, fluids and cell types per individual mouse. This highly integrative approach will maximise the information obtained from the minimum resource.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models of infection, tissue inflammation and tumorigenesis are the best-established models in the field with high relevance to human disease states. They are generally non-invasive and are likely to

yield significant results without causing lasting suffering and pain.

Why can’t you use animals that are less sentient?

The mouse model allows for control over host genetic factors, which is crucial to studying the factors responsible for development of disease. With these models we can investigate how the immune system recognizes and responds to infection, how tissue damage is repaired and how tumours arise which can lead to new avenues of treatment and prevention.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will work closely with the veterinary staff to ensure that we are always refining our protocols to minimize harms for the animals we work with.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will stay up to date with the best practice guidelines developed by the National Centre for the Replacement, Refinement, & Reduction of Animals in Research, and the scientific literature for estimation of sample sizes based on power calculations.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We keep up with the latest developments in the field by reading the relevant literature and we have ongoing discussions of 3R measures in the institute which ensures we are always up to date.

NON-TECHNICAL SUMMARY

54. Evaluation of Novel Strategies for Bone Repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will determine the safety and effectiveness of different natural and synthetic materials, alone and in combination with cells and/or adjunct treatments, that might be used to enhance the healing of bone.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Millions of patients each year develop problems secondary to incomplete healing of fractures caused by trauma or disease (e.g. cancer, osteoporosis). Fracture complications negatively affect the patient's quality of life, with prolonged hospitalisation, potentially crippling disability and, in extreme cases, infection and a risk that the limb may be lost. The average healthcare cost for managing a non-healing fracture has been estimated to range from £17,000 to £79,000 per patient.

There are a number of reasons why fractures fail to heal normally. First, the amount of bone lost as a result of the original trauma or disease may be too great, exceeding the ability of the skeleton to repair itself. The second major reason is that the patient's bone may not be healthy – this is common in elderly patients and in those taking certain medications. Another important reason for fractures failing to heal is that the bone may be infected, either at the time of the original injury or at the time of surgery.

Whatever the underlying cause, there are currently two main ways to replace bone and stimulate healing in patients with these problematic fractures. The first relies on bone that is removed from the patient him/herself, then placed into the site that is not healing. The use of the patient's own bone – so called "autograft" – is relatively easy from the surgeon's perspective – the bone is immediately available (it is usually harvested from the pelvis of the patient) and since it comes from the same patient, there is no risk of disease transmission or of adverse immune responses to the graft ("rejection"). However from the patient perspective autograft bone suffers from some important limitations. For instance collection of the bone graft requires a second incision, which causes additional discomfort for the patient following surgery. Additionally, there is a physical limit to how much bone can be harvested from the pelvis, especially in children and in smaller adults. Finally, the quality of the bone that is collected can be quite variable, especially if the patients are being treated with chronic doses of medications such as steroids, which are known to reduce the biological properties of autograft bone.

As an alternative to using the patient's own bone, the surgeon can elect to use bone that is harvested from cadavers. This bone – known as allograft – is typically obtained through commercial tissue banks. While quite plentiful, allograft can be very expensive to buy. Additionally, because it comes from a different person, there is potential for transmission of infectious diseases such as HIV, Hepatitis B and Hepatitis C. Donors are screened for these diseases, but a small risk is always present.

There is tremendous interest in the development of safe, effective and reasonably-priced alternatives to human tissue for enhancing bone repair following bone loss secondary to trauma or disease. Given the concerns over both availability and potential disease transmission from natural human bone products, there is a necessary drive to develop alternatives to human bone, including the use of non-human (xenograft) bone or bone derivatives, synthetic biomaterials, or combinations of natural and synthetic materials.

We and other groups are actively working to develop these so-called bone graft replacements. In most cases, these are based around either chemically processed forms of native bone, synthetic forms of bone mineral (typically derivatives of calcium phosphate), or some form of natural or man-made polymer (common examples include collagen, poly-lactic acid (PLA) or poly-caprolactone (PCL)).

Our lab has focused in particular on the development of a chemically processed form of bovine bone that might be suitable as a building block for making a bone graft replacement. We elected to focus on bovine bone because of its widespread availability (via the food chain) and established history as an implantable biomaterial (including both soft tissues such as heart valves, and as bone and tendon grafts). Bovine bone has similar macrostructure and microstructure to human bone (more comparable than is seen in sheep and goats, for example) and displays Haversian (osteonal) remodelling. It also has excellent material/mechanical properties that are well aligned with those of native human bone. By combining the processed bone with a resorbable polymer, we will be able to create a bioresorbable patient-specific implant with mechanical properties that are specifically tuned to meet the demands of the site in which it is implanted. The material is amenable to being fabricated into complex structures through the use of 3D printing techniques. Laboratory testing of the processed bone has shown that it is well tolerated by bone cells, and that it its mechanical properties are similar to those of native bone. In order to explore its potential effectiveness in healing bone, we now propose a series of animal studies that will establish whether (a) there is any evidence of toxicity or adverse tissue response when the material is implanted in animals, and (b) whether 3D printed cylinders of the material can serve as a framework, or scaffold, for bone repair.
It is critically important that any new candidate material performs at least as well as currently approved products in vivo - otherwise there is no value to the new material.
This project license describes a series of rodent and rabbit studies that will allow for robust, systematic screening of a range of candidate materials (biomaterials) as scaffolds for bone repair. In addition to testing the safety and effectiveness of these biomaterials as stand-alone scaffolds, we will also establish whether it is possible to further enhance bone healing by adding stem cells to the material prior to implantation, or by using post-operative treatment with biophysical stimuli such as shockwave therapy to see if this further enhances the reparative capacity of the scaffold-cell combination.

What outputs do you think you will see at the end of this project?

We expect to publish a minimum of 2-3 scientific papers reporting the results from the work under this license. These papers will describe the development of a new type of bone repair material. At the same time, positive results from these animal studies would likely lead to interest in the development of a commercial product for use in the veterinary clinic (for repairing fractures in cats, dogs and horses). With time, there may then be interest from the human market for a product that could be used in orthopaedics, dental surgery and possibly spine surgery.

Who or what will benefit from these outputs, and how?

We anticipate direct benefit to veterinary and human clinical patients who require surgical management of bone defects. As part of the work, we will validate both the rat and rabbit models for bone defect studies and our findings (and subsequent publications) should be helpful to other researchers who might be considering similar work in the future.

How will you look to maximise the outputs of this work?

We are working to establish collaborations within our institution, as well as with collaborators at other scientific centres around the world. These collaborations will benefit from the data developed under this project license.

The animal models described in this project license will be published and we would expect this to lead to more general adoption of these models in the future.

Species and numbers of animals expected to be used

- Rats: 120
- Rabbits: 324

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and rabbits are widely recognised as appropriate preclinical screening models for determining the tissue response to orthopaedic, dental and spinal implants. Regulatory bodies that oversee the testing and approval of medical devices recommend the rat and rabbit as appropriate models. The rat model involves a relatively small bone defect and is therefore ideal for screening a lot of different possible materials. The rabbit model involves a much larger and more clinically relevant bone defect that is better suited to providing more detailed information about the materials that perform best in the rat model. We use skeletally mature animals because most of the patients that we see with complex fractures or tumours are adults.

Typically, what will be done to an animal used in your project?

For the surgical models, the common procedures will be anaesthesia, surgical implantation of one or more biomaterials, then follow-up for periods of up to 6 months. For the subcutaneous model in rats, small cylinders of the test material will be placed under the skin. For the rabbit model, a bone defect will first be created by removing a 15-mm length of bone from the femur; this defect will be replaced with a cylinder made from one of the test materials, and the bone will be stabilised with a metal orthopaedic plate and screws. At intervals after the surgery, chemical dyes that mark sites of active bone formation will be injected into the animals so that we can measure bone healing. In some animals, additional treatments (including the use of shockwave treatment to stimulate bone repair) will also be evaluated. None of the animals will have more than one surgery to implant the materials, and for the bone defect models only one leg will be operated.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect to see some weight loss as a consequence of interruptions to normal feeding patterns. For animals undergoing orthopaedic surgical procedures, it is very likely that there will be some degree of lameness secondary to the bone surgery – this is what we see in clinical patients undergoing orthopaedic surgery. We will use clinically approved pain-relieving medication to minimise pain and discomfort after surgery. The risk of infection - also ever present in surgical patients - will be reduced by the use of aseptic technique, sterile instrumentation and appropriate wound monitoring and topical wound care. It is not our routine clinical practice to use antibiotics for elective orthopaedic surgery, so antibiotics will not be used routinely in rats and rabbits on this project.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All of the rats on this license are expected to fall under the moderate category as they will all undergo surgery. The rabbit procedures are also considered moderate severity. That said, we anticipate that the overall impact of surgery will be less for rats than for rabbits - the implants in rats are placed in the tissues immediately under the skin, while those for the rabbits are placed directly into bone. We do not expect to see lameness in rats where we will see this in the rabbits.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed to explore the specifics of the tissue responses that happen following implantation of a biomaterial. Biomaterials are natural or synthetic materials that are designed to replace or augment an organ, or a bodily function, or to stimulate natural tissue repair. For this project, we are focusing on biomaterials that will improve the body's ability to make new bone. All biomaterials that are intended for clinical use in human or veterinary patients must first undergo animal testing to ensure that they are safe and effective. The material that we have developed is novel and has not been tested previously. As such, there is no way to secure approval for clinical use without screening the material in an animal model.

Which non-animal alternatives did you consider for use in this project?

The preliminary work underpinning this project has been performed exclusively using cells growing in the lab. The biomaterials that we have identified as being potentially useful must first be shown to be safe for normal cells. We then go on to test the mechanical properties of the different biomaterials to ensure that they are strong enough to survive in a bone defect environment. None of this preliminary work involves the use of animals, and only biomaterials that pass all of these early tests are considered for animal testing under this project license.

Why were they not suitable?

Although cell culture and lab-based models can be very helpful in exploring the effects of different compositions on biological and material properties, they do not and cannot address fundamental questions regarding the interactions between the material and the tissues in which it is implanted. For example, bleeding at the surgical site may interfere with the integration of the material into bone, while immune reactions stimulated by foreign cells or proteins may lead to inflammation that could compromise new bone formation and integration. Additionally, the rate at which the polymeric (plastic) component of a biomaterial is degraded cannot be determined without testing in animals – if the material disappears too soon the mechanical integrity of the structure may be compromised, while if it too slow it may adversely affect new bone formation. The use of clinically relevant animal models allows us to perform temporal studies that can address these interactions and compare the performance of the new material (in its different compositions) against that of materials that are already in clinical use. Current options for bone replacement in animals and humans exist but all have limitations in terms of cost, availability and flexibility when used in different applications. The materials that we are exploring offer substantial advantages in terms of being cost-effective, safe and adaptable to the patient's unique anatomy (through the use of 3D printing based off CT or MRI scans).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We initially estimated the numbers from a review of previously published data from the rat and rabbit models, which indicate sample sizes of anywhere from N=8 specimens per group (for standard rat subcutaneous models for assessing tissue response to biomaterials) to 10-15 specimens per group (for rabbit bone defect models in which biomaterials are placed into long bones).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We undertook a number of steps ahead of submitting this project application, including:

1. Detailed literature review to look for alternatives and best practices to reduce overall animal numbers

2. Consultation with NC3Rs Experimental Design Assistant to ensure that we are maximising data collection from every animal

3. Sequential design of experiments so that treatments that are found not to be successful in rats are eliminated from further consideration and do not go into rabbits.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Steps to optimise animal use include:

1. Use of shared control groups across the different phases of testing.

2. Use of non-invasive imaging (such as X-ray and CT scans) and non-destructive tests that allow specimens to undergo mechanical testing and still remain sufficiently intact to be useful for biochemical or histological studies. By doing more than one set of measurements on the same specimen, we are better able to make direct comparisons between outcome measures.

3. Use of injectable chemical dyes (fluorochromes) to measure bone formation at different time points in the same animal.

These dyes stain the bone and provide a time stamp - by looking at the pattern of this staining (with a microscope) after the animal is dead, we can retrace the history of bone healing in the animal...rather like examining tree rings and establishing periods of relative drought and relative plenty. Multiple labels can be injected in each animal, allowing us to compare healing patterns at different time points, without the need to kill animals at individual time points.

4. Compliance with PREPARE and ARRIVE guidelines related to the design, conduct and reporting of animal studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain

management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will first start by establishing that the combination materials (composites) are safe (non-toxic) when implanted in subcutaneous sites in rats. The subcutaneous model, with implantation on the dorsum of the rat, is well tolerated, with transient pain/distress that is similar to that seen with repair of a simple surgical incision.
Material and material-cell combinations that demonstrate acceptable safety will then go on to testing in a clinically relevant bone defect model in rabbits.
The rabbit bone defect model provides a clinically challenging environment for bone repair. The instrumentation used to stabilise the femur is strong enough to protect the bone even if the candidate material is ineffective at supporting new bone growth, so we do not expect to see a significantly higher rate of complications in animals that are implanted with biomaterials that prove not to be effective.The alternative to the rabbit would have been the sheep - this would have offered the opportunity for an even larger bone defect, but we felt that this fact alone was insufficient to justify moving up to this species at this time. If the candidate materials are especially promising and we are able to commercialise the material, regulatory bodies may subsequently ask for sheep data, at which time we would submit an amendment to this license.

Why can’t you use animals that are less sentient?

We cannot assess acute or chronic tissue reactions to implanted biomaterials in anything other than a live-animal model. Cadavers and terminal surgery are helpful in optimising surgical technique but can never replace the need for live animals in work of this type.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We leverage the skills of our technical and animal care teams to ensure effective monitoring of animals from both a behavioural and a welfare perspective. Pain-relieving medications are given routinely after invasive or potentially painful procedures, and validated pain scoring/behavioural scoring is used to confirm that pain relief is sufficient. Daily direct observations of the animal, and routine monitoring of body weight and food intake are used to ensure the welfare of animals in our care. When we can, we will train animals to allow for oral (or in-food) administration of pain-relieving medication. We have used shockwave therapy in clinical veterinary patients (dogs and cats) for over 2 years without any need for sedation, and we anticipate that the procedure will be well tolerated in rabbits without sedation. However, to ensure minimal stress we will use sedation or short-acting inhalation anaesthesia in this preclinical study. We use non-invasive and non-painful techniques for imaging, and minimise the number of interventions needed to secure a scientifically valid answer.
All animals will be group housed in order to ensure social interaction and normal behaviours (e.g. play and social grooming). Species-appropriate environmental enrichment will be provided (e.g. Cheerios and plastic shelters for rats; plastic balls for rabbits to play with).
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All of our experimental work is designed and performed in accordance with established best practices. These vary from the use of the LASA Guide, NC3Rs guidance, development of surgical standard operating procedures based on publications, use of validated pain scoring schemes, and the design and reporting of studies using PREPARE and ARRIVE guidelines, respectively.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I receive regular updates on developments in the application of the 3Rs through institutional communications and mailings from international animal care organisations such as the Association for Assessment and Accreditation of Laboratory Care International (AAALAC International). My lab is committed to using best practices in our work and would certainly institute advances in, for example, pain scoring and rabbit analgesia if demonstrated during the course of this project.

Home Office

NON-TECHNICAL SUMMARY

55. EVALUATION OF NOVEL THERAPEUTICS FOR TOXICOLOGICAL SAFETY

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Toxicology, Exploratory Toxicology, Regulatory Toxicology

Animal types	Life stages
Mice	adult, juvenile
Rats	adult, juvenile
Hamsters	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to assess the possible toxicity potential of novel therapeutics for clients/partners using well established regulatory or non-regulatory toxicology protocols in protected animals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to generate scientifically valid toxicological data that can be used in determining the potential safety levels of novel therapeutics to progress them to regulatory work and to satisfy the regulatory authorities prior to potential therapeutic use in humans.

What outputs do you think you will see at the end of this project?

It is reported 10.3-27% of oncological patients experience toxicological adverse events in phase I-III clinical trials with a 0.4-2% mortality rate (Wheler J. J. et al., 2012; Witteles R.M. and Telli M. 2012). Toxicological adverse events are also observed with other pathological conditions during clinical trials (Mehra M.R. et al., 2020, Khan A. et al., 2020, Brass E.P. and Hiatt W.R., 2006). The key benefit of the work under this licence is to be able to eliminate substances, early in their development, that induce unacceptable toxic side-effects in pre-clinical species before they are used in humans.

Short-term benefits, achieved within the life of the project, will include the provision of a package of high quality and robust pre-clinical data that will facilitate the rapid identification and selection of the best candidate drugs and avoid any unnecessary and wasteful *in vivo* tests being applied to inappropriate drug candidates. The main purpose of the project is to identify the No Adverse Effect Level dose, which will advise an optimum safe dose for “first-in-man” studies, this will not only help protect humans but will also safeguard funds which can be used to advance other substances of interest, thus maintaining study integrity. Data generated from acute toxicokinetic studies will also be useful in indicating appropriate drug doses and concentrations used *in vivo* for chronic toxicology assessment, thus maximally reducing the levels of animal potential suffering. The immediate benefit would be the knowledge to inform further drug development. Maintenance of a test substance’s research path continuity will be achieved in some cases, as some substances will be already explored by us during *in vitro* and PK programmes, therefore producing more harmonised data which can potentially lead to animal use reduction due to better understanding of chemical/physical/pharmaceutical properties of drug candidates and improving statistical significance of the data obtained. Additionally, financial income from the research work will allow Company to re-invest in facilities, the most current equipment, training of staff in new relevant techniques to improve delivery of 3Rs.

For the mid-term benefits, achieved within 2-7 years, studies performed under the authority of this licence will allow identification of drug candidate’s suitability for further development towards use in human trials prior to administration to clinical patients.

Long-term benefits will be achieved mostly at the human trials stage and beyond and will include the identification of the dose level and duration of treatment that is likely to compromise optimum efficacy of effective substances in human trials and clinic. Other long-term benefits lie outside the direct control of this project licence, however, ultimately, this project is expected to contribute to the treatment and prevention of disease in the clinical field through screening out harmful drug candidates and allowing only effective non-toxic treatments to be further developed for the benefit of the patients.

Who or what will benefit from these outputs, and how?

It is expected as short-term benefits, a certain number of compounds would be identified as toxic due to the current programme of work and be prevented from going into further development and some compounds would be identified as potentially suitable for use in clinical trials, benefitting client pharmaceutical research

organisations.

Generated data will also assist regulatory authorities, such as MHRA, EMA, or FDA and other regulatory bodies controlling the issue of new drugs to the public, in the decision-making whether to allow the progress of substances for further human clinical trials. The data produced is likely to be submitted to support the dossier of information for a new compound or used to guide the studies required to obtain such information, thus benefitting the wider scientific and pharmaceutical community. The data produced will also be of benefit to other researchers in the field by better understanding of toxicological effects of novel drug candidates and avoiding unnecessary *in vivo* experiments with identified toxic compounds. Recommendations of the dose and schedule to be used in "first-in-man" clinical trials with the new drug candidates will also be made, benefitting both trial patients and clinicians. Elimination of toxic substances early in their development stage would allow us, our clients and, eventually, NHS, to save resources and development time not only for mid-term, but also in the long-term.

Importantly, the animal data generated will provide input in determining the benefit–risk ratio where the potential improvement in the health and welfare of a human patient is compared to the likely health risk to that patient, which will give clinicians crucial information for informed control during drug approval, prescription and treatment process. The likely outcome being that the lead-time for new therapies to reach patients will be optimised, giving greater potential to save lives, improve therapy, alleviate suffering and reduce the incidence of adverse effects experienced with existing therapies in the long run.

How will you look to maximise the outputs of this work?

We follow a proactive publishing policy as it is in the interest of the business to develop new methodologies and to refine pre-clinical research in order to make the organisation more attractive to potential clients. It is anticipated that even though there will be limited opportunities for publishing obtained scientific data that is part of confidential early stages in drug discovery, we will make every effort to partner with our clients to publish relevant data output whenever possible for the wider scientific community. Our participation in the grant-funded projects and collaborations with academia have however resulted in publications, and it expected that will continue in the future from work carried out under authority of this licence. In any case and whenever possible we will try to disseminate our knowledge. Our aim would be that from our service work we would look to present short communications or posters at dedicated meetings, for example highlighting any developments in methodologies related to the 3R’s.

Species and numbers of animals expected to be used

- Mice: 2700
- Rats: 3600
- Hamsters: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice, hamsters and rats, as species of the lowest acceptable order, are the research species models of choice in drug discovery and development due to their size and substantial amount of literature data already available. These models have been used and validated extensively, and have provided much of our knowledge to date in toxicology studies which we plan to utilise to generate the package of high quality, robust and incisive pre-clinical data that we aim to provide. The choice of animals are also dictated by the governmental regulatory bodies which demand that prior to first-in-man studies, toxicology data are provided at least in rodent animal species to ensure that the drug is suitable for human use.

We will continuously monitor the literature to implement the latest animal husbandry legislation and practices. Furthermore, we will minimise animal suffering by using the most advanced technologies where possible, like appropriate anaesthetics, pain relief and infection control.

Typically, what will be done to an animal used in your project?

The careful selection of test substances from laboratory studies will ensure that only non-toxic potential drugs with a positive profile to treat human diseases will be taken forward for use in animal research. The design of proposed experiments will be rigorously considered in order to ensure that a minimum of animals are used at all stages without compromising the integrity of the work. In most cases, small groups of animals will be dosed with the potential drugs at low volumes and concentrations. Dosing could be done in the same ways as humans are dosed in clinic, for example through feeding tablets or powders or via intravenous injections. Animals will be carefully observed after the dose to establish toxic side effects of the drug and whether drug had any negative effect on behaviour. If no unusual behaviour or signs of toxicity will be seen, animals will be dosed with increased concentrations of the drug, until toxic effects will become visible, at which stage experiment will be completed. Each animal will be subjected to only one experiment to reduce potential negative effects of the unknown potential drug substances. Experiments can last either for a short duration, e.g. from one day up to one week, if immediate effects of potential drugs need to be studied, or a longer duration, e.g. for months, if researches want to establish cumulative effects and long-term effects of the drugs in question. During experimental procedure small blood samples can be taken from an animal to establish whether drug is still present in the body, what organs of the body it accumulated in to provide therapeutic effects and whether it affected body in any negative way. At the end of experiment animals will be painlessly put down and organs will be collected to be studied under the microscope to see whether drug has affected tissues even if animal did not show any unusual behaviour or side effects during experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

All procedures will be carried out by trained, experienced and competent members of staff, so no adverse effects are expected from handling animals and experimental procedures. It is envisaged that some test substances at high dose levels may cause discomfort, and those animals undergoing repeat dose regimens may experience adverse effects such as reduced activity, abnormal behaviour, reduced food or water intake resulting in weight loss due to the possibility of drug accumulation. Animals will be monitored frequently throughout the study period and if any animal displays signs of pain or discomfort, such as changes in feeding, drinking or movement, or if the general state of health deteriorates from normal, e.g. non-socialising, excessive aggression or unusual behaviour, the therapy and pain relief procedures will be provided for each animal. In rear cases when pathological condition cannot be alleviated by therapeutic measures, animals will be humanely and painlessly put down to prevent any further unnecessary suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The nature of research aimed at identifying toxic potential of novel drugs during an early drug discovery process anticipates that some substances at some dose levels will cause toxic side effects. As it is difficult to predict which drugs and at what stage of development will cause side effects, we can predict the moderate severity category may be experienced by some animals. In our work we will be using exclusively rodents as species of the lowest acceptable order for the regulatory toxicology type of work. As study animals will be typically subdivided into groups to be subjected to ascending dose levels of the test drugs, e.g. control/low/middle/high dose level groups, we can predict that only around a quarter of all animals will reach moderate severity during studies due to screening-out of toxic compounds and doses. Whenever possible, studies will be designed and implemented to achieve the lowest possible level of severity. One of such refinement methods is a staged dosing approach when a drug is given at the low dose level and study is progressed to the higher dose level only in the absence of significant adverse effects in the lower dose group. Our previous experiments suggest only around 20% of rodents used for our toxicological research have reached a moderate severity with the vast

majority of animals staying within the mild severity level.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is of paramount necessity to determine the behaviour and assure safety of novel drugs in living systems to minimise the fatal risks to human patients. It is also important to select the most appropriate dose rates and administration routes of novel drugs to achieve a maximum therapeutic effect to cure various diseases without causing any unwanted side effects. Whole body assessments as described in this licence are therefore required by statute by regulatory authorities before prospective drugs can be administered to humans.
Which non-animal alternatives did you consider for use in this project?

The use of available data on chemical analogues and known toxicological profiles of related drugs, computer modelling and laboratory studies with isolated human cells and tissues are normally used for initial toxicity assessment, this information is taken into account to either completely eliminate the need for an animal toxicological work (e.g. with known toxicants/irritants or non-tolerated compounds), or significantly reduce the number of animals or potential side effects of the tested drugs proposed for human use.
Why were they not suitable?

Whilst laboratory systems provide us with important data on the properties of novel drugs, it is imperative for these properties to be determined in the intact biological system as computers or cell and tissue cultures have a limited application to the whole body response to potential novel drugs. This is because such experiments can only generate data restricted to few specific types of cells or predictive models and cannot cover hundreds of different cell types and thousands of interaction pathways between neuronal, vascular and immune systems present in a living organism. Despite positive laboratory results, animal work is still needed to confirm that the drug will not produce the undesired effects that have not been previously observed in cell assays. As such, current laboratory systems lack the complexity of living organisms in determining possible negative outcomes of drug-organ and drug organism interactions and establishing the degree of harmful effects caused by a novel drug and cannot be used as an accurate predictive tool to fully replace animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

A typical 90-day regulatory study will require 120 animals. We anticipate that we can do 2 studies/year with mice and 4 studies/year with rats for the duration of the project. To ensure safety of animals on long-term regulatory studies, short term non-regulatory pilot dose selection studies will be performed, which could require around 300 mice, 240 rats or 120 hamsters per year.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For experimental planning and implementation, we will aim to follow “Planning Research and Experimental Procedures on Animals: Recommendations for Excellence” (PREPARE) guidelines to ensure scientific validity of the work and reduction of wastage in animals, time and resources. In our aim to reduce the overall number of animals used for the duration of this licence, and as a good scientific principle, we always insist that there is a well-established scientific rationale for undertaking any animal toxicology work and that prior laboratory data supports such work. Regulatory studies will be carried out in line with approved industry gold standard OECD/ICH guidelines, e.g. OECD 408 Repeated Dose 90 Day Oral Toxicity Study in Rodents, where study design and number of animals required were subjected to stringent international peer-review process, validation and approval. Nonregulatory discovery toxicology work will be primarily based on models available for regulatory toxicology, however other scientific models or methods published in peer-reviewed scientific literature will be used. We will be using contemporary designs for toxicity testing where we can derive a maximum amount of information from a minimum number of animals. Study objectives include determination of the most important clinical signs attributable to high doses of the test substance, time of onset and remission of those signs. These objectives are achieved by means of a comprehensive schedule of animal observations following dosing. For bespoke discovery toxicology work statistical analysis will determine the minimum number of animals that can ensure scientifically-robust results - internal expertise and external statistician consultants are available. To reduce animal use in acute toxicity testing, studies that include more than one dose group will be normally dosed sequentially, with an interval of at least 24 hours between dosing of subsequent groups. This will allow the effects of the previous dose to be fully manifested and will allow selection of the subsequent dose to provide the highest probability of contributing more useful information. Long-term toxicology and carcinogenicity studies requested for the same substance could be combined to allow for animal reduction. NACWO/NVS/AWERB committee may also be involved at the study planning stage to advise on appropriate scientific approach for discovery toxicology projects.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A small pilot study may be planned to validate the proposed study design, staged/staggered dosing approach in a study design will allow meeting scientific objectives whilst minimising the number of animals at risk of suffering. To avoid bias between experimental/control groups and to use optimal minimal number of animals for each study, we will ensure identical study conditions/environment for all animals, which will be strain/gender/age-matched and grouped randomly. Where possible, a single control group as a comparator for a number of test materials will be used. We will aim to use both males and females for all our study designs, however to minimise the number of animals used, the testing can be performed in only one sex if sex is not scientifically important. During study execution it can be evident that not all substances will be allowed to progress through all the steps of protocol due to toxicity, also representing a part reduction in the numbers of animals during drug development process.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Procedures will be carried out in species of choice (either mouse, rat or hamster), which will be agreed with the

client, depending on the properties of the potential novel drug, the scientific test and the knowledge of the drug effects. The overall premise of the license is that the most refined, most relevant and least invasive methods will be used for each study. We expect the majority of work carried out in models with a minimum burden on the animals (short duration of a study, minimal number of procedures). When the experimental question justifies additional burden to the animal (i.e. single housing or repeated drug administration) we will provide additional adequate monitoring and will aim to keep such a burden to minimum levels. The work carried out will be of a moderate severity, with severity reduced where possible.

Why can't you use animals that are less sentient?

The toxicology research is often carried out to enable first-in-man clinical work with an expectation of adequate translation of research findings into human trials. Therefore, the choice of animals is often dictated by the governmental bodies, and as such, the minimally sentient species required for regulatory toxicology work are rodents. As one of the primary experimental endpoints for toxicological research is animal's behaviour as a reflection of toxic effects of the novel drug, e.g. affecting central or peripheral nervous, respiratory or cardiovascular systems, terminally anaesthetised animals are not suitable for required clinical and functional observations to achieve experimental aims and objectives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise suffering and stress, animals will be acclimatised after transportation and may be familiarised with the environment, procedures and handling prior to studies. Novel drug structural knowledge could allow prediction of possible side effects of the related chemicals. The physicochemical properties (e.g. pH, solubility) of test novel drugs would be considered to prevent nonspecific adverse reactions. Cannulation could sometimes be a convenient alternative to frequent animal handling and repetitive injection schedules. Some dose routes, i.e. rectal, can be beneficial by allowing for the avoidance of "first-pass effect" hepatogastrointestinal drug metabolism, thus potentially reducing the required dose concentration due to improved bioavailability, reducing associated side effects, and reducing the use of more invasive routes of administration such as the intravenous route. Appropriate anaesthesia/analgesia will be used, and the advice of the NACWO/NVS will be sought when necessary. Blood sampling volumes would not exceed recommended levels. For acute toxicity studies animals will be frequently monitored, whereas for longer-term studies daily assessment would be employed to minimise the risk of severe side effects being reached, a schedule detailing limiting clinical signs and humane endpoints is in place. In the unlikely event of animals reaching a moribund condition, or expected to become moribund, or experiencing significant pain or distress, they will be humanely euthanised. We will minimise animal suffering by using the most advanced technologies where possible, and by using appropriate anaesthetics, pain relief and infection controls. In addition to the above specific refinement measures, all the work will be completed in the state of the art modern environment using monitored facilities utilising equipment fit for purpose. The use of the individually ventilated caging, surgical suites, the rooms dedicated to particular techniques and robust cleaning techniques will ensure further non-specific infection and cross-contamination control as a refinement of the experimental procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are committed to follow Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE) guidelines, allowing us to ensure experiments are planned and conducted in the most refined way, suitable for Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines implementation. Our research facility is already accredited to Office of Laboratory Animal Welfare (OLAW) and Good Laboratory Practice (GLP) standards, with the strict implementation of the European Union (EU) Directive 2010/63 on education, training, competence, housing, care and use of research animals with a comprehensive set of Standard Operating Procedures (SOPs) based on OECD/ICH recommendations.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our managerial and research personnel regularly attend relevant scientific meetings, workshops, networking

events and continuously monitor scientific literature. The company holds regular Animal Welfare and Ethical Review Body (AWERB) meetings to share the latest animal husbandry, scientific legislation and the best 3R practices. These advances are implemented effectively by research facility Management through HO/NVS/NACWO monitoring programmes and regular training sessions facilitated by the Named Training and Competency Officer (NTCO).

Home Office

NON-TECHNICAL SUMMARY

56. Experimental investigation of microplastic ingestion bias

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Microplastic, Behaviour, Ingestion, Health, Welfare

Animal types	Life stages
Zebra fish	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to investigate whether certain characteristics, including size, concentration, density and composition, alter the tendency of zebrafish to ingest microplastic. We will determine the anatomical position of microplastic accumulation in the body, and investigate whether feeding behaviour influences ingestion.

A retrospective assessment of these aims will be due by 25 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In recent years plastic items have been found accumulating in the guts of marine and freshwater animals due to the increasing quantities of plastic dispersed into the environment. Fish are especially susceptible to ingestion of microplastic because such particles can be mistaken for food, with fish that eat plankton being particularly affected. Many fish species are consumed by higher trophic groups and there is also potential for plastic to be concentrated in the food chain. This research will demonstrate which types of microplastic are most detrimental to fish, with the potential to help improve their welfare in the future.

What outputs do you think you will see at the end of this project?

1. This project will generate new information regarding microplastic ingestion by zebrafish, exploring the extent to which microplastic size, concentration, density and composition biases the likelihood of ingestion; whether microplastic becomes trapped in zebrafish tissues; and if not, what their residence time is in the gastrointestinal tract.

2. We will publish our findings in scientific journals. We will aim for top-tier open access peer-reviewed journals with a broad readership in order to disseminate our findings to as many people as possible. We will also share our findings with the general public via press releases and social media.

Who or what will benefit from these outputs, and how?

Scientists interested in fish welfare will benefit from a better understanding of the correlation between microplastic type and harm caused to fish health. This may help inform future policy regarding pollution of the oceans and the types of plastic to use in manufacture.

Members of the public are increasingly aware of the need to protect the environment, including reducing or removing plastic waste. High quality scientific data showing the impact of microplastics on fish health and welfare will further raise awareness of this important issue.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work through collaboration, publication and dissemination. This project represents the first step in a new collaboration. The results obtained here will form the basis of joint grant

applications. We will publish our findings in open access journals as described above. We will further disseminate our results though our lab Twitter accounts and press releases, approaches that we have used successfully before.

Species and numbers of animals expected to be used

- Zebra fish: 90

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult zebrafish are the ideal animals to use in these experiments. They are small, easy to maintain in the laboratory and we know a lot about their behaviour, which can be used to assess changes to health during the experiment. They are also a model for other fish , allowing the information here to be used to understand other species including wild fish.

Typically, what will be done to an animal used in your project?

Animals will be fed one of two types of microplastic (polypropylene and polyethylene terephthalate) on the first day of the experiment. We will compare two different concentrations and sizes. The animals will then eat their normal diet for the rest of the experiment. Animals will be sacrificed at three time points (48h, 168h and 336h) using a standard method. We will then collect their organs and assess both the amount of microplastic eaten and its accumulation in different tissues of the body.

What are the expected impacts and/or adverse effects for the animals during your project?

The experiments proposed here will be used to generate pilot data for a larger set of experiments. While we do not expect adverse impacts during the course of these experiments, there is a possibility that the fish's health is affected by microplastic ingestion. This could cause a change in behaviour, (such as a alteration of locomotion or feeding, freezing, a loss of balance or increased time spent at the surface of the tank water) or even mortality.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The changes to health caused by microplastic ingestion in this pilot study could be severe. Previous research suggests that microplastic ingestion can be lethal to fish meaning that their behaviour and welfare needs to be monitored very closely. If we do not observe such mortality here we will apply to amend the severity rating for these experiments before carrying out further research.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 25 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research described in this proposal investigates microplastic ingestion by zebrafish. Since we will analyse behavioural preference for different types of microplastic, accumulation in organs and the transit time through the body it is impossible to use cell lines or organ cultures for this research. I have looked at the FRAME website and the NC3Rs website for possible replacement protocols but have not found suitable alternatives.

Which non-animal alternatives did you consider for use in this project?

We considered using organ cultures for this research.

Why were they not suitable?

Organ cultures are not suitable, because we will investigate the feeding behaviour for different types of plastic (e.g. that sinks or floats) and the accumulation of microplastic in many different organs of the body.

A retrospective assessment of replacement will be due by 25 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated these numbers based upon data collected during pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In general, we use the NC3R's Experimental Design Assistant tool when designing experiments in our laboratory. This allows us to check the statistical analyses and number of animals to use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to refine the size and quantity of microplastic to use in our main experiment. We will collect data from multiple tissues in each animal, reducing the total number of animals needed overall.

A retrospective assessment of reduction will be due by 25 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We have chosen to use zebrafish for this research because of the combination of well-established behavioural protocols and ease of maintenance in the laboratory. Adult wild-type zebrafish (AB/AB strain) will be housed in the best possible conditions in our aquarium. This aquarium has constantly circulating water which is regularly monitored for quality. Fish are maintained at low stocking density in specially designed tanks.

Fish will be minimally handled during the project. Pilot experiments will be used to calculate the concentration and size of microplastic to use in our experiments. In the case of unexpected adverse effects caused by feeding plastic (e.g. a reduction of swimming, freezing, loss of balance or surfacing), the experiment will be terminated. The Named Veterinary Surgeon and Named Animal Care and Welfare Officer will be contacted for advice before feeding microplastic to fish again.

Why can’t you use animals that are less sentient?

The goal of this research is to characterise the fate of microplastic in fish following ingestion. Species that are less sentient or that have been terminally anaesthetised may not eat any microplastic, making it impossible to carry out these experiments.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will refine the procedures that we use by monitoring the behaviour of fish during the course of this research during routing health checks. We will look for signs of distress, including changes to swimming, freezing behaviour, or an increase in opercular beat rate or tail beat frequency, indicators of pain in zebrafish. In case of unexpected change to behaviour we will terminate the experiment and contact the Named Veterinary Surgeon and Named Animal Care and Welfare Officer for advice before carrying on.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE and PREPARE guidelines, both when designing our experiments and publishing our findings.
How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs by reading scientific literature as it is published and by monitoring the NC3Rs website. We will use this information to update the protocols that we use when possible.
A retrospective assessment of refinement will be due by 25 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

57. Experimental modelling for a richer understanding of the biology of dementias

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Central nervous system, Cognition, Dementia - Alzheimer, Proteinopathies, Novel therapies

Animal types	Life stages
Mice	neonate, juvenile, adult, aged
Rats	adult, juvenile, aged, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Diseases of the central nervous system, and dementias in particular, are amongst the most difficult to cure and have been on the rise given the ever more ageing population. The global ambition of this project is to translate the disease from the human to the animal (here mouse and rat) and re-create models of the disease states so that a richer understanding of the underlying mechanisms can be achieved.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is vital to develop better and more appropriate experimental animal models of these diseases if we wish to make headway in 1) understanding the mechanisms underlying the diseases, 2) gathering knowledge about the underpinnings of the progression and endpoints of the disorders, and the putative targets for remedial actions so that novel therapeutics can be developed and tested.

What outputs do you think you will see at the end of this project?

1. New information: We will achieve a much more detailed and physiological relevant understanding of the mechanisms underlying dementia.

2. Publications: As in previous years, we will endeavour to publish our work in high ranking journals.

3. Models: We will have developed new and more realistic animal models of dementia, have investigated them in terms of their physiological pharmacological, cognitive anomalies and explore the usefulness of new and existing drugs.

Who or what will benefit from these outputs, and how?

As this is a translational approach, we aim for benefit to human patients (both median and long-term). We will test the generalisability of our animal findings in the patients (for example through direct translation of the EEG from mouse to man). This can be readily exploited and, if connected with drug testing, reveal immediate read-outs as to the benefit of the potential treatment.

How will you look to maximise the outputs of this work?

We already collaborate with a many colleagues around the world, especially in techniques which we have little or no expertise in, or where equipment is too expensive for single use in our laboratory. Moreover, we publicise our work at many conferences each year to engage in scientific discussions about our experimental directions and interpretations of our novel results. We develop new tests when old ones seem to be outdated or not applicable for the question we are asking. This all is published, independent of positivity or negativity of results. In case of particularly interesting findings, we would instigate press releases.

Species and numbers of animals expected to be used

- Mice: 15400
- Rats: 3650

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

During this project we will continually strive to develop/use novel animal models that more truthfully mimic the diseases. Advantages of using mice for studying human ageing and disease models include that the genetic and physiological parameters can be easily manipulated and they can be generated in a short period of time.
We will utilise a multitude of GA models, mainly mouse, which have been developed specifically based on the underlying pathology of diseases. In term of neuronal disorders, our focus in on dementias (e.g. Alzheimer, Parkinson, Fronto-Temporal, Lewy body and vascular dementia) and we seek to determine a complete disease profile. Most of these animals behave normally in their day-to-day home cage behaviour and endophenotypes only appear in an age-dependent manner and are revealed through our sophisticated scientific equipment only. Many of these diseases (dementia) are age dependent and only appear in older subjects. Our GA lines seek to accelerate the onset of these phenotypes to between 6-12 months of age. Animals will be kept up to a maximum of 18 month of age. To determine the exact age of onset may include juvenile subjects as pre-symptomatic.
- We will also use rat models (normal and transgenic or knock-out) with the same aims. Advantages include the size of subjects when surgical procedures are concerned, and the genetic similarity to human, which is greater than for rodent. These cannot always outweigh the disadvantages including weight of subject (in case of drug substance required for administration), breeding cycle, space requirements when it comes to size of equipment, etc.

Typically, what will be done to an animal used in your project?

There are potentially 5 methods of interference.
1. Genetic: this relates to the introduction (most frequently human derived) or deletion of genetic material to generate GA lines that mimic characteristics thought to be hallmarks of the disease in question. We have many of those seat our disposition and subject to availability, our collaborators will create new ones when novel more precise genetic tools become available, or when novel information about genetics needs consideration. GA lines of mild or subthreshold severity relevant to the plan of work may be added subject to a University approval process involving the NVS, the NACWO and scientist(s) out with the group. Information on mouse strains lines are held in a separate document (GA Record/Passport) available within the establishment.

2. Behavioural: This constitutes a principle read-out for the diseases investigated here (mainly dementias). We have a great variety of tests available and are constantly developing new paradigms with higher sensitivity or more appropriate for the research questions. Behavioural Tests which do not increase the harms currently detailed under the licence and are of relevant to the plan of work may be added subject to a University approval process involving the NVS, the NACWO and scientist(s) out with the group followed by consultation with the Home Office Inspector. Information on the Behavioural Tests is held in a separate document (Behavioural Record) available within the establishment.

3. Metabolic: Many older people are sensitive to metabolic syndromes, and these can enhance the risk for dementia. We have analysed numerous GA dementia lines and found that there are often comorbidities for

metabolic syndrome (type 2 diabetes like). Consequently, we will explore the influence of dietary manipulations in GA models and their influence on behaviour.

4. Pharmacological: Approaches to determine mechanisms in vivo include the administration of substances to block or activate cellular molecules. This is highly relevant for the understanding of what is wrong with the mouse, and at the same time instructive when it comes to developing new medicines.

5. Physiological: Coincident with behavioural alterations must be a change in neuronal firing patterns. These can readily be monitored using non-invasive EEG in humans, but it requires surgical implants in rodents. These, however, provide powerful tools to determine how abnormal physiological signatures can occur, and when combine with behaviour and pharmacology, how they may be corrected.

These 5 processes may be used as stand-alone protocols but may also be combined (see Table 1) to develop a much richer and holistic understanding of 'what is wrong with my mouse'!

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may experience some form of side effects when novel drugs / drug classes are explored but this will be unusual and short term. Animals will be closely monitored for example for weight loss
Pain experienced during electrode implantation and other types of surgery is transient and mitigated by analgesic regimes. It is usually related to weight loss, which again is transient and animals quickly recovers.
Behavioural anomalies are normally subtle in most GA lines and only revealed by specialist equipment.
But we also have included some higher impact GA lines for Rett syndrome, in which young animals (similar to humans) mentally retard within the first 4-8 weeks (equivalent to 18 months of a human) of life and are co-morbid for movement and breathing abnormalities. We make particular provision for these subjects and have enhanced monitoring and early interventions in place to ensure they do not suffer.
The impact of single housing might be stressful for some animals, especially when working with female mice. This may be less so for male mice as they are used to solitary environments. There are multiple arguments for single housing, especially when metabolic analyses are attempted. To record exact food intake during high fat diet and limit food intake during dietary restrictions, animals need to be housed individually. This is the only way to accurately record food intake (and water consumption). It has the added benefit that all animals (male or female) are on the same housing regime and this enables reproducibility of study design and reduce variance in observations. Being single housed would facilitate behavioural observations also connected with single housing and reduce any interim stress periods otherwise occurring when animals are separated and re-united and this circle is implemented several times. Again, data robustness is of concern here.
As for the length of single housing (in mice and rats), the following arguments apply: i) for dietary studies, we cannot at present estimate the onset of effect in sone GA dementia lines so have applied for a long-term regime of up to 12 months. The exact regimes will be specified in study plans and are likely to be shorter, especially when an early intervention at <3 months is attempted. This may be different when we assess the dementia phenotype first and explore the add-on of dietary interventions thereafter.
ii) electrophysiological studies, the time lines would be similarly long as we would attempt repeat recordings in home cages in 3-6 months intervals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severities range from mild or sub-threshold to moderate. Although many protocols are classified as of moderate severity, only a small proportion is affected to this degree and many more subjects do not present with any harm. For both rats and mice, we therefore expect an 80:20% split in terms of mild versus moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are the only option for the analysis of behavioural functions correlated with brain activation. Towards this end, we seek to identify disease relevant markers (relevant for dementia) in the behavioural domain. These will be correlated with physiological recordings of brain activity, but also of metabolic influences (blood glucose). Including pharmacological treatments and post-mortem ex vivo analyses provides an enormously powerful tool to determine the mechanisms underlying the disease and to identify novel drug targets and novel treatment options.

Which non-animal alternatives did you consider for use in this project?

There is no suitable replacement or alternative e.g. cell culture, computer model, organelle, nematode, insect etc to using the whole animal to study behavioural / physiological changes and related brain function. For this we have opted to work with rodents as their behavioural repertoire is close to human, GA variants are readily available and translation between patient and animal can be achieved.

Why were they not suitable?

We need to use the whole animal in order to understand how changes in brain activity relate to behavioural / cognitive traits observed in normal and impaired individuals following ageing or neurodegeneration and this is not possible using the alternatives listed above. Although our laboratory also conducts in vitro / ex vivo based activities using neuronal cell cultures and molecular and biochemical technologies, these preparations alone cannot determine the behavioural and mechanistic objectives of this project.
During this project we will continue to improve and refine our experimental techniques and where possible minimise the number of animals used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- The animal numbers used during the course of this project will be the minimal necessary to draw statistically robust conclusions. We typically perform power projection analyses based on our expertise (behavioural, physiological, pharmacological and GA models) whilst taking into account that variables including age (we typically work with 6 weeks to 18-month old subjects) sex, species and background strain can influence sample sizes. Alternative means of power calculation may be derived from literature.

- Keeping up to date with the latest developments i.e. monitoring of the literature and attending conferences will ensure that we don't duplicate or repeat procedures with animals where data has already been obtained. An exception to this being when validation of the study via replication of the data is necessary (confirmatory experiments). Our laboratory is currently involved an EU Horizon 2020 funded project to assess reproducibility in preclinical studies (both within laboratory and between laboratories) with an impact on the Reproducibility Network UK and the 3Rs. We draw valuable information from this network in terms of study design and data robustness.

- Given our considerable expertise with many of the tests proposed in this licence, we would typically estimate a group size between 12-14 subjects in young subjects with clear genotype/drug dependent differences of 30%. Otherwise, cohort sizes may need to be bigger and variance will need to be established for novel tests.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- This project will employ within-subject experimental designs where possible allowing repeated testing of an individual animal in a longitudinal design either across different experimental conditions or at different stages of development/age. Longitudinal designs have been found to reduce animal numbers by at least 50% compared to cross-sectional between-subject study designs.

- Multi-disciplinary/multi-factorial approaches will be employed in order to maximise the information obtained from a minimum number of animals e.g. implementation of a test battery of different behavioural assays or combination of EEG recordings with behavioural assessment.

- At all stages of experimental design, we will follow ARRIVE 2.0 guidelines with experimental blinding and randomisation in order to avoid any bias. We are also seeking to implement a novel 'Data Quality System' as pioneered by our EU project partners).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Pilot studies involving smaller numbers of animals will be utilised when exploring novel procedures. The data generated from these initial tests would be subjected to a power analysis in order to inform the appropriate sample sizes for subsequent studies required.

- Utilisation of advanced and sensitive analysis tools (incl. video analysis software, Matlab routines etc.) can also reduce the number of animals required to make data more reliable. Previous experience suggests, that markers in disease models need to differ by >30% from control values to be useful for drug assessment. This high level of abnormal behaviour goes against our objective to determine early small symptoms in order to initiate early treatment. Consequently, late onset phenotypes may require greater cohort sizes to differentiate from controls (n=16-19 when young or n=24-30 when >12months of age). The development of novel analytical methods using computational approaches allows us to identify endpoints during the early stages of disease and lower the putative suffering / noisier data set of older subjects. These analyses may reduce cohort sizes by 20-30%.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- During this project we will continually strive to develop/use novel animal models that more truthfully mimic the diseases. Advantages of using mice for studying human ageing and disease models include that the genetic and physiological parameters can be easily manipulated, and they can be generated in a short period of time.

- We will utilise a multitude of GA models, mainly mouse, which have been developed specifically based on the underlying pathology of diseases. In terms of neuronal disorders, our focus in on dementias (e.g. Alzheimer, Parkinson, Fronto-Temporal, Lewy body and vascular dementia) and we seek to determine a complete disease profile. Most of these animals are normal in their day-to-day home cage behaviour and symptoms only appear in an age-dependent manner and are revealed through our sophisticated scientific equipment.

- The use of inducers/repressors, that activate/inhibit the expression of certain transgenes is typically not harmful for the animals. In terms of repressors, the inhibition of gene expression has beneficial effects for the subject and frequently improves live span and health status.

- While behavioural testing (cognition, movement related dysfunction, emotional responding) is the principle read-out of this project, it is difficult to draw conclusions on the underlying mechanisms from these tests. We therefore use additional endpoints, such as pharmacological treatment and metabolic blood parameters as informative tools to instruct on the underlying mechanisms of the malfunctions.

- These methods will be used as singular protocols, but a more powerful analysis is provided through the use of multiple approaches in the same animal. These include surgical administration of extracts/synthetic proteins/viral expression cassettes and pathological spreading of toxic proteins in all but some control animals.

- We will also use rat models (normal and transgenic or knock-out) with the same aims. Advantages include the size of subjects when surgical procedures are concerned, and the genetic similarity to human, which is greater than for mice. These cannot always outweigh the disadvantages including weight of subject (in case of drug substance required for administration), breeding cycle, space requirements when it comes to size of equipment, etc.

Why can't you use animals that are less sentient?

There is no suitable replacement or alternative to using the whole animal to study behavioural changes and related brain function. We need to use the whole animal in order to understand how changes in brain activity relate to behavioural/cognitive phenotypes observed in normal and impaired individuals following ageing or neurodegeneration. Many of these diseases (dementia) is age dependent and only appears in aged animals. Our GA lines seek to accelerate the onset of these phenotypes to between 6-
12 months of age. To determine the exact age of onset may include juvenile subjects as presymptomatic.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Animals undergoing surgery that need to be single housed post-surgery will be single housed one week prior to the surgery in order to try and minimise the stress induced in the animals following surgery.

- Self-dosing of analgesia will be utilised in animals with analgesia given via drinking water, we have also implemented bespoke analgesia regimes depending on the strain of animals used (eg. TG4510) and our experience of using them for surgical techniques. This has involved the administration of analgesia via drinking water prior to surgery.

- Refinements utilised in behavioural testing procedures include the use of advanced video observation tools and novel computational analysis tools/software to facilitate a more sensitive and effective profiling of animals in behavioural tests.

- We have developed a series of standard operating procedures for all regulated procedures and behavioural tests to ensure high quality data that is consistent and standardised with all laboratory members trained in these procedures.

- All surgical procedures will be carried out using aseptic techniques and performed to the HO Minimum Standards for Aseptic Surgery and the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery. Peri-operative and anaesthetic care measures will be implemented

following consultation with the NVS. The invasive procedures we use including implantation minipump or electrodes have also been refined (and will continue to be refined).

- Ageing rodents will be assessed and observed using scoring systems and humane end points established by other researchers with experience of ageing colonies and postoperative care typically including the appropriate use of analgesics and fluid food rations to support recovery. Selection of behavioural testing will account for frailties in their state of health (for example reduced movement, sensory impairments like visual, auditory or olfactory).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- We are currently trailing a new Data Management System on the conduct of studies, their design and analysis tools, specifics required when working with collaborators from industry or academia and so on.

- We also use Design assist amongst other software tools for power calculation etc. We routinely use Matlab for writing new code for analysis scripts.

- Also, we follow the guidelines provided by commercial breeders (CRL: Guidebook on mouse and rat colony management) for housing and breeding of our colonies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The team have signed up for updates of the NC3Rs (as well as Norecopa) and get information forwarded automatically. We are fully aware of the advances made, as they also affect our work in several funded projects.

Home Office

NON-TECHNICAL SUMMARY

58. Exploring novel strategies for cardioprotection

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cardiovascular disease, cardioprotection, disease models, cardiotoxicity, cardiorenal protection

Animal types	Life stages
Mice	juvenile, adult, pregnant, embryo, neonate, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to identify new ways of protecting the heart, improve current therapies, and possibly re-purpose some of the treatments already available for other diseases, if there is an indication that these can help improve heart disease. These new strategies will be tested on appropriate preclinical animal models with the view to translating into patients with different degrees of heart disease and with co-existing complex diseases such as diabetes, obesity, chronic kidney disease (CKD) and cancer; and corresponding medications.
A retrospective assessment of these aims will be due by 05 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ischaemic heart disease is associated with narrowing or blockage of one or more blood vessels supplying the heart muscles resulting in deterioration of heart pump function. This is the largest cause for mortality as per the global estimates for 2016 published by World Health Organization (WHO). Projections for year 2030 suggest that if measures for reducing the prevalence of this disease are not in place, it will continue to be the single largest cause for death globally.
Coronary artery disease, the most common type of heart disease, causes blockage of one or more blood vessels supplying blood to the heart muscles leading to heart attack. When this occurs, the heart does not get enough oxygen and a part of the heart muscle wall that is supplied by the affected blood vessel becomes damaged. A large number of cells in the affected area die and since new cells cannot replace the dead cells in the heart, the damaged area will not be able to function normally. This increases the workload on the rest of the heart, which will further worsen the heart function with time leading to what is called heart failure and eventually death. The first obvious step to reduce the extent of injury to the heart is to restore blood flow by opening the blocked vessels using drugs and surgery. However, this sudden return of blood flow (called reperfusion) is known to make the injury worse. In addition to finding ways to limiting such reperfusion injury, an additional approach to decrease the global heart disease burden would be to reduce the incidence of coronary artery disease itself.
Coronary artery disease results from the presence of several cardiovascular risk factors such as high blood cholesterol, high blood pressure, obesity, diabetes etc. Most of the heart therapies in use are based on treating these risk factors and also implementing life-style modifications. Despite improvement in treating these diseases, the number of patients with heart disease continue to rise globally. This suggests that there are other, yet unidentified, harmful effects of co-existing diseases that may point to additional ways of protecting the heart and improving outcomes in these patients. Recent clinical trials have confirmed that in order to get the maximum benefit, it is important to understand how the different organs in human body interact in a state of health and ill-health, which in turn seem to affect how the body responds to treatments including those for cardiac disease. In addition to the diseases, advanced age is a non-modifiable, untreatable factor that has significant effect on cardiac health and efficacy of treatments.
Limiting the pandemic of heart disease is extremely important not only to reduce the global burden of this disease on health services and healthcare costs, but also to improve outcomes in certain other disease states such as diabetes, CKD and cancer. For instance, a vast majority of patients with diabetes and CKD die of

cardiovascular complications. Patients with diabetes mellitus (DM) are 2-4 times more likely to develop cardiovascular disease, which is the main cause for death in ~65% of patients with DM. In 2010/11, diabetes cost NHS about £9.8 billion, of which around £3 billion was spent on heart disease and associated complications. With diabetes projected to become the 7th leading cause of death worldwide by 2030, improving efficacy of treatment/management of heart disease in diabetic patients is essential to reduce the healthcare expenses. Another factor that can increase the chances of heart problems in the clinical setting is treatment with anti-cancer drugs such as anthracyclines. These drugs are cardio-toxic – i.e., they can weaken the heart muscle within a span of as little as a couple of weeks to as much as 10 years after treatment. As many cancer patients are over the age of 50, the chances are fairly high that they already have heart disease when diagnosed with cancer; and the cancer treatments can make their hearts more vulnerable. Hence the provision of life-saving chemotherapy is restricted in cancer patients presenting with cardiac risk factors. It is also known that cancer survivors with no history of cardiac diseases may develop heart diseases and heart failure as a result of chemotherapy. For instance, a significant proportion of childhood cancer survivors who received these chemotherapy agents show the development of heart failure in a fairly young age.
It is also extremely important to note that, not only do other diseases and certain drugs used for cancer treatment increase the propensity to developing cardiac disease, but heart disease can also increase the incidence of other diseases. For example, acute kidney injury is a frequent complication of heart attack and can strongly affect the short-term and long-term survival in these patients. Therefore, in order to effectively prevent and treat cardiac disease in young and old patients with/without co-existing pathologies, it is extremely important to understand how effective current heart treatments are in different patient populations.
To obtain data with potential beneficial effect for large patient groups, pre-clinical research involving use of animals mimicking human diseases are essential – more importantly to ensure that the refinements and new strategies do not pose health risk contrary to being beneficial. The insights from these will help refine and personalise current treatments and if needed, devise new treatment modalities.

What outputs do you think you will see at the end of this project?

The project detailed in this licence outlines research intended to 1) improve knowledge of mechanisms of cardiac cell death caused by decreased blood flow and other causes of cardiac injury; leading to 2) identification of new therapeutic targets; 3) development of new methods/drugs based on these newly identified targets for protecting the heart; 4) testing these new methods and also refining available treatments in animals harbouring diseases similar to human patients (e.g. diabetes).
Additionally, our project will undertake studies aimed at re-purposing clinically approved non-cardiac medications for application to cardiac diseases and chemotherapy-induced cardiotoxicity, if there is an indication that these may help protect the heart.
The insights gained from the studies carried out under this project will help improve the ways by which heart can be protected in the larger patient population who may present with several other clinical conditions in addition to cardiac disease. The knowledge obtained from this research can also contribute to the scientific understanding of injury caused by both the lack of blood flow and subsequent return of blood flow by drug or surgical interventions, as occurs in other vital organs such as brain (stroke), kidney and liver, and during procedures such as cardiac surgery and transplantation. The new therapies may also provide valuable adjuncts to current clinical interventions.

Who or what will benefit from these outputs, and how?

Our work aims to improve current methods/drugs and to find new ways of reducing injury in patients who experience a heart attack. Since those who survive a heart attack frequently develop heart failure due to the damage to the heart, improving available treatment methods and developing new techniques will help patients to survive longer and have a better quality of life. A decrease in the occurrence of heart failure following heart attacks would also provide substantial cost benefits to the public health service. Using animal models that have disease conditions similar to humans (e.g., animal models with diabetes, chronic kidney disease or cancer models receiving anti-cancer drugs) we also plan to estimate the success of cardiac treatments in patients with

other diseases. This is particularly important since different diseases can increase the risk of developing heart disease and can change the way patients respond to treatments.
Short-term outputs from the project will be mostly in the form of new scientific information regarding how the cardiac disease progresses and new ways of targeting cardiac cell injury. These will be presented in the form of peer-reviewed scientific publications. Other research groups studying cardiac diseases and pharmaceutical companies developing therapies will be the immediate beneficiaries of these findings.
Medium-long term outputs expected of the project mainly include information obtained from studies using currently available therapies - where the refinement of current treatment methods is aimed for. The data from these will also be presented in scientific journals and may translate into modifications in clinical practice benefiting patients directly.
A decrease in cardiovascular morbidity and mortality in different disease settings can translate into substantial cost benefits to the NHS. Thus, the major beneficiaries in the long run are the healthcare network who can provide better care at reduced costs and most importantly, the patients who receive optimum personalised treatments positively impacting their quality of life.

How will you look to maximise the outputs of this work?

We will try to maximise outputs from our project by

1. planning the experiments such that maximum amount of data can be obtained while reducing number of animals used - e.g., using non-invasive techniques (such as echocardiography) to obtain important information on cardiac function as well as collecting tissue samples for biochemical analysis at the end of experiments

2. collaborating with other groups who carry out research in similar fields so as to optimise experimental protocols and avoid unnecessary repetition of experiments

3. collaborating with other groups who may be able to obtain data from the same animals - e.g., in experiments involving diabetic animals, other research groups interested in pancreatic cell function may be able to obtain tissue samples of interest in their research

4. publication of all important data (both positive and negative findings) from the research in peer reviewed scientific journals - regardless of the immediate impact on existing scientific knowledge in the field

Species and numbers of animals expected to be used

- Rats: ~5500
- Mice: ~5500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are planning to use rats and mice in our studies because;

- These species exhibit anatomical, physiological and genetic similarity to humans
  The small size, ease of maintenance, and short life cycle offers the advantage of studying the different
-

phases of disease processes within much shorter time span

- Heart attack can be induced and the resulting damage to heart muscle can be assessed with accuracy and ease

- Heart function can be maintained by perfusion with crystalloid buffers, allowing examination of factors that are altered within the heart in the absence of external influences

- Reduced collateral blood supply in the heart - reduces the variability in the results between animals and thereby reducing the number of animals used in each experiment
- These animals can be genetically modified to express diseases that are seen in humans (e.g., diabetes kidney disease). This will provide a good model to understand how these diseases affect heart and to improve the use of currently available heart medications in patients who often also suffer from such diseases.

- These animals can be genetically modified to express proteins that are shown to be relevant to the development of heart disease or relevant to rescuing the heart from injurious insults like heart attack. This will provide a good model to test new treatment targets leading way to new drug development.

In experiments, where the immediate effect of a treatment on heart muscle function and injury, young adult animals will be used and they will be used in experiments under anaesthesia and humanely killed while still under anaesthesia - the tissues from these animals will then be used to obtain relevant information.
In experiments where the long-term effects of treatments and/or other diseases are to be studied, young adult animals will be treated with different medications or disease-inducing factors; maintained for duration sufficient to observe the effect of these treatments and then used in experiments. These animals will be monitored at regular pre-specified intervals to ensure that the relevant experiments are carried out at the correct stage of disease and the animals do not suffer unduly.
Aged animals may be used in both the above types of experiments, as a way to understand how and why the aged heart responds differently to heart injury and treatments.
Animals with changes in protein expression or harbouring disease-causing mutations will be obtained from established commercial suppliers and if possible bred locally. These will be checked to ensure the presence of desirable gene changes at the time they are weaned as pups and then let grow normally until they are young adults or aged before being used in experiments as stated before.
The choice between mice and rats will be based on the desirability of gene mutations in the study design. The commercial availability of large number of transgenic mouse models with gene expression changes desirable for studies involving cardiovascular disease makes it a desirable species to work with. Despite this, the relative larger volume of blood and tissues from rats makes them ideal for experiments involving repeated blood sampling for circulating marker measurements. Also, the recent development in inducing gene expression changes in rats may help decide the species chosen for each study protocol.

Typically, what will be done to an animal used in your project?

Breeding protocols - Mice will be mated and maintained under ideal conditions of housing. The litter of pups obtained will be checked for presence of the gene mutation and the randomly assigned to experimental groups. In some cases, these mice may receive pre-treatment with drugs that can modify their response to subsequent heart attack.

Tissue studies - Part of our work involves collecting tissues from animals and analysing these for different markers of injury and drug. In these studies, the animals may or may not receive treatment with drugs before or during heart attack; with the corresponding effects observed in tissues collected. The animals will be deeply anaesthetised (terminal anaesthesia) before inducing heart attack for a specific duration and then collecting the tissues. These experiments are particularly important to see any early harmful effects of treatments with respect to how the heart function when subjected to the injurious insult. Only after a beneficial effect or absence of

harmful effect at this point is confirmed that the treatment can be tested in a long-term recovery model (as stated below). An additional advantage of this model is that a lot more information can be obtained from the different tissues we collect from each animal.
Whole animal studies - Once the early/immediate phase of injury has been studied, the findings will then need to be extended to the whole animal model which sustain heart attack, survives with some heart injury and then goes on to develop heart-failure. This is particularly important if we want to take any promising intervention to the next step of clinical application in humans. In these experiments, the animals may receive treatments before, during or after the heart attack procedure, which will be done under deep anaesthesia. The animals will be allowed to recover after the heart attack, the pain being managed using pain medications as in humans. The duration of these experiments will range from a few days after the heart attack procedure to up to 4 months. The duration will be decided based on the extend of complications of heart failure we need to see in order to meet the study objective. In some of these studies we will use animals harbouring diseases like diabetes and kidney disease. This is especially important since the human patients who sustain heart attack often present with many more disease and health concerns in addition to the heart disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will be used in experiments deemed absolutely necessary, based on initial data from nonanimal models. In a few experiments animals may be treated for a defined period of time with drugs which are already being used in patients, or in preclinical/clinical trials. Hence the safety, dose, and the methods of treating animals with these drugs are well-documented. This will help design experiments taking into account possible non-desirable side effects and effective management of the same. Although most of the drugs used are not expected to cause adverse reactions at the concentrations intended, the animals will be closely monitored and necessary steps taken to ensure their well-being.
- The severity limit set for the different procedures ranges from ‘Non-recovery’ to ‘Severe’. All the animals will be observed regularly for food and water intake, general features of discomfort (e.g. starey (puffed-up) coat, hunched position, lethargy, reluctance to move, isolation from the group, self-harm, changed nesting behaviour) and weight loss (maximum 20%). If these symptoms develop, the animals will be humanely killed.

Experiments using animals in this project involves administration of drugs and monitoring their effects on body tissues. These can be broadly classified into two:
- Non recovery – experiments carried out under general anaesthesia; deep anaesthesia will be maintained throughout the duration of experiment followed by a final overdose of anaesthetic to kill the animal without waking it up from the experiment. This method is not expected to cause any suffering as the entire protocol is carried out under deep anaesthesia.

- Recovery – experiments carried out under general anaesthesia; deep anaesthesia will be maintained throughout the duration of experiment. Upon completion of the experiment, animals will be allowed to recover from anaesthesia. These animals will be under continuous observation until they become fully mobile and start to feed and drink; which normally happens in the first 3hrs after completion of procedure. In animals undergoing heart surgery, wherein the chest cavity is opened, surgery performed and the wounds closed surgically before recovering the animals from anaesthesia, effective pain relief by medication will be provided to ensure that the animals are not in pain while recovering from the procedure and in the days thereafter.

Further, we also undertake studies on animal models with diseases such as diabetes, kidney disease and chemotherapy-induced heart failure. In these animals, the severity is due to the disease severity - a factor we need to include in our experiments so as to make any new findings applicable to the wider human patient population.
The animals will be killed by humane methods after the experiments and tissues of interest collected for further studies, making maximum possible use of the animals. At all points in time either during maintenance of the animals or during experiments or afterwards all possible steps will be taken so that animals do not suffer unnecessarily. Where the pain/suffering is not transient (occurring within the duration of recovery as a result of

the procedure undergone) and cannot be resolved by pain-relief medications, humane methods of killing will be used to end suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - **Mild** severity (~20% in breeding experiments, <25% in tissue studies or non-recovery experiments, ~50% in diabetic mice), **Moderate** severity (<5% in kidney disease models, ~5% in diabetic animals), **Severe** effects (~5% in diabetic animals, ~15% in recovery/whole animal models, ~10% in chemotherapy studies).
Rats - **Mild** severity (<25% in tissue studies or non-recovery experiments, ~50% in mutant diabetic rats), **Moderate** severity (<5% in kidney disease models, ~5% in diabetic animals), **Severe** effects (~5% in diabetic animals, ~15% in recovery/whole animal models, ~10% in chemotherapy studies).
All the remaining animals will fall under the category of **Non-recovery** (i.e, no procedure afflicting painful, distressing or harmful effects has been carried out in these). Additionally, the animals used only for breeding purposes will not be used for any other experiments and therefore categorised under **Subthreshold** severity category - unless unexpected suffering observed, in which case the animal will be treated to minimise suffering and severity category recorded appropriately.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 05 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to help heart survive better after a heart attack and to treat heart disease in patients with other co-existing diseases. The overall aim is that the findings will help improve treatment options for all patients regardless of their general health status. Such personalised medicine will improve the quality of life in the long term in these patients. Our initial ‘proof of concept’ experiments will be carried out on experimental models of non-animal origin. These models include cell lines - cells available commercially and grown in the laboratory, and also cells and tissue samples from human volunteers. Based on this pilot data, experiments that show promising results will have to be confirmed in more complex biological systems similar to the human heart and whole body before the treatment can be tested in patients. Since these studies cannot be carried out in humans until more information on the safety and effectiveness of the treatment is available, experimental models of animal origin have to be used. Among animal-based work, we initially use the isolated heart and cell models (which are of lower severity), and also get relevant additional information from other tissues from each animal. This will help to increase the output from each animal used. The studies will then be expanded to the whole body and recovery models (higher severity) only if positive results are obtained in the initial animal experiments.

Which non-animal alternatives did you consider for use in this project?

In vitro non-animal models -

Includes single types of cells, co-culture systems, cardiac tissue slices (organotypic heart slices), microphysiological systems like organ-on-a-chip and organoids - maintained in culture. All of these can be specialised by using cells or tissues obtained from patients with specific disease type. These can be useful in replicating the disease phenotype, validate possible genetic differences while comparing tissues from groups of patients who are more susceptible to disease or adverse reaction to certain drugs compared to other patients. These properties make in vitro models involving cells and tissues from humans ideal in drug toxicity and safety testing and to a certain extent can also help understand the interaction between different cells within the same organ (e.g. organotypic heart slices) and between limited number of organs (human-on-a-chip, where different compartments containing cells from different organs are maintained).

Ex vivo tissues from humans -

Tissue biopsies can be obtained postmortem or from live human patients (with prior consent) during cardiac surgical procedures. These may be a good alternative to tissues obtained from animals subjected to interventions so that they develop disease phenotype.

Why were they not suitable?

In vitro models - We do use *in vitro* cell cultures, specifically immortalised cell lines from humans or animals in our preliminary experiments. We also use tissues from consenting patients whenever possible, however the usability of these tissues is greatly restricted by the short duration within which the experiments need to be carried out. These tissues are usually obtained from patients with heart diseases and due to lack of blood flow within the tissue after excision, the core of the tissue dies with time rendering it unusable in subsequent experiments that require prolonged incubation with test drugs.
While the cell and tissue biopsy models are ideal to test the 'proof of concept' or 'test the effect' studies, these do not replicate the complexity that is seen within the intact human heart - be it in terms of the structure, the function or how the cells react in the native tissue to injurious insults. In order to achieve this, we will need to test the treatments in intact organs. Although the organoids and organs-on-a-chip seem like an attractive alternative for this purpose, we are not able to use this owing to the following reasons:
Firstly, the technical expertise and facilities required to develop, establish and maintain these are beyond our reach and are prohibitively expensive to set up.
Secondly and more importantly, the premise of our project is to look at how the changes within the whole body affects the heart - in different disease conditions and in response to different treatments, over a period of time recapitulating the duration that it takes in human body.
The human-on-a-chip, at its current state is still limited by the absence of all the neuronal and blood borne factors that keep changing in response to the different bodily and environmental cues - for e.g., disease states, diet types, medications, physiological stress, gender differences, diurnal variations - to name just a few.

So, although we use *in vitro* models to obtain as much pilot data as possible and are an essential part of our overall research programme, we will need to rely on animal models when it comes to confirming our findings in the complicated biological system - that is the working heart complete with the circulatory and nervous systems that conveys signals between the heart and the rest of the body.
A retrospective assessment of replacement will be due by 05 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animals will be assigned to experimental groups randomly, as appropriate and necessary, and blinding of data prior to analysis will be done so as to prevent bias and ensure best research practice. Appropriate statistical tests will be used as applicable to the study design. The number of animals required in each experiment will be determined by statistical analysis - based on expected effect size of each output/data (pilot data), significance threshold set at 5% and at a statistical power of 85%. The statistical analysis used will be based on the number of factors studied in each animal (single factor, multi-factorial or randomized block designs). We use the

Experimental Design Assistant (EDA) available within the NC3R's, to design and arrive at the optimum number of animals required for more complex studies. Based on our previous work, we expect ~80-85% success rate considering all proposed protocols. This has been factored in while estimating the number of animals required for the different protocols. However, a considerable number of animals are expected to be common to one or more protocols. Hence, taking into account the number of different treatments we want to undertake in our research, the different experimental models that will be used in arriving at useful, reproducible, clinically relevant information, we have arrived at the number stated above for a project duration of 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whenever possible, we undertake small scale pilot studies to estimate the size of change in the measured parameter(s) as an indicator of expected biological effect. If the effect is too minuscule to be of any clinical/biological relevance, then the study using that particular treatment modality will be discontinued. If the results are suggestive of clinical importance, but need further validation, then we plan studies involving animals. In this phase of planning and designing animal experiments, we use different guidelines/tools - For example, the (https://norecopa.no/media/7864/prepare_checklist_english.pdf); the 3Rs resources and the NC3R's Experimental Design Assistant (EDA). The PREPARE checklist provides us a framework to ensure we have closely considered all required factors including available literature in the field and the novelty of our own preliminary findings - so as to avoid unnecessary repetition of research and animal use. EDA helps design the study considering the different treatment groups, interacting/affecting factors and also suggests the number of animals required for obtaining robust, reproducible and statistically significant data. It also suggests the appropriate statistical tools that can be used for subsequent analysis of results.
In addition to the EDA, we plan to enlist support from the institute's statistics experts for calculating the number of animals prior to large-scale animal studies. For simple two group studies, we use online statistical tools or software like G*Power or ClinCalc.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To reduce animal use we will:

- Use alternative methods that do not rely on use of animals wherever possible - e.g. non-animal derived models in preliminary experiments.

- Using pilot data from non-animal studies to assess the need of extending the investigations to animal models.

- Plan experiments using minimum statistically relevant number of animals.

- Use of experimental techniques that will give maximum amount of data from least possible number of animals (e.g. using whole heart, aortic ring, blood and other tissues from same animal)
.
- Use viral vectors for mutagenesis – reduces (by at least half, if not more) the number of mice bred to produce transgenic strains
.
- Careful experimental planning to include the minimum required number of animals in experiments without compromising the quality of results - e.g. repeated cardiac imaging of animals to examine changes in heart structure and function with time
. This will reduce the number of animals needed to study all the time points and also will avoid variations that may be present between the animals.
- Regular monitoring of the experimental activity in the lab by the project licence holder and experienced senior scientists to ensure high quality of research and optimum use of animals.

A retrospective assessment of reduction will be due by 05 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and mice will be used in this project as it is easy to measure extent of damage to the heart and experiments can be performed in a controlled manner
. Rats and mice with diseases similar to human conditions (for e.g. diabetes) will also be used in the project for studying heart disease in a setting similar to human diseases.
The study will use protocols where the animals are terminally anesthetised and tissues collected for further investigations. These methods will cause no pain, suffering, distress or lasting harm and will be the mildest amongst all the procedures in the project. In other experiments, animals will have to be subjected to cardiac surgery under anaesthesia and then recovered for a specific duration of project to study the effects of treatments on the heart. In these studies, unfortunately, occurrence of pain and suffering in the initial duration after surgery is unavoidable. To reduce the pain and suffering, the animals will be provided with pain medications at appropriate dosage and monitored regularly to ensure that there is pain relief. If these steps do not remedy the suffering, then advice will be sought from the Named Veterinary Surgeon on other possible measures, failing which the animals will be euthanized.
As refinement to techniques used during the study, we aim to

- assess cardiac function/infarction using minimally invasive techniques (MRI, Echocardiography)

- for studies involving genetically modified animals, we plan to use ways of inducing genetic changes that will greatly reduce the number of animals used (viral vectors for transgene induction)

- use drug-filled minipumps implanted under the skin for chronic drug administration. The process of implanting minipump itself does not cause any suffering, since this is done under anaesthesia and the region chosen for implantation is such that the process can be achieved with the smallest of openings on the skin and the implanted mini pump will not interfere with any regular activity

- use microsampling techniques (tail vein prick) for assessing diabetes in animal models. This will be done in animals fed normally, avoiding stress due to overnight fasting and also less harmful compared to cannulation of vein where larger volumes of blood may be lost

- use drugs for developing obese/non-obese diabetic models with different disease severities in a much shorter duration than genetic models; minimises suffering especially in studies addressing effect of diabetes and age on heart

Heart disease affects the long-term survival and quality of life in patients. To help provide better treatments for the varied patient population, it is important to have a better understanding of how the heart disease itself and heart's response to treatments is affected by different disease states. For this purpose, we will need to use animal models with diseases like diabetes followed by induction of heart attack. Unfortunately, no available non-

animal alternative is able to replicate all the complex responses that are seen in a whole animal model as this. We will ensure that the minimum necessary level of clinical symptoms are evident in these animals and not to the extent that it causes severe harm.

Why can't you use animals that are less sentient?

The development of cardiac disease has strong association with the aging process and the presence of cardiovascular risk factors such as high cholesterol. It has been shown that the incidence of these in juvenile/ adolescent or young humans is very less unless the disease is due to a genetic condition. It is also known that the hearts of young humans are more resilient to injurious insults compared to the adults and the aged. We find similar differences between cardiac cells prepared from neonate rats/mice versus that prepared from adult animals. The neonatal cells are different from the adult cells not only in their appearance, but also in their susceptibility to injury and general functional properties. Considering these and also the fact that our research is aimed at translation into the clinical setting where the vast majority of patients are adults with other disease states, we use mostly adult/aged animals in our studies. Where parallels can be drawn to clinical conditions in the young - for e.g. childhood survivors of cancer developing heart failure, we may use juvenile animals to mimic this disease of the young.

In order to keep the animal suffering to a minimum, wherever possible in our studies, we use animals that are terminally anaesthetised.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Refining experimental skills: In addition to the training undertaken for obtaining personal licence, new members of the research team will be trained, supervised and guided by more experienced investigators in all aspects of animal research including designing experiments, handling animals, recognising signs of pain, suffering, lasting harm and distress; and sacrificing animals by humane methods when necessary.
- Researchers will be assessed for competency before being allowed to carry out experiments on animals.

- Where animals are to be subjected to repeated experimental interventions (e.g. blood sampling at regular intervals in diabetic animals), the animals will be conditioned to the repeated handling by the same researcher or team of researchers - this will reduce the stress associated with the unfamiliarity towards the researchers.

- The researchers will be encouraged to adhere to the least stressful procedures for the animals, where possible. For example, microsampling of random blood glucose by tail vein prick will be carried out for routine glucose level checks as opposed to overnight fasting (for fasting glucose levels) and invasive blood vessel cannulation.

- At all instances special care will be taken to prevent and reduce animal suffering caused by the experiments. In experiments known to cause some degree of harm, the researcher will work closely with the animal care team ensuring that the general body condition and any signs of stress are recorded and remedial steps taken as soon as possible. To this end, a body condition score sheet will be made available on which all findings are recorded.
- We will work closely with the Named Veterinary Surgeon (NVS) and the Biological Services to help us refine our procedures and also for advice while planning new procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

<u>For general guidance on compliance to best practice in conducting and reporting research on animals:</u>

Guidance on the operation of the Animals (Scientific Procedures) Act 1986

Legislation for the protection of animals used for scientific purposes Directive 2010/63/EU as amended by Regulation (EU) 2019/1010
Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE) guidelines
Animal Research: Reporting of In Vivo Experiments (ARRIVE) guidelines

For choosing appropriate models of cardiovascular disease:

We will use the established models available in peer-reviewed publications, as appropriate to answer the questions we are trying to address - with refinements/ updates implemented if it supports the 3Rs. (E.g., Lindsey ML, Bolli R, Canty JM Jr, et al. Guidelines for experimental models of myocardial ischemia and infarction. Am J Physiol Heart Circ Physiol. 2018;314(4):H812–H838. doi:10.1152/ajpheart.00335.2017)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in 3Rs by keeping track of refinements in techniques published in the literature and also by discussions with other research teams undertaking similar techniques and experiments. In our experience, we have found that involving the animal care technicians, the Institute's Animal Welfare Officers and the Named Veterinary Surgeon in the experimental planning phase is extremely helpful in implementing small but significant refinements to our procedures resulting in considerable improvement in animal experience. This may be as small a change as the bedding material to as significant as changing the route of drug administration and improving post-treatment monitoring. Additionally, we will make use of information available in resources such as NC3R's website to identify useful modifications with the view of refining and replacing animal use in research.
A retrospective assessment of refinement will be due by 05 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

59. Extracellular matrix mediated control of immune cell recruitment and positioning in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Leukocyte, Migration, Inflammation, Brain, Extracellular Matrix

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how extracellular matrix structures and inflammatory agents work together to regulate recruitment of immune cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Movement of immune cells from the blood to tissues is important in allowing us to fight infections by bacteria and viruses. However, movement of immune cells is also central to problems associated with a wide range of diseases including inflammatory arthritis, atherosclerosis and cancer.

The extracellular matrix is a network of factors (proteins and sugars) released by cells to provide scaffolds which provide structure to tissues. We are now beginning to understand that the extracellular matrix plays a more specific and dynamic role in biological processes beyond simply being a structural support.

Specifically the extracellular matrix lines blood vessels and forms a barrier called the glycocalyx. The glycocalyx is critical in controlling the ability of immune cells to leave the blood, a process that is vital in fighting infection. The role of this glycocalyx extracellular matrix barrier has been overlooked and a more complete understanding of this process will allow us to understand how immune cells are recruited during disease. Once we better understand this process we can develop drugs to treat and limit immune cell recruitment and help treat people with a wide range of diseases.

This project will define how these processes work during the body's normal response to inflammatory stimuli, e.g. infection. In the longer term these findings can be used to understand how these processes go wrong in disease, e.g. rheumatoid arthritis.

What outputs do you think you will see at the end of this project?

The main outputs of this project will be new information explaining how immune cells are recruited to fight infection and also during inflammatory based diseases.

In the longer term these insights will drive development of new ways to control immune cell recruitment and produce new drugs.

This knowledge will be critical to understanding and finding new ways to treat patients with autoimmune diseases, such as rheumatoid arthritis, and vascular diseases, such as atherosclerosis and cancer.

Who or what will benefit from these outputs, and how?

This project will investigate how the extracellular scaffold (glycocalyx) helps to control the immune system response to infection. Importantly, this includes the positive elements of the immune system allowing us to fight infections, but also diseases where the immune system goes wrong. The chemokine system controls the movement of immune cells from the blood to tissue, vital for fighting infections but also important in inflammatory based disease. We have previously failed to make drugs that target the chemokine system during inflammatory diseases. Inflammatory diseases remain a key hindrance to quality of life and health in the UK and globally.

This project will also produce findings that will help to improve the use of a new approach where the thickness of the extracellular matrix barrier (glycocalyx) is being used to diagnose disease and decide on the best treatment approach.

The same mechanisms of recruitment studied in this proposal also play a role in cancer cell metastasis and tumour survival.

How will you look to maximise the outputs of this work?

The data generated, both positive and negative, will mostly be suitable for sharing via publication or by being uploaded to publicly accessible data repositories.
Any outputs will be assigned a digital object identifier (DOI) to facilitate sharing and accessibility of them.
Outputs beyond traditional publications may include video demonstrations of our validated protocols that would be of use to the wider community.

Species and numbers of animals expected to be used

- Mice: 1700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are chosen as they have been used in related approaches, paving the way for my research and providing vital details that will inform our design and understanding of this work.
Using mice for this proposal will enable comparison with existing knowledge and allow future development of drugs based on our work.

The life stages chosen will be to undertake experiments on mice at the adult stage of development. This will allow comparison to previous work which was done on adult mice.

Typically, what will be done to an animal used in your project?

In the first experimental approach animals with have an air pouch produced by injection of sterile air under the skin, while the animal is anaesthetised, on 3 separate occasions, each 48 hours apart to allow recovery. Reagents will be injected into the air pouch to induce and/or inhibit immune cell recruitment and the animal will be humanely killed.
In the second experimental approach animals will undergo surgery to implant a glass window over the skull, before injection of reagents to promote and/or reduce immune cell recruitment and to label the endothelial glycocalyx and immune cells.

What are the expected impacts and/or adverse effects for the animals during your project?

Air pouches are made while the animals are anaesthetised and they display minimal adverse effects. Injection of reagents to induce immune cell recruitment may cause low levels of inflammation over the next few hours, however, the mice do not display signs of discomfort.
Cranial window implantation, imaging and induction of immune cell recruitment are performed under anaesthesia, as a result animals have few associated adverse effects. Local bleeding lasting no more than minutes is possible during surgery to implant the cranial windows and weight loss (1-4 days) after surgery is also

possible, but the animals will recover quickly.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity of breeding is mild.
The expected severities of the experiments are moderate and will consist of 100% of the animals involved.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently there are no good cellular models of the glycocalyx, partly because we do not have a good understanding of the glycocalyx structure in live animals. Thus, it is essential to do these measurements in live animals
It is not possible to replicate the complexities involved in immune cell recruitment using cell-based assays, therefore, these experiments must be undertaken in live animals.

Which non-animal alternatives did you consider for use in this project?

The first alternative to be considered are cell-based models of immune cell migration, including transwell and adhesion under flow systems. Transwell systems monitor the movement of purified immune cells in a plastic dish. Adhesion under flow systems analyse movement of immune cells in the presence of mechanical flow produced by a machine, this models the effect of blood flow.
We have used these approaches, in combination with biophysical experiments, to screen mediators of immune cell movement that can interact with components of the glycocalyx. These approaches have been used to screen for reagents that can interfere with these interactions and possibly inhibit immune cell recruitment and will be continually used to reduce the number of animals used.
Another consideration is the developing field of organoid cultures to recreate live animal conditions. These are simplified and miniaturised models of organs produced in vitro.

Why were they not suitable?

Following on from biophysics and *in vitro* cell models it is now vital to use *in vivo* approaches.
Neither of these systems (or organoids) can replicate the glycocalyx. We do not have a complete understanding of the glycocalyx structure at different parts of the blood vessel system, this must first be established to allow comparison for cell-based studies.
The complexity of immune cell recruitment cannot be recreated in cell-based experiments. The air pouch model and live cranial window imaging approach both allow analysis of the role of the glycocalyx in immune cell recruitment.

Our findings will help to try and inform development of better non-animal model systems for these processes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

From analysis and consultation with a statistician and use of the National Centre for the Replacement, Refinement and Reduction of Animals in Research experimental design assistant ('NC3r's' EDA) has been used to calculate the number of animals needed:
Glycocalyx structure at rest and following treatment with mediators of immune cell recruitment using 30 individual experiments, each comparing a control and a treatment group.
Immune cell recruitment analysis, consisting of 20 experiments comparing a control and treatment group.
Analysis of glycocalyx content, consisting of 15 experiments.
Analysis of the effect of changing glycocalyx content (sugar chemistry) on immune cell recruitment, 3 different sugar chemistries and 3 different mediators of immune cell recruitment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible multiple read-outs will be measured in the same experiment, e.g. glycocalyx structure before and after treatment with a reagent that produces immune cell recruitment.
The 'NC3r's' experimental design assistant has been used, and will continue to be used, to determine the minimum number of animals to provide sufficient power to analyse relevant effects sizes of treatments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where necessary breeding will be designed to produce the number of animals needed and experiments will be undertaken on animals bred to optimise the number of animals used in this project.
Pilot studies will be undertaken when starting new experiments to inform experimental design, i.e. power calculations, again optimising animal use. Where possible these will be informed by cell-based analysis.
A continued effort will be made to share tissue from experimental animals. In particular it may be possible to undertake analysis of the glycocalyx from tissue from animals which have been humanely and also from tissues following systemic treatment with mediators of immune cell recruitment. Tissue from experiments analysing the glycocalyx in the brain blood vessel system may allow analysis of the glycocalyx in other tissues as well and inform future studies by ourselves and others.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques

during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The air pouch and cranial window approaches will be run separately but the data from both, in combination, will allow analysis of immune cell recruitment and the role of the glycocalyx using the minimum possible pain, suffering, distress or lasting harm to the animals involved.
The air pouch model will firstly be used to screen the numbers and types of immune cells recruited in response to different reagents and for compounds that may inhibit this process. This reduces the need for the more invasive cranial window approach, that involves surgery, thus acting as a refinement by using a less invasive experimental approach.
Implanting cranial windows involves surgery but is the only way to simultaneously directly image the glycocalyx and immune cell recruitment within a tissue. Thus the associated pain and suffering is the least possible to achieve this outcome.
Both involve moderate severity and direct glycocalyx analysis (via cranial windows) will be undertaken whilst the animal is anaesthetised. In the majority of cases mediators of immune cell recruitment, that may produce some inflammation in the animal, will be administered whilst the animal is under terminal anaesthesia.

Why can’t you use animals that are less sentient?

Our knowledge of the production and relevance of the glycocalyx is uncertain beyond its existence and importance to inflammation. For this reason analysis must begin in adult mice where we know the glycocalyx is formed, regulates immune cell recruitment and replicates effects seen in humans in health and disease.
Where possible glycocalyx imaging experiments will be undertaken during terminal anaesthesia. The only exceptions will be unavoidable as they will involve analysis of the glycocalyx over time and therefore the same animal must be analysed then allowed to recover before further anaesthesia and glycocalyx analysis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring of all animals will be continually undertaken as described alongside all possible postoperative care and pain management.
Refined handling technique will be utilised throughout, all operators will be highly skilled and/or continually trained and updated with the latest refined approaches, e.g. handling.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All relevant NC3R's guidance and updates will be engaged with, including sign posting to published studies, e.g. FRY, D. 2014. Chapter 8 - Experimental Design: Reduction and Refinement in Studies Using Animals. In: TURNER, K. B. V. (ed.) Laboratory Animal Welfare. Boston: Academic Press.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Continued engagement with the NC3R's resources will be undertaken. In particular continued use of the experimental design assistant (NC3R's EDA) will facilitate regular assessment of the 3R's and recent developments whilst also enhancing experimental design.
Attendance of workshops organised by the animal facility will be undertaken as well as continued consultation with staff at the facility.

NON-TECHNICAL SUMMARY

60. Extracellular regulation of insulin response and tissue function

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Diabetes, Insulin resistance, Obesity, Extracellular matrix, Glucose and lipid

Animal types	Life stages
Mice	embryo, juvenile, neonate, adult, pregnant, aged
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

Obesity and Type 2 diabetes manifest a defect in responding to the hormone insulin ("insulin resistance") and fail to maintain normal stable glucose levels in the blood. These conditions are among the major health problems affecting western and developing societies and are associated with significant impacts on individual well-being and economic cost to society. The aim of this project is to understand how insulin resistance develops and how we can target it to develop novel therapies for Type 2 diabetes and its associated metabolic conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Conventionally, research into insulin resistance has mainly focused on studying the direct action of insulin on molecular pathways INSIDE the cells. Our recent work has shown that the proteins and molecules OUTSIDE the cells also undergo changes during the development of insulin resistance. Furthermore, when we removed one of these molecules in mice, we found that they had an ability to improve response to insulin, especially in the muscle and fat. This finding opens up an entirely new area of diabetes research and may prove more specific to diabetes than trying to target the inside of the cells.

What outputs do you think you will see at the end of this project?

Today, very few groups work in the area of studying the role of extracellular matrix remodelling in metabolic regulation. I believe that progress in this field will bring novel understanding of the pathogenesis of metabolic dysregulation and will generate a new paradigm involving the extracellular matrix signalling for hormone action and energy homeostasis. These efforts are motivated by public health demands as the prevalence of metabolic-associated diseases has increased to the point that it is in danger of overwhelming the financial and social resources of numerous countries and has devastating and long-lasting consequences for the quality of life of afflicted individuals. This epidemic of nutrient excess driving metabolic and cardiovascular disease will not be resolved without the development of new and more effective treatments.

Our newly funded research on the role of the extracellular matrix in cardiac insulin resistance and cardiac dysfunction will provide important novel insights into metabolic regulation and lead to new therapeutic opportunities for preventing heart failure in patients. Our studies utilising clinical and preclinical anti-fibrotic agents have huge translational potential. If proven promising, these studies will offer new strategies to improve health conditions of patients with diabetes and heart failure.
The final outputs of this project will include new information and publications.

Who or what will benefit from these outputs, and how?

Our study will provide significant benefits to other researchers in the field of obesity, insulin resistance, and metabolic disorders. The proposed study will generate a new paradigm for hormone action. Therefore, the results are highly relevant to all researchers with interest in hormonal regulation (e.g. leptin, glucagon, sex hormones, and steroids). I have a wide-ranging network in the scientific community of groups working on various aspects of metabolic diseases. These colleagues will learn about the results of the project through publications and meetings.

In addition to my primary questions on muscle insulin resistance, this project is relevant to understanding insulin resistance in general as data from other tissues that are important for glucose homeostasis including adipose tissue, liver, and brain will also be generated from the applied approaches. The generation of these data will benefit academics in other disciplines including neuroscience (behaviour, neuro-degeneration), hepatology (liver disease), and cardiology (heart failure), as well as all chronic age-related diseases. The proposed research also employs a wide range of methods including the unique two-catheter protocol of insulin clamp, laser Doppler imaging in mice, and various genetic and pharmacological approaches. These techniques will catch attentions of researchers not only in the basic science, but basic clinical science and scientists in pharmaceutical companies. We will ensure all potential academic beneficiaries are aware of the findings from the study by publishing them in appropriate broad interest, high impact scientific journals, and by presenting the results at national and international scientific conferences.

How will you look to maximise the outputs of this work?

For the academic audience of the project, the results of the research will be published in high quality peer-reviewed journals and presented at scientific meetings. The research findings will also be disseminated to the general public via outreach activities. For example, research results will be available to the members of the general public through public presentations, media, e-Newsletters, and multimedia releases. The outreach activities will be achieved through a specialist public engagement and innovation service at the establishment. We will also engage with contacts in the pharmaceutical industry through meetings and invited talks. We have strong pharmaceutical industry links with internationally respected partners, with which translating our research into practice will be greatly facilitated. I have extensive experience in oral presentations at conferences and have previous experience in working with industrial companies, which will enable the full success of my communication plan.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Genetically altered mice and mice that are treated with substances known or suspected to alter glucose metabolism will be studied in this proposal. Approximately 3000 mice will be bred, and 2000 might undergo further regulated procedures, over 5 years. The proposed research will provide significant benefits to other researchers in the field of obesity, insulin resistance, and metabolic disorders. The proposed study may generate new insights into how hormones like insulin actually work. These might, in future, lead to new and effective treatments for diabetes and its related metabolic disorders.

Typically, what will be done to an animal used in your project?

Animals may be on a special diet or receive drug treatment to intervene metabolic regulation and energy balance. For the measurements of metabolism and cardiovascular function, animals may undergo surgical procedures for the access of major blood vessels or the left ventricle of the heart. Animals are usually put on a special diet at 6-7 week old and the final metabolic measurements are performed at 23 week old and followed by a humane end point.

What are the expected impacts and/or adverse effects for the animals during your project?

The genetic alterations themselves are not expected to cause adverse effects but may influence whether the mice become diabetic (e.g., after being fed a high-fat diet). Diabetes in mice is often first suspected when the animals' water intake (and output of urine) increases. It can then be confirmed by a blood test. Close observation of the clinical condition and body weight will then ensure that animals are killed humanely while these deviations from normal welfare are still moderate. Tissues will be collected post mortem for further laboratory analysis.

Survival surgeries (e.g. vascular cannulation and implantation of minipump and telemeters) may cause pain and weight loss. Animals will be continuously monitored post-operatively and have their weight monitored at least daily. Analgesia will be administered as advised by the NVS. These adverse effects are expected to be temporary and their weight returns to pre-operative weight within a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding and maintenance of genetically altered mice are expected to cause no pain, suffering or distress (Sub-threshold). A small proportion of these mice (<5%) may develop clinical signs of diabetes (Mild to Moderate). Survival surgical implantation of vascular catheters may cause a short term moderate pain (Moderate). Close observation of the clinical condition and body weight will ensure that animals are killed humanely when deviations from normal welfare are not improved with remedial. The estimated proportion of severities are: 40% Sub-threshold, 40% Mild, and 20% Moderate.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The mechanisms by which animals (including humans) regulate their body weight, glucose levels and fuel storage/energy expenditure are complex and involve the interplay of multiple organs (e.g. muscle, liver and fat) and pathways. These cannot easily be mimicked in vitro. For example, an antiobesity/anti-diabetic effect can really only be assessed properly by examining intact animals. The mouse is our best alternative species currently available for genetic manipulation and for the analysis of metabolism and metabolic pathways that mirror that observed in humans (particularly in relation to diabetes and obesity).

Which non-animal alternatives did you consider for use in this project?

In vitro cell culture systems (e.g. C2C12 mouse myoblast cell line, 3T3-L1 adipocyte cell line, and H9C2 rat myoblastic cells) have been considered and will be used to further understand the signalling pathways of a gene product which has been shown to play a significant role in glucose homeostasis in vivo. Moreover, computer simulations will be applied for mimicking functions of physiology or for the purpose of training protocols when available.

Why were they not suitable?

While these studies will provide insight into the basic cellular mechanisms behind glucose transport, extramyocellular factors involved in the control of glucose uptake (e.g. glucose delivery to muscle) are necessarily absent. Moreover, glucose uptake by isolated muscle preparations is extremely resistant to insulin (requiring suprapharmacological insulin levels) and contraction (requiring extremely high intensity contraction). It is likely that in some instances the rates of glucose uptake in vitro do not become high enough to test the glucose phosphorylation capacity of muscle.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This number is estimated based on the number of animals used in the current active project licence of the applicant and the trajectory of the research activity in the group in the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the experimental design phase, online tools (e.g., the NC3R's Experimental Design Assistant) and local advice will be used to inform the appropriate design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Several methods will be applied to optimise the number of animals in the project.

- Pilot studies will be used to estimate variability and evaluate procedures and effects.
- Power calculation will be applied before and throughout the experiment to reduce the number of animals.
- Sharing of tissues between studies and projects will be considered whenever possible.
- Computer simulations will be applied for mimicking functions of physiology or for the purpose of training protocols when available.
- Efficient breeding and the use of quality animals and veterinary care will be applied to decrease variability, avoid unintended breeding and loss of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically manipulated mouse models combined with dietary intervention and pharmacological approaches will be used during this project. Adverse effects are not expected from the generation of these models and therefore these should not cause pain or stress.

Metabolic phenotyping methods including tolerance tests, calorimetry, vascular cannulation and the clamp experiments etc will be used for functional tests. Adverse effects are thoroughly considered and will be controlled and limited as explained in the earlier sections.

Why can’t you use animals that are less sentient?

The project aims to investigate mechanisms by which humans regulate their body weight, glucose levels and fuel storage/energy expenditure during adulthood. Therefore, animals at a more immature stage won't be suitable.

It is necessary to use mice for these studies because this species has been extensively used as a model organism in the understanding of human metabolic diseases. Importantly, gene targeting technology and dietary manipulation is widely available for the mouse and thus allows investigators to precisely establish casual relationships between genes and biologic processes. In order to determine the role of extracellular matrix remodelling on in vivo regulatory systems (e.g. muscle insulin sensitivity) associated with obesity, it is necessary to use mouse as the model species.

Terminally anaesthetised animals are not ideal for many of the non-invasive metabolic tests including tolerance tests and calorimetry tests. Moreover, it is widely understood that anaesthesia has a major impact on metabolic regulation, which will most likely cause more variation and make interpretation of data difficult.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As aforementioned in the earlier sections, refinements include increased monitoring (e.g. immediate after the surgery, frequent checks will be made for the first 2 hours, then approximately every 4hrs including hours beyond 9am-5pm, or more frequently if so advised by the NVS, until condition stabilized), post-operative care (e.g. placing the animals on a heating pad during surgery and in a warming cabinet during recovery, until normal motility resumes), and pain management (e.g. analgesia will be administered as advised by the NVS). With regard to the infection, the use of antibiotics to treat apparent infections, or prophylactically in the case of any

immuno-compromised animals, will be as advised by the NVS, and training of animals (e.g. animals will be acclimatised for single cage housing prior to calorimetry studies, and animals will be acclimatised to the treadmill by initially placing mouse in the treadmill without the motor turned on followed by being habituated at walking pace (5m/min) for 10min) will be used to minimise the welfare costs for the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE guidance will be followed to ensure experiments are conducted in the most refined way. In addition, research publications in the area will be closely monitored and followed to ensure any advances in the techniques implemented.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Updates from the NC3Rs will be regularly checked by monthly newsletters. The Laboratory Animal Science Association (LASA) is another good resources for access to policy updates, support and guidance relevant to laboratory animal science, and regular sector news, training and events information through LASA’s newsletter and conferences.

Home Office

NON-TECHNICAL SUMMARY

61. Feed conversion efficiency and methane emissions in cattle and sheep

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
    - (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Feed efficiency, Methane emissions, Rumen microbiome, Ruminants, Methane mitigation

Animal types	Life stages
Cattle	adult, juvenile
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall project aim is to increase feed conversion efficiency (FCE) and reduce the environmental impact from cattle and sheep by providing tools and an improved understanding of mechanisms to underpin the development of breeding programmes and novel (precision) management strategies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Feed is the largest single cost in cattle rearing and lamb production systems, so reduced feed consumption (for the same amount of weight gain) will lead to increased farm profitability and reduced food costs. A reduction of £100 in feed costs for a finishing beef animal would represent up to a £10 million annual saving if there were 5% uptake across the approximately 2 million prime cattle slaughtered in the UK each year. In addition, ruminant production is under continued political and social pressure to reduce greenhouse gas (GHG) outputs, since cattle and sheep contribute to 66% of total UK agricultural emissions (BEIS, 2018). This project will contribute to government targets for reduction in UK emissions of greenhouse gases (net zero by 2045), through targeting direct reduction of methane emissions as well as through reduced feed use resulting from more efficient conversion of feed into products. This project will develop minimally intrusive alternative methods to estimate feed efficiency or methane emissions, and precision management strategies designed to optimise production efficiency and/or directly target methane output.

What outputs do you think you will see at the end of this project?

Outputs from the project will be:

- Data on feed conversion efficiency (FCE) and related/component traits for groups of animals of known genetic background.
- Rumen samples and genotypic information of a large set of animals including those showing extreme phenotypes for FCE.
- Understanding the relationships between FCE and methane emission traits and other animal traits (e.g. animal health, rumen microbial imbalance).
- Understanding diet effects (and novel feed additives) on FCE and methane emissions.
- Understanding the host genetic effects on the rumen microbial genes and communities by estimation of the genetic parameters.
- Cost-effective predictions of FCE, methane emissions, feed intake and growth rate using microbial genes and communities.
- Development of a functional microbial microarray including the most informative microbial biomarkers to predict the genetics of FCE and methane emissions as well as animals prone to rumen dysbiosis.
- Identification of networks and functional pathways of rumen microbial genes impacted by host genomic effects.
- Marker/proxy methods and low-cost instrumental approaches to estimate FCE and methane emissions. These could either be used in subsequent breeding programmes or form the basis of on-farm monitoring

tools to improve nutritional management of cattle and sheep.

- Data to support the development of precision livestock management tools that directly target the measurement, capture (and combustion) of methane from housed-ruminants.

Who or what will benefit from these outputs, and how?

The beneficiaries of this work will include academic scientists, animal breeding companies, farmers, governments, regional assemblies and other policy-makers, climate scientists, environmentalists, animal health and welfare groups and the general public.

Academic Impact:

- The research will reveal the host genomic impact on the rumen microbiome to an extent that has never been achieved before. It will provide considerable contributions to understanding of the host genome affecting the functional and genomic architecture of the rumen microbiome in bovines, with fundamental new knowledge that will also improve our understanding of the microbiome in other ruminant or monogastric species, including humans.

- The results of using rumen microbial gene abundances as selection criteria to genetically improve traits such as feed conversion efficiency (FCE) and methane emissions would provide a blueprint for any other trait potentially associated with rumen microbial information such as animal health and welfare traits or meat omega-3 fatty acid concentrations.

- The host genetic influence on the complex microbiome network and its association with performance traits will give new knowledge about the host genomic control of the rumen microbiome and its impact on performance traits and methane. Because most of the functions of the microbial genes are known, this will provide novel insight into the host genetic effects on rumen microbial functions.

- Using comparative functional genomics, the differences and similarities of the host genomic effect on the microbial genetic and functional architecture between species will be uncovered providing substantial new knowledge about the host genome - microbiome interactions across species. Of particular interest is the relevance to humans, e.g. research on the host genetic effects on the rumen microbiota and its association with body composition may give background information for human personalised medicine approaches to reduce obesity.

- This work will provide an understanding of the impact of novel feedstuffs (e.g. seaweed, oils) on methane output and feed efficiency in ruminants. It will also provide new knowledge on diet effects on abundances of the microbial community and microbial genes.

- The project will generate a database of key performance, efficiency and environmental metrics associated with housed cattle production linked to waste management, renewable energy and vertical farming. Knowledge will be gained on the development of integrated technologies and farming components which have extensive application for monitoring productive output and environmental impact of UK agriculture, with potential applications to further sectors.

The UK:

- Meeting the food demands of the growing world population, whilst reducing the effects of agriculture on climate change is one of the greatest challenges that agriculture has faced to date. This research project is expected to provide a unique animal breeding strategy, methane-reducing diets/additives and precision livestock farming solutions to address these challenges in order to achieve sustainable cattle production -

in particular considering that 39% of the global GHG emissions from livestock production are enteric methane emissions from ruminants. Methane is a highly potent greenhouse gas - a reduction of these emissions will help to meet the legallybinding national target of net zero emissions by 2045.

- Reduced production costs and improved efficiency will enhance the sustainability and reputation of UK beef, and ultimately increase the value of UK beef exports.

- Sustainable beef production will provide long-term stable rural employment, land economy and communities.

UK beef producers:

- Performance traits, such as FCE, vary substantially between cattle therefore genetic improvement is expected to have a substantial impact on the efficiency of using limited feed resources, as well as having a major financial impact - since feed is the largest variable cost of production.

- Based on the associations between the microbiome and phenotypes, algorithms will be developed to predict traits like FCE or methane emissions so that these traits can be predicted from the rumen microbial genes without the need for measurement of feed intake and growth rates. These measurements typically last at least 2 months, so there will be substantial financial savings for animal breeding.

- The reduction in methane emissions and utilisation of carbon dioxide from housed cattle will allow marketing of beef products and high value crops (such as leafy greens) as having a low environmental footprint. The climate impact per unit of beef produced will be reduced. This will provide a significant market advantage as the consumer demand for sustainably produced food with low environmental impact is increasing rapidly.

Consumers:

- The demand for food with low environmental impact is increasing, the development of a technological solution and aligned precision management tools (breeding strategies, technologies to optimise efficiency, low-methane feeds) will produce low carbon beef and crop products and will increase the acceptability of UK produce for local and foreign consumers.
  Animal welfare will be safeguarded.

Meat processors and supermarkets:

- Market research highlights the increasing consumer demand for more environmentally friendly produce, and reduced consumer confidence in meat-products has resulted in a reduction in red meat consumption in the UK. By sourcing animals from producers using the proposed developments, supermarkets will be able to market premium low-carbon produce, and increase consumer acceptability of UK red-meat.

Industry:

- Our extensive range of industry partners (breeding companies, feed providers, agricultural equipment manufacturers, technology developers) will ensure that outcomes of the research can be immediately implemented.

How will you look to maximise the outputs of this work?

Scientific outputs of the work will be disseminated through journal-publications, national/international agricultural conferences and through social media/dedicated web-pages. Results will be embedded into undergraduate degree programmes and doctoral-training programmes and leveraged in wider research activities (e.g. animal behaviour and welfare).
The work is supported by a large network of commercial industry partners linked to each objective. These

partners will support in disseminating project outputs and developed solutions and knowledge to the beef and sheep industry**.**
Dissemination of the work will be across the agricultural community and wider network of businesses connected to each collaborating industry partner. This will include trade events, farmer-workshops, press and online channels and the wider network connected to collaborating industry partners. **Species and numbers of animals expected to be used**

- Cattle: 4500
- Sheep: 300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using animals that are used in beef production, which includes juveniles and adult life-stages. Ruminant production systems are under significant and continued political and public pressures to reduce their environmental impact and optimise feed use efficiency. It is important to investigate methods of alleviating this impact using ruminants.

- It is not possible to develop new proxy tools for the measurement of methane and feed efficiency of livestock, or relevant breeding strategies without working with the relevant farm animal species under normal management conditions.

- Previous work has demonstrated the potential for modifying the diet of ruminants to mitigate methane and/or improve feed efficiency. There is also growing evidence that novel feedstuffs and feed additives can significantly reduce methane production. It is not possible to evaluate dietary effects on feed efficiency/methane output, without working with the relevant farm animal species under normal management conditions.

- Furthermore, the use of technologies and data-driven solutions for improving efficiency and reducing environmental impact of ruminant production systems are growing in importance. It is not possible to fully evaluate the use of technology and novel management systems designed for commercial application, without using farmed animals managed under commercial farming conditions.

Typically, what will be done to an animal used in your project?

Typically, animals in this project will be subject to experiments where feed efficiency and/or methane emissions will be measured using gold-standard techniques for measuring these traits. Feed efficiency is measured over a test period which typically lasts 56-60 days using feed testing stations (on both research and commercial environments) where electronic feed intake recorders are used. Methane emissions is measured using respiration chambers where animals are housed individually within the chambers for up to 4 days and gas emissions (methane and respiratory gases) measured.
Animals will be involved in one of the following: (i) studies aimed to develop commercially relevant breeding solutions for feed efficiency/methane emissions where genetic information will be obtained from blood and/or

rumen fluid samples; (ii) studies aimed to test commercially relevant diets and feed additives for reducing methane emissions where animals will be offered carefully formulated diets; or (iii) studies aimed to develop and use technology which directly mitigate methane emissions and/or improve feed efficiency - such as methane capture from environmentally controlled housing.

What are the expected impacts and/or adverse effects for the animals during your project?

We aim to ensure that animals perform well, according to their genetic potential, and all procedures in this project are mild. Dietary treatments are only likely to cause mild, transient digestive upsets. Sampling procedures (blood, faeces), methane measurements in respiration chambers, and recording of feed efficiency are minimally intrusive, whilst sampling of rumen fluid through naso-gastric tubes is non-surgical and causes only transient discomfort.
Animals will return to our or commercial herds and flocks, subject to veterinary certification and them not having received treatments that exclude them from the human food chain.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We anticipate that the severity of the procedures used in this project will be mild. Our aim is to mimic commercial farm practice as far as possible, and to develop solutions which are commercially applicable.
The most severe procedures used in this study is blood and rumen sampling where only short-term transient discomfort is anticipated.
It is not anticipated that animals will experience severe stress, fear or discomfort as a result of the procedures noted above.

What will happen to animals at the end of this project?

- Kept alive
- Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to evaluate between-animal variation in feed conversion efficiency and methane emissions, nor to test the use of new precision livestock farming tools for the monitoring and management of livestock without working with the relevant farm animal species under normal management conditions.

Which non-animal alternatives did you consider for use in this project?

Whilst we take appropriate opportunities to screen treatments that influence feed efficiency or methane emissions using *in vitro* systems, which may use either enzymes or rumen fluid, this work seeks to identify the animal genetic effects as well as interactions with animal management. It is not possible to evaluate between-animal variation

or novel markers, proxies or sensors to monitor animal feeding, performance, feed efficiency or methane emissions without using them with the relevant farm animal species under normal management conditions. It is not possible to assess the systems to capture and combust methane, without testing them on the relevant farm species and under commercial farming conditions.

Why were they not suitable?

These methods (lab-screening and pilot work) are helpful to refine and improve design, but to assess strategies for commercial application requires work to be conducted in farm animals, under commercial farm conditions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For each component of the project, experimental designs and methods of analysis have been or will be discussed with a statistician. The exact numbers of animals required will vary with particular experimental designs and will be based on previous experience and the scientific literature.
For each experiment, an experimental protocol is submitted to the organisational Animal Experiments Committee which includes statisticians in its membership. The protocol includes: a statement of the objective(s) and a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group), and the experimental material. Furthermore, protocols for each experiment including the above information and other matters such as methods of analysis are produced to conform to Institutional Research Quality Assurance requirements.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For each component of the project, experimental designs and methods of analysis have been or will be discussed with expert statistical support. The design of individual experiments will maximize the information obtained from the minimum resource and will draw on the expertise of our collaborators and our own experience of running similar experiments to optimise the number of animals required for the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will take appropriate opportunities to screen treatments that influence feed efficiency or methane emissions using in vitro systems, which may use either enzymes or rumen fluid. Where required, pilot studies will be used to provide the baseline data to inform on larger trial work, and to refine sampling procedures and techniques for data capture. We will also use the opportunity to share data and samples with collaborators (internally and externally) to achieve maximum value from minimum resource.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain

management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All measurements will be made on breeds of cattle and sheep and diets representative of major production systems in the UK. Methods to measure feed efficiency conform to International Committee for Animal Recording (ICAR) guidelines for recording to be used for animal breeding programmes. The respiration chamber methods of methane measurement is one of the few methods accepted by the Intergovernmental Panel on Climate Change (IPCC) for purposes of compiling national GHG emissions inventories. The chamber method is calibrated against reference standards and is necessary to validate less invasive, marker/proxy or high-throughput sensing methods. Until such methods are developed there are no alternatives to the chamber methods.

All sampling procedures are mild and designed to be minimally intrusive because we need animals to be performing according to their genetic potential and as per normal commercial practice.

Why can’t you use animals that are less sentient?

It is not possible to use immature, less sentient or terminally anaesthetised animals. The study aims to develop methane mitigation tools and methods of optimising efficiency that are commercially applicable to farming environments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures described here are already refined as a consequence of our work over the last 10 years and in use by our team. These include measurements of feed efficiency and methane emissions and sampling procedures for blood, faeces and rumen contents. Where we are developing new methods - i.e. capturing methane from a semi-sealed environment - we will implement pilot testing within the respiration chamber facility before up-scaling to a shed-sized system.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The feed efficiency methods conform to International Committee for Animal Recording (ICAR) guidelines for recording feed efficiency to be used for animal breeding programmes. The respiration chamber methods of methane measurement are the only methods accepted by the Intergovernmental Panel on Climate Change (IPCC) for purposes of compiling national GHG emissions inventories. Animal housing and husbandry will at least meet, and may exceed, that required under ASPA.
When publishing our research we will use the ARRIVE guidelines to ensure that we make all the relevant information known to others and help refine further studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continually review our procedures throughout our work and seek less harmful alternatives whenever these are available. We will regularly visit the NC3Rs website to check for any new developments.

Home Office

NON-TECHNICAL SUMMARY

62. Functional Organization of the Midbrain Serotonin System

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

serotonin, dorsal raphe, neuronal development, mental illness, behavioural tests

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how the midbrain serotonin system is organized to modulate psychiatrically relevant

behaviours (including depression, anxiety, post-traumatic stress disorders and etc.), how the organization of the serotonin system is determined during development, and how disruptions in the developmental programs alter this organization, possibly underlying diseases such as post-traumatic stress disorders, depression and anxiety.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will advance our understanding of the relationship between brain development and psychiatric disorders. This will enable the discovery of novel potential targets for the treatment of human neurological disease.

What outputs do you think you will see at the end of this project?

The principal benefits of this work will be the increase in our basic knowledge of how the nervous system works. We hope to better understand the relationship between the serotonin system and behaviours, including behaviours that are relevant in psychiatric disorders (including depression, anxiety, post-traumatic stress disorder, etc.). By way of context, psychiatric disorders are among the leading causes of disability globally with one in four people in the world affected by psychiatric disorders at some point in their life. In both the mouse and human brain, the dorsal raphe (DR) and median raphe (MR) are the source of serotonin to the forebrain and the most relevant serotonin neurons to psychiatric disorders. In this project, we shall address the outstanding question in the field, how is the DR and MR serotonin systems organized to modulate psychiatrically relevant behaviours? Second, we shall reveal how is the organization of the serotonin system determined during development. The answer to this question is the fundament of the third question, that is how do disruptions in these developmental programs alter this organization, possibly underlying pathology? The answers to these questions will advance our understanding of neuromodulation in health and aid the development of effective therapies for brain disorders such as anxiety and depression.
In addition, we anticipate making significant technical advances in the areas of imaging synaptic transmission events in acute brain slices and the technology of neuronal cell-type specific proteomics, which we hope will be taken up broadly by neuroscientists.
The intended outputs of the project, therefore, will be new knowledge as well as new reagents (viral vectors, genetically modified reporter mice) and technologies (tools and protocols for proteomic procedure and microscopy). They will be disseminated via the open access scientific literature and presentations, and also via the institute's public engagement team. Moreover, institute policy ensures free distribution of reagents, including mouse strains, after publication, and vector constructs are submitted to appropriate repositories for onward distribution.
Who or what will benefit from these outputs, and how?

Short-term and medium benefits will be new knowledge and methods, but longer term will be enhanced appreciation of the genes-to-cells-to-behaviour model for neuroscience, as well as the application of basic neuroscience knowledge to understanding mental disorder progression and providing a neuromodulatory context for the epidemiology of psychiatric diseases.

How will you look to maximise the outputs of this work?

Cross-labs collaboration is the signature of my institute and I will work closely with the neuroscientist in the department to disseminate any technical developments and knowledge. The culture of the local neuroscience society is very collaborative and there are tremendous opportunities for collaborating with a neuroscientist in the neighbouring institutes and universities. Building on our previous achievements, I have rich experience of collaborations around the world. I am confident that these collaborations will contribute significantly to maximize the outputs of this work.

The data, reagents, tools, protocols and software generated by this project will be disseminated via the scientific literature and presentations, and also via my institute's news media operation. For all objectives (including unsuccessful approaches), we communicate our data at scientific meetings
(conferences) and publish in peer-reviewed open access journals

Species and numbers of animals expected to be used

- Mice: 40000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Serotonin system in the brain is the most targeted neural system for treating mental disorders, including anxiety, depression, autism, PTSD, and so on. However, there are up to 43% of the patients stopped taking antidepressants due to the side effects [Carvalho et al.]. The side effects are caused by the non specificity of drug targeting, meaning the entire serotonin system is targeted but not just the subgroup of serotonin neurons that are actually responsible for the symptoms. To solve this problem, we need to understand which subgroup of serotonin neurons is related to what mental-disorder relevant behaviours, and what are the genes can be used to target these neurons specifically. By doing this, we can discover better therapeutic agents then would have better treatments for mental illnesses.
In order to achieve this, we have to use mouse models to screen for the neurons and genes that can be used as drug targets, and then record the activity of these neurons to confirm their function.
First, Mice are the least sentient animals that can be used for satisfactory tests of the roles of genes and neuronal pathways in mental illness relevant behaviours. There are depressed-like mouse models but not depressed-like fly models.
Second, the characteristics of serotonin system are highly conserved between mouse and human, and the data we obtained from mice are relevant to human.
Third, mice have readily modifiable genetic systems, including lines carrying genomically encoded modifications (recombinase drivers and conditional alleles). These are widely available from centres such as JAX and GENSAT. Furthermore, a large number of genetic tools have been developed and validated specifically for mice: AAV-, Rabies- and Lentivirus based viral vectors; fluorescent reporters and activity indicators; genetic manipulators such as CRISPR, optogenetics and chemogenetics.
Finally, the genetic and electronic/imaging technology now available ensures very refined experimental procedures and relatively large data-sets from fewer experimental animals.
All the behavioural tests are only for adult mice. Surgeries or drug administration may apply to younger stages because most mental disorders start to develop in young ages of the patients.

Typically, what will be done to an animal used in your project?

Perfusion fixation or Decapitation: All the animals undergoing either of the procedure will be euthanized under

anaesthesia by intraperitoneal injection (IP) of anaesthetic. Further procedures (e.g. decapitation or abdomen incision) will not be carried out until the anaesthetic depth is confirmed by using the toe pinch-response method to determine the depth of anaesthesia. After it is confirmed that the animal is unresponsive, perfusion fixation or decapitation will be carried out for brain tissue collection.

Non-surgical injections: Drugs like tamoxifen, 4-hydroxytamoxifen, clozapine-N-oxide, or their variants and etc., will be by administrated. Animals undergoing this procedure are not expected to exhibit any harmful phenotype.

Surgical procedures: Stereotaxic injection and surgical implantation in the mouse brain: During surgeries, we will typically make very small windows in the skull to gain access to the brain, deliver dyes or genetically modified virus. For some animals, we then will implant optical fibres or cannulas. After that, we will secure everything with dental cement prior to wound closure, if appropriate.
In utero electroporation: During the 30 mins surgeries, DNA will be injected into the embryos' brains followed by the delivery of very mild electric pulses. After electroporation, the embryos develop normally in utero and are born naturally.
All the behavioural paradigms used in this protocol are frequently used standard mouse tasks that are for models of mental disorders. All the tests used are acute tests and animals have a break in between tests to limits harms. There is no need for showing clinical signs in any of the steps. Animals will be observed closely during and after these tests to ensure they are physically capable to perform them and that no lasting harm occurs.
Behaviour tests in mazes and open field chambers: These behaviour tests include open field test, novelty suppressed feeding test, place preference test and elevated plus maze related mazes. In these behaviour tasks, the mouse is placed in either a new cage, an open field box, a maze or a chamber with lick-ports. The animals will move freely under a recording camera for 10–60 mins. The animals will be returned to the home cage after the test. These tests are expected to result in mild transient anxious feeling in the mouse.
Appetitive learning tasks: During the training session, in order to generate enough motivation for the animals to participate in the training, mice will undergo sustained food restriction for up to 2 months, maintaining 85% body weight. Mice have access to food during training trials. Right after the training session, when the bodyweight is still maintained at 85%, mice will be tested acutely in the assay. The animals will be returned to the home cage after the test. The tests do not result in more than mild discomfort during food restriction.
Sucrose preference test: One property of depressed patients is that they lack enjoyment of enjoyable activities. It has been found that mice can also develop this property. Mice always enjoy things that taste sweet under normal circumstances. In this assay, depressed-like mice enjoyed sweet (sucrose water) significantly less than normal mice. This test measures how much a mouse enjoys sucrose water compare to normal water. Before the test, mice are acutely deprived of water and food for 16hrs. This is essential to motivate the mice to drink from both the sucrose water bottle and the normal water bottle. During the test, the numbers and volume that they drink from each bottle are used for quantitative measurement reflecting their ability to enjoy sweet. The animals will be returned to the home cage after the test. The tests do not result in more than mild discomfort during food and water restriction.
Social behaviour tests: here we apply the social recognition, approach behaviours test and the tube test. In these tests, the test mouse will be placed with a second mouse and the interactions between the two are monitored. There will be no fighting between the two mice during these tests because of the design. The tests on this protocol are not expected to produce adverse effects any greater than transient discomfort, and no lasting harm.
Aggression test evaluates male aggression and social dominance. The assay allows two male mice to interact for 10 minutes. The procedure will be supervised for its entire duration. The mice may approach, sniff and chasing at each other. There may be a fight, however, we do not expect any injuries caused by the fight, and the session will be terminated early if open wound injuries are caused by an attack (very rare) or one single episode of attacking (biting) is longer than 5 seconds. Animals exhibiting any unexpected harmful phenotypes will be killed humanely. Animals will be killed humanely with 5 days after this test.
Aversive(fear) learning tasks:
Some of our experiments have to use aversive stimulation in order to model fear-inducing events, including the emotion associated learning and the memory of learned fear. These are key aspects of mental illness in which

strong emotional memory component is present, such as phobia, or posttraumatic stress disorder (PTSD). To study aversive learning, animals have to expose to stressors that mimic aversive experience happened to patients, and in this behavioural assay, we use mild electric shocks as the aversive stimulus. Animals will only experience one session (up to 20 mins) containing several mild electric shocks (up to 0.7mA) per lifetime. At least 60 seconds in between of each shock and no more 10 seconds of the total shock time. This is sufficient to allow us to study the psychological processes that underlie learning about stressful events. This is a well-established model for the fear learning component of PTSD and represents a refinement over some other models (e.g. underwater trauma). It allows us to precisely control the timing of cues predictive of an aversive outcome and the outcome itself (unlike more general stressors, such as exposure to the scent of predators) and because it engages the same brain circuitry as the mental health disorders that we are studying (unlike, for example, air puffs to the eye, which engages reflexive circuitry with has little relevance to our scientific questions), however, we will investigate further refinements to this procedure in parallel with our behavioural studies. Animals will be killed humanely with 8 days after this test.

What are the expected impacts and/or adverse effects for the animals during your project?

In terms of welfare costs, the mutations to be used in this programme are benign, the surgical procedures and associated kit are well established and so the needs for after-care monitoring and analgesia are well understood. It is critical to our scientific success that the mice behave normally because that is our measured dependent variable. It is therefore paramount in our design of studies and use of animals that we minimise all aspects of stress and discomfort.
Animals undergo non-surgical injections are not expected to exhibit any harmful phenotype.
Surgery: Stereotaxic injection, surgical implantation and in utero electroporation will be carried out aseptically. In all cases, animals will undergo one or two episodes of surgery under general anaesthesia. Peri- and post-operative analgesia will be provided; agents will be administered as agreed in advance with the NVS. Animals are expected to make a rapid and unremarkable recovery from the anaesthetic. They are expected to recover quickly and will be given painkillers and postoperative care. Animals are expected to reach the moderate level of severity exclusively during surgery and during the period immediately following the surgery, which represents <2% of the time spent by the animal. One day after surgery animals normally show no signs of discernible discomfort for the presence of implanted devices or as a result of injected tracers/virus. Any additional risk is readily mitigated by appropriate technique and after-surgery care.
After in utero electroporation, the embryos develop normally in utero and are born naturally. The dams will only undergo one episode of surgery and are not expected to show any signs of distress. In the uncommon event of post-operative complications, animals will be killed unless, in the opinion of the NVS, such complications can be remedied promptly and successfully using no more than minor intervention.
Non-aversive behaviour tests: These behaviour testing will be under standard protocols that will not cause any lasting harm and in most cases will cause only momentary mild discomfort or anxiety. Animals will be observed closely during and after these tests to ensure they are physically capable to perform them and that no lasting harm occurs.

Electric foot shock: Each mouse will only experience one foot-shock session (up to 20 mins) containing several mild electric shocks (up to 0.7mA) per lifetime. At least 60 seconds in between of each shock and no more 10 seconds of the total shock time. Although stressful for the animals, electric foot-shock yields very rapid learning and consequently the low shock intensities and short durations of shock used that tissue damage is never seen. Animals will experience pain during the shock.
Water and Food restriction: Animals undergoing food or/and water restriction are not deprived below 85% of their calculated free-feeding weight based on published growth curves of age-matched controls. On the rare occasion that an animal exceeds 15% weight loss compared to the published growth curves (with no other clinical signs) then it is given immediate access to additional food. Animals used in these assays are not expected to experience any long-term pain or distress. We will continue to monitor animals for any signs of distress. The tests do not result in more than mild discomfort during the withdrawal.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

85% of the mice are expected to undergo mild severity symptoms, i.e. breeding and mild behaviour tests. A further 15% will experience moderate severity i.e., surgery, electrical shock etc.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

My research seeks to understand how serotonin system modulates behaviours that are relevant to mental disorders such as post-traumatic stress disorders, depression and anxiety. These are products of an intact nervous system. It is the case that a large part of my work (ca. 60%) uses ex vivo brain tissues and so the requirement for animals is in suitable breeding programmes to generate intact tissues.
Beyond this, the use of conscious adult mice is unavoidable if we are to study the integrated circuitry and the dependent behavioural states and outputs: cell lines or computer simulations cannot yet come close to reproducing the complexity of the brain. Importantly, the starting point for our analysis of molecular mechanisms is our broad view of the existing literature of physiological and molecular biological studies of the serotonin system and much of this is derived from in vitro and cell-based studies.
Which non-animal alternatives did you consider for use in this project?

The starting point for our analysis of molecular mechanisms is our broad view of the existing literature of physiological and molecular biological studies of the serotonin system and much of this is derived from in vitro and cell-based studies.

Why were they not suitable?

Cell lines or computer simulations cannot yet come close to reproducing the complexity of the brain

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to pursue the aforementioned objectives, we will need to make use of transgenic animals. We estimate that over the course of five years we will need to make use of about 30 distinct transgenic lines. These include mostly but not exclusively: population-specific CRE and FLP mouse lines, which will be used to identify genetically defined neuronal populations: various versions of reporter lines, which will be needed to visualize

those neuronal populations; activity modulators that will be crossed to FLP and CRE lines in order to alter the activity state of the identified neuronal populations. The establishment of those colonies will require about 3000 animals. Breeding and maintenance of the established lines is estimated to require, based on our recent experience, around 27000 animals for the duration of the licence. This is taking into account the need for refreshing colonies per year and expected usage of about 20 distinct mouse lines per year. We plan to maintain active colonies with 12 females and 6 males. These numbers ensure a smooth workflow for 4 lab members in order to provide access to the lines also in the case of parallel work with the same lines of multiple members (a situation that will occur frequently for the most commonly used lines, such as reporter lines). Six lines will be bred in the homozygous state and a further 14 lines will have multiple alleles which will give rise to high progeny but a low number of offspring with the correct genotype for experiments.
We estimate to use around 1000 animals for in utero electroporation, including wild type and transgenic animals. 500 animals in the protocol of administration of modifying agents will be used for activity dependent labelling of neurons. About 2000 mice will undergo behavioural testing without any surgical procedure. The use of approximately 1500 animals will only undergo surgery but not behavioural tests for tracing experiments, including 8 neural circuits. We estimate to use around 500 animals in the surgery and behavioural testing protocol for brain slice imaging and electrophysiological recording. 1000 animals in this protocol will undergo behavioural assays. 1000 out of 1500 animals in the aversive behaviour with or without surgery will undergo surgery. This is based on our goal to perform fibre photometry imaging (300 animals) and GRIN lens imaging (400 animals), given an expected statistically required sampling of 10 animals per recording site per mouse line. We expect to use 300 animals for the optogenetic manipulation for each protocol. We will use approximately about 1400 wild type animals as control and as the cage-mate/social partner in the behavioural assays.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where animals are necessary, we control breeding programmes tightly. Based on my 11+ years' experience of working with mice as the animal models, I will ensure the robust experimental design and generate statistically valid results from the minimum requirement of the experimental stock.
Dose ranges will be based on my prior experience and the literature. For initial work with newly acquired lines or viral vectors, small group pilot studies will be used to scope phenotypes. In order to use a statistically correct number of animals, we routinely perform power calculations to set the extension of our experimental cohorts. Furthermore, we take a number of steps to reduce variability in our procedures. The largest source of variability derives from the behavioural performance. To reduce this we take two steps: Firstly, we use isogenic lines so to reduce behavioural variability linked to genetic variability. By using inbred strains we shall ensure consistency of results, and minimise the variations between individuals, thus allowing us to keep the experimental cohorts relatively small. Regular breeding of core lines to a C57bl/6 background will ensure genomic integrity. Secondly, we will perform all the behavioural work at the same time of the day across different groups to avoid any potential circadian influence on the behavioural results.
Data generated by these studies will take the form of differences in behaviour between experimental and control animals; histological preparations showing the site of viral injections, localisation of electrode tracks or sites of labelled substances or reaction products; and electrophysiological firing patterns in different brain areas. Satisfactory results will be judged on the basis of comparisons between control and experimental groups using analysis of variance statistics.
The studies we intend to conduct will be designed so as to minimise the number of animals used to demonstrate a given statistically significant effect. Generally, we run pilot studies to explore the parameters of an effect before the final design is decided upon. Whenever a non-standard experimental design will be required, statistical advice will be sought.

Whenever possible we make use of ex vivo recordings, this will reduce the instances in which we have to perform in vivo acute or chronic recordings. which greatly decreases the number of animals used under these protocols. However, in most of these cases, we still rely upon a phase of in vivo work and rarely on behavioural training prior to the ex vivo work.
All publications are made consistent with ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cryopreservation will be used to preserve important lines and remove the necessity to hold stock for extended periods. On occasion, we may need to ensure that our protocols are optimised and this may require the re-implantation of un-manipulated oocytes, embryos or blastocysts. Cryopreservation of embryos and sperm will be used for long-term storage of genetically altered mouse lines and pedigree lines with in vivo viability assessed to ensure that lines can be re-established successfully.
Rederivation will be undertaken should the health status of the animals be compromised in a way that would significantly affect the welfare of the animals or where the experimental results might be altered unduly.
Whenever possible we make use of human Embryonic Stem cell (hESCs) derived neurons in substitution for the in vivo work. We will collaborate with colleagues who devise neural organoid to develop neural circuit model for the serotonin system to reduce the number of animals.
We will significantly reduce our reliance on animal models by performing preliminary studies in cell lines. We will also employ, as far as possible, in silico and in vitro techniques, to minimise the use of intact animals as well as inform that use.
We hold ex vivo tissue in freezers available to use for molecular anatomical studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mice as the animal models because 1) mice are the least sentient animals that can be used for satisfactory tests of the roles of genes and neuronal pathways in metal disorder relevant behaviours. There are depressed-like mouse models but not depressed-like fish or fly models; 2) the characteristics of the serotonin system are highly conserved between mouse and human. Investigation of the role serotonin system in mental disorder relevant behaviours in mice is therefore relevant to humans; 3) the mouse is the only animal for which transgenic strains are currently available that allow us to genetically identify serotonin populations that would be otherwise indistinguishable. This is crucial for the success of our project, as it relies on assigning individual function to identifiable neuronal populations.
The mutations to be used in this programme are benign. The surgical procedures and behavioural tests are well established and so the needs for after-care monitoring and analgesia are well understood. It is critical to our scientific success that the mice behave normally because that is our measured dependent variable. It is therefore paramount in our design of studies and use of animals that we minimise all aspects of stress and discomfort.
Why can’t you use animals that are less sentient?

In this protocol, we are going to address how genes and neurons in the serotonin systems control metal illness relevant behavioural phenotypes. By doing this, we can discover better therapeutic agents then would have better treatments for mental illnesses.
To achieve this, we have to use mouse models to screen for the neurons and genes that can be used as drug targets. We have to use adult mice for the behavioural tests because most of the mental illness behavioural phenotypes are most obvious and less variable during adulthood. We cannot use animals with a lower capacity to experience pain or distress because 1) mice are the least sentient animals that can be used for satisfactory tests of the roles of genes and neuronal pathways in metal disorder relevant behaviours. There are depressed-

like mouse models but not depressed-like fish models; 2) the characteristics of the serotonin system are highly conserved between mouse and human. Investigation of the role serotonin system in mental disorder relevant behaviours in mice is therefore relevant to humans. We cannot use animals that have been terminally anaesthetised because the two main outputs of this protocol are 1) behavioural phenotypes 2) changes of neuronal activity during behavioural tests. The mice have to be awake and freely moving to achieve these outputs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The mutations to be used in this programme are benign, the surgical procedures and associated kit are well established and so the needs for after-care monitoring and analgesia are well understood. It is critical to our scientific success that the mice behave normally because that is our measured dependent variable. It is therefore paramount in our design of studies and use of animals that we minimise all aspects of stress and discomfort.
Many of our experiments require neural manipulations (brain surgery). The surgical approaches used are the least severe available, involving the smallest amount of tissue damage. Animals are given extensive post-operative care including analgesics. Animals are closely monitored throughout the experiments and any signs of problems with implants or other aspects of surgery are immediately dealt with, or, if this is not possible, the animal will be culled. Similarly, animals are closely observed and monitored during the recording experiments and interactions with other animals. All surgical procedures are carried out with the best possible level of asepsis and according to best practice (internal guidelines).
We routinely administer peri-operative analgesia, with scoring sheets to monitor animal welfare for a minimum of three days post-surgery. We routinely use non- steroidal anti-inflammatory drugs such as carprofen or meloxicam.
Some of our experiments necessitate the use of inescapable shock procedures in order to model aversive conditioning and fear learning. These emotional aspects are crucial components behind the mechanism of post-traumatic stress disorder (PTSD). We have to use foot shock as the fear-inducing events. For traditional fear conditioning test, we employed the most refined and well-accepted conditions, with 5 mild foot shocks (up to 0.7mA and 2s) in a session. Each animal will only experience one session (up to 10mins) per lifetime. For neuronal recording coupled with foot shocks, each mouse has to receive multiple foot shocks to minimise variables and ensure reproducibility. To ensure that we use the most refined conditions here to achieve the scientific goals, we carried out a pilot experiment in a collaborator's lab. We compared different shock numbers, duration time and foot-shock intensity and record the serotonin neurons' activity simultaneously. We found that, to generate statistically meaningful data for each animal, we have to use at least 12 shocks. Although the shock numbers increased compared to the traditional fear condition test, we also found that up to 0.6mA with 0.5s duration per shock is sufficient to evoke serotonin neurons' reaction. Taking together, after refining the protocol of behavioural test j, the total shock time an animal has to experience in one session is only 6 seconds, which is even shorter than in the traditional fear condition test. Moreover, conditions used in our ‘fear conditioning’ procedures are much more refined than the stressors employed by other behavioural paradigms, including forced-swimming, tail-suspension, learned helplessness, etc.
Overall, we are committed to refinement and minimization of animal suffering from ethical and scientific perspectives. As the outcomes of our experiments are primarily (often subtle) behavioural differences, a high standard of animal welfare is required for us to obtain meaningful data.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the published Guidelines issued by LASA, NC3Rs, and RSPCA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continually refine our techniques as far as is reasonably practicable and we work closely with other PPL holders in the UK and across the world using similar techniques to share developments in best practice.

Home Office

NON-TECHNICAL SUMMARY

63.Gene and cell therapies for Ischaemic disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

pericytes, gene therapy, vascular grafts, angiogenesis

Animal types	Life stages
Mice	juvenile, adult, aged

Retrospective assessment

> The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to find new cures for patients suffering from heart attacks and poor circulation in the legs.

A retrospective assessment of these aims will be due by 21 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease caused by the narrowing of arteries and capillaries that provide oxygen and nutrients to the heart, brain, and legs, is the number one killer in the UK. Current treatments reduce the risk of death after a heart or a brain attack and delay the need of foot amputation as the last resource to save the life of patients with very poor circulation to the legs; however, many patients continue to have a poor quality of life. This is because current treatments are not enough to create new blood vessels around the occluded ones. In addition, grafts used by surgeons to create a new route around the blocked section of the artery tend to occlude after few years from implantation.

What is needed is a definitive solution for building up new blood vessels of different diameter, ideally large arteries to carry blood around the narrowed artery and capillaries to transport oxygen and nutrients to the suffering tissue. To reach this goal we will investigate new methods based on:

1) Testing drugs that can encourage the formation of new arteries and capillaries. For instance, using a protein which protects people who live a long life (centenarians) from suffering from blood vessel occlusion as they become old.

2) Producing artificial tubes containing human cells to create grafts like a real artery

What outputs do you think you will see at the end of this project?

In the medium term, 5 years from now, we expect that this research will demonstrate the proposed solutions are safe and capable of being done. We also expect to obtain new knowledge of how these treatments work. We will publish the results in medical journals where the acceptance for publication is warranted only after careful evaluation by expert reviewers. This will be a demonstration that the research is novel and accurate and has an important medical impact.

In the long term, the project aims to make these new cures available to the patients. This will require (1) preparation of documentation of main findings supporting efficacy and safety, (2) approval from agencies responsible for introduction of new medical treatments.

Who or what will benefit from these outputs, and how?

In the short/medium term, during the next 5 years, the work will generate new information about diseases that cause heart attack and poor circulation to vital organs in the body. We will pay particular attention to vascular cells that have not been investigated sufficiently in the past, such as pericytes, which are regenerative cells lining around the small and large vessels. One major goal is to incite the pericytes to act as building blocks to rebuild new and well functioning blood vessels. We will also work in the lab at producing new tube grafts containing pericytes and other vascular cells. We expect that, once implanted, these grafts containing human vascular cells will be superior to the ones used by surgeons to bypass blocked circulation.

In the long term, the work is expected to lead to clinical trials in patients. In due course, the work will be of direct benefit to patients and reduce the burden on the national health system and society caused by the disabling effects of vascular disease.

How will you look to maximise the outputs of this work?

The full demonstration that the proposed methods are valid and applicable to patients require skills and expertise that cannot be found in a single laboratory. We will therefore collaborate with other investigators, including doctors, surgeons, and scientists, to achieve the best results.

Clinicians are the best partners for maximising the impact of our research toward patients' benefit, but also to inspire new ideas from the bedside back to the bench. Scientists, with whom we collaborate, can bring new technologies and methods to the research.

We have established contacts with several small and large pharmaceutical companies (where some of our previous research fellows have relocated) and consult them frequently to see if they can be interested in helping us to develop our research and make faster the application to the clinic.

Results will be disseminated through scientific publications and presentations at national and international meetings. This is the most effective method to speed up the progress of science among the experts in the field. We will make sure that methods and results in publications contain enough details for other scientists to repeat the experiments and confirm or extend the acquired knowledge. The data will be communicated, either they confirm (positive results) or reject (negative results) the initial hypothesis. The report of data will follow the current international guidelines.

We have extensive experience in communicating the results through press release, having had articles covered in national news media (radio, television, and newspapers). The team is also experienced in communicating with lay persons through seminars to patients' forums and public lectures. We will use all the above methods to communicate results to the public and patients' associations after consultation with the Research and Development office.

Species and numbers of animals expected to be used

- Mice: 1350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice, which are the mammals with the lowest neurophysiological sensitivity suitable for these studies. Wherever possible, we use the least severe model for our investigations. The disease we want to investigate occurs during adulthood and advanced age, which requires using adult and older models.

Typically, what will be done to an animal used in your project?

The animals will be subjected to surgical procedures to create the condition of blood flow blockade to the heart or limbs as occurs in patients. In other experiments, animals will not be operated but the natural evolution of vascular disease will be evaluated. Treatments will be given through local injections or systemic route. The duration of experiments will last from 2 weeks to 4-6 months, and we plan to use ~1350 animals during the 5 years of the project.

What are the expected impacts and/or adverse effects for the animals during your project?

Transitory pain after surgical induction of ischaemia will occur like that experienced by patients with a heart attack. Occasionally, we expect loss of weight and difficulty in breathing caused by heart failure and poor ambulation due to reduced blood flow to the lower extremities occurring for the maximum duration of 2 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

50% mild, 25% moderate, 25% severe.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 21 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will be using mice for these studies because the complexity of cardiovascular disease and the efficacy of proposed treatments cannot be effectively tested in non-animal systems. However, preliminary studies of cell functions will be carried out before engaging with animal studies. In addition, simulation experiments are planned.

Which non-animal alternatives did you consider for use in this project?

Cellular models. Simulation of blood flow alterations using theoretical modelling.

Why were they not suitable?

Because the final demonstration of efficacy requires the complexity of a living organism.

A retrospective assessment of replacement will be due by 21 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on an average number of 30 animals per experiment for a total of ~45 experiments in 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Well designed and correctly analysed experiments can lead to a reduction in animal use whilst increasing the scientific validity of the results. To this aim, we constantly refer to the NC3R's Experimental Design Assistant as a guideline.

Here, we summarise the main steps considered in the experimental design to reduce the number of animals, control bias and ensure that the results are scientifically valid.

1) Pilot studies comprising a small number of animals to generate preliminary data and/or allow the procedures and techniques to be solidified and “perfected” before large-scale experimentation.

2) The minimum number of needed subjects will be calculated based on the expected average benefit and the expected variability of the benefit (assessed from the literature or pilot studies).

3) The allocation of animals to different groups of treatment will be at random: 1) to avoid biases, 2) to guarantee that groups have the same probability to receive a treatment, and 3) to control experimental variability. When planning attribution of animals to groups, the assignment of animals at random to different groups and sub-groups will be improved by dividing animals in blocks to achieve minimal variation.

4) We prefer to use genetically selected strains of mice because they show a more homogeneous response to the disease, meaning lower variability will allow a reduction in number of animals needed.

5) Important variables as sex, age and weight of the animal should be similar among the groups, again allowing reduction in variability.

6) Our facilities provide state of the art in environmental enrichment. We ensure that all the animals are exposed to the same enriched environment.

7) Collection of data will be done in a manner that the treated and control group have their measures collected at similar time and by the same investigator.

8) Biases will be avoided by ensuring that researchers analysing experimental outcomes are unaware of the treatment received (blinded) until the final statistical analysis.

9) Data will be treated according to the principle intention-to-treat, where all participants who are randomised are included in the statistical analysis and analysed according to the group they were originally assigned, regardless of what treatment (if any) they received

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We based our optimal number of animals and experiments based on experience in previous successful projects, pilot data and computer modelling. We also referred to the NC3R's Experimental Design Assistant to ensure that only the minimize number of animals are used.

We will use the best available technology and make sure that all the equipment is regularly calibrated for precise measurements.

A retrospective assessment of reduction will be due by 21 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the less neurological developed species that can be used to test the therapeutic interventions we hope to progress into the clinical application. We will use the best measures and practices to attenuate pain, discomfort, infections, and stress. We will adopt refined microsurgical techniques to minimise the adverse effects of surgery. All animals will be carefully monitored after surgery and recorded individually. Wherever possible animals will be group housed and provided with enriched environment. Interventions to assess pain and suffering are refined to provide the maximum benefit for restoring wellbeing without interfering with the physiology of the animals. Therefore, observation frequency is calibrated to the risk of adverse events, which is highest during post-operative surgery. The definition of stress and pain severity is addressed using sensitive scales that have been elaborated for specific use in the specific protocol, for instance to identify low level of pain in mice with heart attack or occluded leg arteries. We also designed the protocol in a way the goal of the research is reached before animals reach the most severe outcome.

Why can’t you use animals that are less sentient?

Less sentient animals, e.g. fish or reptiles, cannot be used because do not reproduce the type of response a human being put in place following injury of the adult cardiovascular system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have monitoring charts and post-operative charts in place which will be adjourned and improved as new evidence emerges from real experimentation or the available literature. Where appropriate, the animals will be trained to drug administration regimen associated with the lowest possible stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgical procedures will be undertaken in line with the recommendation set out in the LASA and institutional guidelines for aseptic surgery. Injection and drug administration will be conducted in line with NC3Rs recommendations.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about advanced in 3R by reading the literature, attending courses and webinars. In addition, we will attend at least 1 meeting every year on animal welfare, such as the RSPCA/UFAW Rodent and Welfare Meeting or other 3Rs symposium.

A retrospective assessment of refinement will be due by 21 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

64. Gene silencing in early mouse development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

X chromosome, Gene regulation, Development, RNA

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this work is to address a fundamental question in biology, how are genes regulated (switched on or off) during development from a single cell, the fertilized egg, to a complex organism made up of hundreds of different cell types. To tackle this question we study the process of X chromosome inactivation in female mammals, a highly informative model for understanding developmental gene regulation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The proposed work will contribute to international research efforts aimed at understanding gene regulation during development. As we have now determined the entire DNA sequence (or genome) for many different animals, a central challenge is to understand how different genes, of which there are several tens of thousands, are regulated during embryonic development, in adult animals and in disease. Key findings that we make in our research contribute to our basic scientific knowledge, as described in textbooks, and this in turn is critical for the development of new applications, for example
in medicine and commerce. To disseminate our discoveries we publish our work in leading international peer reviewed scientific journals such as Nature, Cell and Science.

What outputs do you think you will see at the end of this project?

Through performing the studies under objective 1 we expect to make important discoveries towards understanding the role of a protein named SmcHD1 and its associated protein factors in X chromosome inactivation, and more widely in developmental gene regulation in mammals. Mutations in the human SMCHD1 gene are linked to the disease Facioscapulohumeral muscular dystrophy (FSHD) type II and our results should help to better understand the molecular basis of this disease and thereby to identify further areas of study. Our findings will be published in peer reviewed scientific journals and disseminated through presentations at international and national scientific conferences and at seminars in national/international research centres.
The X chromosome inactivation process is controlled by a ribonucleic acid (RNA) molecule, termed Xist, which accumulates over the entire inactive X chromosome to be. Our studies on Xist RNA localisation under objective 2 are aimed at understanding this process and will accordingly lead to discoveries concerning the fundamental mechanism of X chromosome inactivation. Our work will also inform our understanding of other examples of developmental gene regulation involving RNAs that localise to large chromosomal regions. Again, our findings will be published in peer reviewed scientific journals and disseminated through presentations at international and national scientific conferences and at seminars in national/international research centres.
X chromosome inactivation serves as a textbook model for understanding gene regulation and key discoveries that we make through the work described herein will be included in descriptions of the process used to teach students at undergraduate and postgraduate levels.

Who or what will benefit from these outputs, and how?

The impact of scientific publications resulting from this project will be realised in the short-term, influencing the

direction of research efforts in other labs around the world. Ensuing scientific advances will also have medium and long-term benefits in terms of providing scientific explanations in school and university textbooks. Discoveries may also be exploited in efforts to understand human diseases, notably FSHD type II.

How will you look to maximise the outputs of this work?

Collaborations with other colleagues/research groups offering different expertise/resources will play a central role in increasing the impact of published outputs. Dissemination will be through publication and presentations at conferences and seminars as above. Where possible negative findings and unsuccessful approaches will be publicised using newly established peer reviewed platforms such Wellcome Open Research and by depositing data in open repositories, Mendeley data, protein and relevant DNA/RNA/Protein databases.

Species and numbers of animals expected to be used

- Mice: 15700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use the laboratory mouse to study the process of X chromosome inactivation that occurs during early embryo development. The laboratory mouse is the best studied and most widely used model for analysing embryonic development in mammals. Importantly, methods have been developed that allow specific genes to be added or removed in early mouse embryos, and these approaches allow us to investigate the molecular events that underpin X chromosome inactivation. For our work we analyse very early- through to mid-stage mouse embryos, the time window during which X chromosome inactivation occurs. Occasionally we use tissue from later stage embryos or adult animals.

Typically, what will be done to an animal used in your project?

The majority of mice produced under this licence (no more than 10,000) will be used for breeding to maintain strains with specific genetic characteristics and for embryo production. Up to 5% will be recorded as having experienced a mild procedure (those for which a second biopsy sample needs to be taken to determine their genetic type). All other animals will experience little or no effects from the breeding programme, referred to as sub-threshold.
A smaller number of animals will undergo surgical procedures (no more than 100 female mice will receive embryo transfers and no more than 100 male mice will undergo a vasectomy). These animals will undergo one procedure with full recovery expected without incident. The surgical procedures are needed to produce new genetically modified mouse lines.
No more than 500 female mice will be used for the production of early embryos using a hormonal injection procedure termed super-ovulation. This is performed to obtain embryos for experimentation or for long-term storage/archiving (cryopreservation).

What are the expected impacts and/or adverse effects for the animals during your project?

Superovulation procedures are expected to result in no more than transient discomfort and no lasting harm.

Surgical procedures will be carried out aseptically. In the unlikely event of post-operative complications, animals will be killed In the case of wound breakdown, uninfected wounds may be re-closed on one occasion within 48 hours of the initial surgery. Animals are expected to make a full recovery from the anaesthetic within two hours. The production or breeding of our mouse lines are not expected to produce a harmful phenotype in adult mice. Any transgene inducing agents normally have very little or no adverse effects on the overall welfare or health of the animals. In extremely rare cases, adverse effects may arise in the mother from the expression of genes in her foetuses, induced by the administration of substances. There is a very low risk of harm to the mothers from the method of delivery(<1%).
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Subthreshold 93%
Mild 1%
Moderate 6%

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

X inactivation is developmentally regulated and occurs only in mammals. For this reason our experiments are carried out using the laboratory mouse as a model organism.
In order to establish tissue culture models we need to first carry out a certain number of animal studies. For example to make tissue culture cells which have a particular genetic modification we must first make the genetic modification in mouse embryonic stem (ES) cells. The ES cells are then used to make a mouse with the modification on one of a pair of chromosomes. We then need to breed the mouse so that both chromosome copies carry the modified gene. Finally we make genetically modified tissue culture cells required for the study.

Which non-animal alternatives did you consider for use in this project?

Advances in genome engineering methods mean that some experiments can now be carried out in tissue culture models without recourse to animal experiments and we apply these strategies wherever possible.

Why were they not suitable?

In some cases tissue culture models are not sufficient to recapitulate the complex interplay of different cell types in a developing embryo and in these instances experiments need to be performed in live animals. Additionally, aspects of our tissue culture models are artificial and it is therefore important that we verify our conclusions in a truly physiological setting, mouse embryos.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Production and rederivation of genetically modified (GM) mouse lines will be carried out using standard methods and the estimate for numbers of animals used is based on previous work in labs performing this type of work, including our own. These numbers include allowance for the production of GM lines from independently derived embryonic stem cell lines as is standard practice in this field. The total numbers we have calculated for the duration of this project allow for the production of four novel GM lines, and the importation of two further GM lines obtained from colleagues or international mouse repositories.
Breeding of genetically modified animals will include matings to maintain established GM lines and matings required for specific experiments. For maintenance purposes we have assumed that four regularly used mouse lines will be maintained throughout the course of the project. We estimate that GM lines engineered to modify molecular factors implicated in X chromosome inactivation will result on average in the need to maintain a further 4 experimental mouse lines. The calculations take into account that during maintenance, only one of the two available copies of a gene is modified (referred to as heterozygous), reducing possible harmful effects. In some instances we make use of genetic modifications that are engineered to manifest only when early embryos are exposed to an inducing signal (a hormone or drug given to the mother). In these instances the GM mouse line can be maintained with both copies of the gene being in the unmodified state.
Calculations for required breeding of experimental mouse lines considers that each line an average series of experiments comprised of crosses within the line (x2), and with different GM mouse lines (x6).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

A thorough literature search is conducted to ensure that experiments that are undertaken do not duplicate reliable data that is already published or present in data/resource repositories. Principles of experimental design are applied in order to minimise the number of experiments required to achieve reasonable statistical significance and data reproducibility.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible we will import previously generated GM mouse lines from colleagues/collaborators/resource centres. To avoid unnecessary breeding/maintenance of strains we will archive (embryo/sperm cryopreservation) an estimated 6 lines in the course of the project. We will supply cryopreserved embryo/sperm for defined lines to other investigators on request in order to reduce duplication of animal experimentation. All vasectomised males are shared between several groups to avoid duplication and to ensure males are not singly housed for large amounts of time.
Stock levels of mouse strains will be set to minimise animal breeding whilst at the same time ensuring that given strains are not lost. Trained animal house staff will carry out the majority of breeding and maintenance, constant contact and instruction will ensure the colonies are maintained at the correct levels.
Tissues/embryos, DNA/RNA and protein samples obtained from experimental animals/embryos are preserved, usually by storing in liquid nitrogen or at -80c, to allow where scientifically justified, use in other experiments by ourselves or other scientists who may request such reagents.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse is the system of choice for experimental genetics/genetic modification in mammals and represents the only appropriate animal model for studying the molecular mechanism of X chromosome inactivation. The techniques used here are the most refined at the moment.
Vasectomy:- Animals are expected to suffer no more than moderate harm due to the nature of the scrotal sac method which is the most refined method for this procedure. Where available and cost efficient, we will acquire genetically altered or naturally sterile males that don't require vasectomy. The ability to buy vasectomised males from a commercial supplier is also an option but only if the most refined method is used in their production.
A surgical procedure termed laparotomy is routinely carried out on pseudo-pregnant recipient female mice (after mating with sterile males) for the implantation of embryos during production or rederivation of genetically altered animals. The procedure can be performed on one (unilateral) or both (bilateral) sides of the abdomen depending on the number of embryos requiring implantation, the stage of development at implantation and the number of pseudo-pregnant recipient mice available. An alternative non surgical procedure termed transcervical transfer can be carried out but only on embryos at a specific late stage, referred to as blastocyst.
Superovulation by hormone injection is the standard method to collect the most oocytes and zygotes from the least amount of females. The appropriate concentration of hormone is age, weight and strain dependent, having been optimised in studies over many decades.

Under breeding and maintenance GM mice are not expected to suffer any more than mild pain.
Expected actual severity is sub-threshold. Adults that do show any harmful effects will be culled.
Administration of substances will be carried out by the most refined method available, usually orally.

Why can’t you use animals that are less sentient?

We analyse the consequences of specific genetic modifications for X chromosome inactivation in early mouse embryos. X chromosome inactivation only occurs in mammals so less sentient model organisms are not an option. The embryos need to be produced and maintaining these lines enables us to do this. The majority of the embryos we produce are collected from humanely killed females prior to stages when embryos are considered sentient. Cell lines are derived from early embryo stages and occasionally from humanely killed adult animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will keep up to date with all surgical procedures and their refinements and will attend any relevant workshops.
Laparotomy surgery will cause moderate suffering. Non surgical implantation through the cervix may cause distress if the handler is not as proficient but is not expected to cause harm. Animals are expected to make a rapid and unremarkable recovery from the implantation procedure. Analgesic agents will be administered.
Animals to undergo surgery are given 7 days to acclimatise before procedure starts.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery.
Code of practice for the housing and care of animals bred, supplied or used for scientific purposes

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By regularly attending the NC3Rs days available.
Regular contact with transgenic groups within our institution allow us to update each other with advances in techniques and training.
Departmental animal welfare meetings held termly allow us to communicate any 3Rs implemented within our group and invited members including NACWOs and NVS ensure that any new advances are disseminated.

NON-TECHNICAL SUMMARY

65. GENE AND CELL THERAPIES FOR ISCHAEMIC DISEASE

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

pericytes, gene therapy, vascular grafts, angiogenesis

Animal types	Life stages
Mice	juvenile, adult, aged

Retrospective assessment
The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to find new cures for patients suffering from heart attacks and poor circulation in the legs.
A retrospective assessment of these aims will be due by 21 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease caused by the narrowing of arteries and capillaries that provide oxygen and nutrients to the heart, brain, and legs, is the number one killer in the UK. Current treatments reduce the risk of death after a heart or a brain attack and delay the need of foot amputation as the last resource to save the life of patients with very poor circulation to the legs; however, many patients continue to have a poor quality of life. This is because current treatments are not enough to create new blood vessels around the occluded ones. In addition, grafts used by surgeons to create a new route around the blocked section of the artery tend to occlude after few years from implantation.

What is needed is a definitive solution for building up new blood vessels of different diameter, ideally large arteries to carry blood around the narrowed artery and capillaries to transport oxygen and nutrients to the suffering tissue. To reach this goal we will investigate new methods based on:

3) Testing drugs that can encourage the formation of new arteries and capillaries. For instance, using a protein which protects people who live a long life (centenarians) from suffering from blood vessel occlusion as they become old.

4) Producing artificial tubes containing human cells to create grafts like a real artery

What outputs do you think you will see at the end of this project?

In the medium term, 5 years from now, we expect that this research will demonstrate the proposed solutions are safe and capable of being done. We also expect to obtain new knowledge of how these treatments work. We will publish the results in medical journals where the acceptance for publication is warranted only after careful evaluation by expert reviewers. This will be a demonstration that the research is novel and accurate and has an important medical impact.
In the long term, the project aims to make these new cures available to the patients. This will require (1) preparation of documentation of main findings supporting efficacy and safety, (2) approval from agencies responsible for introduction of new medical treatments.

Who or what will benefit from these outputs, and how?

In the short/medium term, during the next 5 years, the work will generate new information about diseases that cause heart attack and poor circulation to vital organs in the body. We will pay particular attention to vascular cells that have not been investigated sufficiently in the past, such as pericytes, which are regenerative cells lining around the small and large vessels. One major goal is to incite the pericytes to act as building blocks to rebuild new and well functioning blood vessels. We will also work in the lab at producing new tube grafts

containing pericytes and other vascular cells. We expect that, once implanted, these grafts containing human vascular cells will be superior to the ones used by surgeons to bypass blocked circulation.
In the long term, the work is expected to lead to clinical trials in patients. In due course, the work will be of direct benefit to patients and reduce the burden on the national health system and society caused by the disabling effects of vascular disease.

How will you look to maximise the outputs of this work?

The full demonstration that the proposed methods are valid and applicable to patients require skills and expertise that cannot be found in a single laboratory. We will therefore collaborate with other investigators, including doctors, surgeons, and scientists, to achieve the best results.
Clinicians are the best partners for maximising the impact of our research toward patients' benefit, but also to inspire new ideas from the bedside back to the bench. Scientists, with whom we collaborate, can bring new technologies and methods to the research.
We have established contacts with several small and large pharmaceutical companies (where some of our previous research fellows have relocated) and consult them frequently to see if they can be interested in helping us to develop our research and make faster the application to the clinic.
Results will be disseminated through scientific publications and presentations at national and international meetings. This is the most effective method to speed up the progress of science among the experts in the field. We will make sure that methods and results in publications contain enough details for other scientists to repeat the experiments and confirm or extend the acquired knowledge. The data will be communicated, either they confirm (positive results) or reject (negative results) the initial hypothesis. The report of data will follow the current international guidelines.
We have extensive experience in communicating the results through press release, having had articles covered in national news media (radio, television, and newspapers). The team is also experienced in communicating with lay persons through seminars to patients' forums and public lectures. We will use all the above methods to communicate results to the public and patients' associations after consultation with the Research and Development office.

Species and numbers of animals expected to be used

- Mice: 1350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice, which are the mammals with the lowest neurophysiological sensitivity suitable for these studies. Wherever possible, we use the least severe model for our investigations. The disease we want to investigate occurs during adulthood and advanced age, which requires using adult and older models.

Typically, what will be done to an animal used in your project?

The animals will be subjected to surgical procedures to create the condition of blood flow blockade to the heart or limbs as occurs in patients. In other experiments, animals will not be operated but the natural evolution of vascular disease will be evaluated. Treatments will be given through local injections or systemic route. The

duration of experiments will last from 2 weeks to 4-6 months, and we plan to use ~1350 animals during the 5 years of the project.

What are the expected impacts and/or adverse effects for the animals during your project?

Transitory pain after surgical induction of ischaemia will occur like that experienced by patients with a heart attack. Occasionally, we expect loss of weight and difficulty in breathing caused by heart failure and poor ambulation due to reduced blood flow to the lower extremities occurring for the maximum duration of 2 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

50% mild, 25% moderate, 25% severe.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 21 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will be using mice for these studies because the complexity of cardiovascular disease and the efficacy of proposed treatments cannot be effectively tested in non-animal systems. However, preliminary studies of cell functions will be carried out before engaging with animal studies. In addition, simulation experiments are planned.

Which non-animal alternatives did you consider for use in this project?

Cellular models. Simulation of blood flow alterations using theoretical modelling.

Why were they not suitable?

Because the final demonstration of efficacy requires the complexity of a living organism.

A retrospective assessment of replacement will be due by 21 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken

to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on an average number of 30 animals per experiment for a total of ~45 experiments in 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Well designed and correctly analysed experiments can lead to a reduction in animal use whilst increasing the scientific validity of the results. To this aim, we constantly refer to the NC3R's Experimental Design Assistant as a guideline.
Here, we summarise the main steps considered in the experimental design to reduce the number of animals, control bias and ensure that the results are scientifically valid.

10) Pilot studies comprising a small number of animals to generate preliminary data and/or allow the procedures and techniques to be solidified and “perfected” before large-scale experimentation.

11) The minimum number of needed subjects will be calculated based on the expected average benefit and the expected variability of the benefit (assessed from the literature or pilot studies).

12) The allocation of animals to different groups of treatment will be at random: 1) to avoid biases, 2) to guarantee that groups have the same probability to receive a treatment, and 3) to control experimental variability. When planning attribution of animals to groups, the assignment of animals at random to different groups and sub-groups will be improved by dividing animals in blocks to achieve minimal variation.

13) We prefer to use genetically selected strains of mice because they show a more homogeneous response to the disease, meaning lower variability will allow a reduction in number of animals needed.

14) Important variables as sex, age and weight of the animal should be similar among the groups, again allowing reduction in variability.

15) Our facilities provide state of the art in environmental enrichment. We ensure that all the animals are exposed to the same enriched environment.

16) Collection of data will be done in a manner that the treated and control group have their measures collected at similar time and by the same investigator.

17) Biases will be avoided by ensuring that researchers analysing experimental outcomes are unaware of the treatment received (blinded) until the final statistical analysis.

18) Data will be treated according to the principle intention-to-treat, where all participants who are randomised are included in the statistical analysis and analysed according to the group they were originally assigned, regardless of what treatment (if any) they received

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We based our optimal number of animals and experiments based on experience in previous successful projects, pilot data and computer modelling. We also referred to the NC3R's Experimental Design Assistant to ensure that only the minimize number of animals are used.
We will use the best available technology and make sure that all the equipment is regularly calibrated for precise measurements.

A retrospective assessment of reduction will be due by 21 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the less neurological developed species that can be used to test the therapeutic interventions we hope to progress into the clinical application. We will use the best measures and practices to attenuate pain, discomfort, infections, and stress. We will adopt refined microsurgical techniques to minimise the adverse effects of surgery. All animals will be carefully monitored after surgery and recorded individually. Wherever possible animals will be group housed and provided with enriched environment. Interventions to assess pain and suffering are refined to provide the maximum benefit for restoring wellbeing without interfering with the physiology of the animals. Therefore, observation frequency is calibrated to the risk of adverse events, which is highest during post-operative surgery. The definition of stress and pain severity is addressed using sensitive scales that have been elaborated for specific use in the specific protocol, for instance to identify low level of pain in mice with heart attack or occluded leg arteries. We also designed the protocol in a way the goal of the research is reached before animals reach the most severe outcome.

Why can’t you use animals that are less sentient?

Less sentient animals, e.g. fish or reptiles, cannot be used because do not reproduce the type of response a human being put in place following injury of the adult cardiovascular system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have monitoring charts and post-operative charts in place which will be adjourned and improved as new evidence emerges from real experimentation or the available literature. Where appropriate, the animals will be trained to drug administration regimen associated with the lowest possible stress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Surgical procedures will be undertaken in line with the recommendation set out in the LASA and institutional guidelines for aseptic surgery. Injection and drug administration will be conducted in line with NC3Rs

recommendations.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about advanced in 3R by reading the literature, attending courses and webinars. In addition, we will attend at least 1 meeting every year on animal welfare, such as the RSPCA/UFAW Rodent and Welfare Meeting or other 3Rs symposium.
A retrospective assessment of refinement will be due by 21 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

66. Generation of antibodies to detect hazardous agents and their simulants

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (g) Forensic enquiries

Key words

No answer provided

Animal types	Life stages
Guinea pigs	adult
Mice	adult
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to generate antibodies to enable the detection of hazardous agents and their simulants.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are a number of dangers posed by “hazardous agents” including, but not limited to, adverse effects on human/animal health, contamination of the environment and damage to infrastructure. These hazards can include disease causing bacteria and viruses, e.g. those that can cause deadly illnesses such as meningitis or pneumonia. They may also include chemicals/toxins, the properties of which may, as with biological hazards, pose a risk to health of one or more of the following: humans, animals, aquatic-life, crops and naturally-present fauna and flora.
Knowing whether a person, animal or plant is infected with, or exposed to, these hazardous products, or whether the environment itself is contaminated, is very important in mounting an appropriate response, whether that be a targeted therapeutic treatment or wider-scale environmental decontamination. Knowledge of the presence of dangerous substances and disease-causing micro-organisms is also very important in public health monitoring.
Antibodies are able to be harnessed to identify the presence of a specific substance they have been “raised” to detect. The antibodies produced in this work will be produced to identify specific dangerous organisms/substances and help facilitate the research into and production of: therapeutic treatments, detection and decontamination methods and health surveillance, among other benefits.
Antibodies can also be used in a laboratory-setting in experiments designed to better understand hazardous organisms/substances. These antibodies can facilitate research at a fundamental level, producing publications and high quality research.
New, better antibodies will have great benefit, both furthering fundamental research and improving technologies that involve using antibodies to diagnose, detect and study health hazards.

What outputs do you think you will see at the end of this project?

A key output will be antibodies which can be modified to give off a measurable signal to detect and identify hazards discussed in the “why is it important to undertake this work?” section.
Antibodies produced under this licence will target (and therefore identify) certain specific hazards. An example would be developing antibodies to identify a disease-causing micro-organism which poses a public health risk. The output would be antibodies which can be used to facilitate research into this organism, through use in, for example, laboratory-based testing or screening. Antibodies can be incorporated into diagnostic or environmental detection devices pertaining to these hazards.
Another output will be cells (called “hybridomas” made from collection of animal tissue on a single occasion) which can be stored in cryo-preserved banks and cultured in flasks to make target-specific antibodies as a replacement to obtaining antibodies directly from animal serum.

Development of a methods to produce antibodies with less (and potentially in some cases without), animals will be pursued under this licence.

Who or what will benefit from these outputs, and how?

Correct use of antibodies, in the right scenario, can provide many benefits. Antibodies targeted to bacteria, for example, can be used in a research setting to study specific organisms and publications can be derived from this work, aiding in the diagnosis and treatment of infection. This may benefit industrial and academic research groups.
Applied uses of antibodies include drug discovery, antibody therapy, detection of substances in the human bloodstream or environment, screening for contamination (e.g. in commercially produced food products or scientific samples) and in a diagnostic setting whereby public health threats can be identified/monitored. Academic research groups, and biotechnology and pharmaceutical companies focussed on research into combatting risks from disease-causing and/or dangerous microorganisms/chemicals are examples of organisations which will benefit from antibodies.
In all the above cases, successful utilisation of antibodies to combat/prevent adverse effects of hazardous substances can have a downstream effect that will benefit any individual with actual or potential exposure to, or infection with, these hazardous substances.
Benefits of the antibodies produced in this licence are likely be realised in the short to medium term as they are used in experiments and assays (experimental tests or tests using a device). Cell lines, which produce antibodies, will be retained by the group to help our own work. Cell lines will also be supplied to other research groups, companies and/or organisations to perform research and/or use in assays.
Antibodies and hybridoma cell lines generated have been historically shared with other researchers, for example, those in academia and industry. This sharing will continue under this licence where collaborations are forged. These antibodies and cell lines can be used to support post/undergraduate projects, help develop therapeutics and facilitate microscopy experiments, for example.
Benefits will be realised within the timeframe of this licence; however cell lines can be stored for decades, therefore the potential for further benefits is enduring into the long term.

How will you look to maximise the outputs of this work?

Some work generated under this licence will be deemed confidential, for a number of reasons. This could include non-disclosure agreements between companies or agreements not to share data given by academic groups. Reports will be made available to any researchers with sufficient, relevant permission and authority to view to documents/data. Where the ability to share data and reagents with other companies and/or organisations is not prohibited because of this, it will be pursued. Where relevant antibodies will be made available for other groups to perform research, which may result in scientific publications. These groups and individuals may include companies, academics and students.
Ultimately, however this licence is to supply antibodies, rather than data and findings, and as such it is not expected that scientific papers will arise directly from the work (though use of antibodies by other groups could support this). Rather, the antibodies and cell lines themselves will provide the multitude of benefits as discussed under the "Who or what will benefit from these outputs, and how?" section. **Species and numbers of animals expected to be used**

- Mice: 70
- Guinea pigs: 6
- Rabbits: 3

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the least sentient animals that can be used to suitably make "hybridomas", where cells from a mouse that has been immunised are collected after humanely killing the mouse, altered to make them able to grow in cell culture and then cultured in a flask. This means that cells from one mouse can enable later production of large amounts of antibody in the flask.
Production of antibodies by purifying them directly from animal serum will only be used when there is no other feasible option. In this instance larger animals, specifically rabbits or Guinea pigs, will be used so that a larger volume of serum can be collected from a smaller number of animals. This will avoid using large numbers of mice. Rabbits, being larger than Guinea pigs, will be more suitable for this purpose. However there are instances where Guinea pigs may elicit a better immune response than rabbits.
Polyclonal antibody production takes a shorter time than monoclonal antibody production, and it is expected that animals for polyclonal antibody production will begin the process as an adult, and be humanely killed before they can be considered "aged" animals. For monoclonal antibody production, an immunisation schedule and long rest period can mean that some animals may be considered aged towards the end of the process. However it is important to note that animals will <u>never</u>: **a)** be bought as already aged animals
b) be purposefully aged
All animals used to generate antibodies must have a mature immune system, which excludes animals younger than those stated in this licence.

Typically, what will be done to an animal used in your project?

For animals being used for either polyclonal or monoclonal antibody production, they will be administered with a primary immunisation (an injection via a suitable route for the animal), followed by blood sampling to analyse the titre (usually around 1 week later). If the titre is insufficient they will receive up to 6 boosts to increase the titre. At this point if the animal is used for polyclonal production it will be humanely killed and antibodies will be purified from the serum. This entire process will generally last 3-4 months.
Should the animal be used for monoclonal antibody production it will likely enter a rest period (required to produce immune cells needed for subsequent work) for >8 weeks, at which point it will receive a prefusion boost (usually an intravenous injection), then will be humanely killed a suitable amount of time later, with its immune tissue used in the production of hybridomas, which secrete monoclonal antibodies. This entire process will generally last around 6-9 months.
Blood samples will withdraw a blood volume no greater than 10% total blood volume on one occasions, and no more than 15% over 28 days. Animals will have a maximum of 8 samples taken and sampling will not occur more frequently than one per day, though it is likely they will be separated by around 1-2 weeks.
Animals <u>are not</u> expected to display symptoms of infectious disease or intoxication associated with any disease-causing or toxic agents used in this licence, as the agent will be suitably **<u>inactivated</u>** before it is administered. This is analogous to vaccination, where an immune response is produced without causing disease. In some instances, animals may be immunised with isolated parts of a harmful organism, in a format which is considered non-hazardous.
In instances where chemicals are used, these will be produced by synthetic chemists with expertise in the substance produced. This will ensure that the substance is suitably inactive so as to minimise the chance of adverse reactions in animals.
In as many instances as possible, immune tissue from immunised animals not used in polyclonal or hybridoma generation will be used to support the development of recombinant methods of antibody production, which can reduce and in some instances replace animal use

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will likely shows signs of distress and discomfort during the collection of blood samples however this should resolve immediately after the sample is taken as the distress is mainly due to the animal being held for blood sample collection.
For animals that are administered with the antigen, there may be local reactions which are generally not painful for example, formation of a nodule at the site. If a nodule bursts, it should close within 24 hours.
Injection of antigens may cause abdominal pain which is expected to be generally mild, extending to moderate on occasion.
Exposure to the antigen should induce an immune response, this can cause animals to feel generally unwell for up to 3 days.
As the number of boosts increases, using the antigen, the likelihood of adverse effects increases, however the number of boosts is capped at 6, with some protocols requiring another single boost after at least 8 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: Most (60-80%) of animals are expected to experience a local reaction to injection sites which is expected to be mild. This will typically result in formation of a nodule. In up to 25% of these animals the nodule will rupture, which is considered moderate severity. Due to the smaller size of mice, nodules forming in tissues (after intramuscular injections, for example in the thigh), may have more of an adverse effect on the mouse than in larger animals. All animals will experience at least mild abdominal pain with certain injection sites, in some instances (dependent on the antigen used) this may increase to moderate severity. Some animals may appear generally unwell due to a systematic immune response, this is expected to be uncommon and is often (but not exclusively) associated with use of live (non-hazardous) agents which will be avoided where possible.
Guinea pigs: Most (60-80%) of animals are expected to experience a local reaction to injection sites which is expected to be mild. This will typically result in formation of a nodule. In up to 25% of these animals the nodule will rupture, which is considered moderate severity. All animals will experience at least mild abdominal pain with certain injection sites, in some instances (dependent on the antigen used) this may increase to moderate severity. Some animals may appear generally unwell due to a systematic immune response, this is expected to be uncommon and is often (but not exclusively) associated with use of live (non-pathogenic) agents which will be avoided where possible. The use of live (non-hazardous) agents in Guinea pigs is even less likely than its use in mice.
Rabbits: Most (60-80%) of animals are expected to experience a local reaction to injection sites which is expected to be mild. This will typically result in formation of a nodule. In up to 25% of these animals the nodule will rupture, which is considered moderate severity. Injection of rabbits will not use routes which are likely to cause abdominal pain (as sometimes seen in mice and Guinea pigs). Some animals may appear generally unwell due to a systematic immune response, this is expected to be uncommon and is often (but not exclusively) associated with use of live (non-pathogenic) agents which will be avoided where possible. The use of live (non-hazardous) agents in rabbits is even less likely than its use in mice.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Antibodies are the product of an extremely complex immune response, occurring within organisms that are challenged with an antigen. This process is too intricate to be replicated fully and exactly in a test tube with current technology. Some methods are available which mimic, or adapt certain aspects of this, which utilise fewer animals, or potentially no animals, however none have yet been determined as suitable to fully replace animal-derived antibodies for our purposes.

Which non-animal alternatives did you consider for use in this project?

Display platforms- e.g. phage display, using phage viruses to display millions of combinations of antibodies by having them express a library of different genes. Antibody-displaying phage are screened for interaction with the target. Other display platforms include ribosome and yeast.
Naive libraries of antibody fragments (scFv and Fab)- Pre-existing libraries or randomised antibody fragments screened to look for binding to agents, often displayed on phage
Synthetic aptamers and affimers: Biological molecules selected based on ability to bind an antigen, where randomised DNA or protein sequences (libraries) are displayed and analysed for binding to antigen.

Why were they not suitable?

Display platforms such as phage display: The technology is not advanced enough to replace animal derived antibody production for our purposes. There is promise with this technology, and it is in the process of being compared to traditional hybidoma production (supported by this licence). Limitations of phage display currently being addressed include, insufficient library size to give suitable diversity and optimising screening methods to ensure we get sufficient representation of these libraries. Native pairing of antibody chains can occasionally be an issue. Finally, unless performed de novo, with a pre-existing positive control antibody, some animal derived antibodies may be required for phage display as a screen or positive control.
Naive libraries of antibody fragments (scFv and Fab): Attempts at generating antibodies using naive libraries of antibody fragments (scFv and Fab) have not yielded the selectivity, specificity and affinity characteristics required for use in our detection assays. This is likely due to the fact that these libraries are not large enough, and without a robust enough display method for these libraries, this technology is not suitable for our uses. We continue to watch this technology in the hope that it will become viable.
Synthetic aptamers and affimers (biological molecules synthesised to bind to certain agents): Previous tests has demonstrated these are unsuitable at their current technology level. Affimers have been demonstrated to not bind to antigens for long enough, while both technologies can have bias in how the libraries are derived. Being smaller molecules also makes them very difficult to apply in certain assay formats with current technology.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to immunise to each target is decided through: previous similar data generated in house, other empirical data, subject matter expert input, NACWO/NVS input. Decades of immunisation reports exist which we can draw on to make decisions, along with knowledge of numbers of animals required for previous, similar targets. A statistician was consulted on the animal numbers used in this licence and how these are derived.

The numbers stated directly in the Objectives section are based on the minimum number of animals expected to generate a sufficient amount of immune tissue for hybridoma generation or, where relevant, recombinant methods. Where recombinant methods, are used, they may be more efficient than creating hybridomas, thus the numbers of mice used are decreased to reflect this.
The number of animals required for polyclonal production is based on the amount of antibody needed compared to the volume of serum produced by a rabbit/Guinea pig and the expected concentration of antibody in the serum. The minimum number of animals is selected to obtain the amount of serum, and therefore antibody, needed.
In all the above instances, if a target is expected to produce an excellent immune response, based on previous experience and/or open literature, fewer animals may be used in antibody production as the chance of obtaining a good panel of monoclonal antibodies is increased. It is important to recognise however that downstream hybridoma efficiency can also have a large impact on the success of the work.
The remainder of the animals are to cover the maximum number required for forecasted future work, based on the workload that is expected, split across monoclonal and polyclonal production. When forecasting the number of animals to be used, the "worst case" is used where the maximum number of requests for antibody are pursued.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Previous similar antibody production work and statisticians were consulted to identify a minimum number of animals, which was used to obtain a sufficient panel of hybridomas for monoclonal antibody production or amount of serum for polyclonal production.

Improvements to the downstream processing of mouse tissue are currently under investigation; methods such as gentle mechanical and enzymatic separation of spleen tissue to obtain splenocytes more efficiently and B-cell enrichment, which may lead to less mouse use in the future.
Where possible multiple animal groups all being immunised to the same target are started with an approx. 1 month stagger. If the immunisation is much more successful than expected in earlier groups, and it is decided that not all animals that were estimated to generate sufficient immune tissue are required, then ordering of the full anticipated number of animals will be re-evaluated. This will mean less animals are used.
Deep tissue sequencing technology, as well as antibody display library technology are being investigated to reduce animal usage in antibody production. By sequencing the immune tissue, the genetic code of antibodies can be identified and antibodies produced recombinantly (i.e. synthetically). Less animals will be required using these methods than traditional hybridoma production.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For monoclonal antibody production, spleen cells are primarily used, however where possible, immune cells will also be harvested from the mouse femur, for example.
Best endeavours will be made for remaining tissues from rabbits or Guinea pigs immunised with antigen to be used to support the development of new antibody production techniques which require fewer animals, or potentially none, in some circumstances, making possible the identification of rabbit or Guinea pig monoclonal antibodies (recombinant) without the risk of needing to perform repeated rounds of mouse hybridoma generation in order to discover reagents suitable for filling our requirement

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs

(harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice: An animal model with one of the lowest capacities to feel pain, suffering, distress, or lasting harm but still generate suitable immune tissue. Species lower than a mouse generally do not have complex /suitable immune systems to generate required antibodies.
Rabbits and Guinea pigs: For experiments where larger volumes of serum are required (i.e. polyclonal antibody production), the use of fewer larger animals will be preferred over the use of a higher number of smaller mice. The species selected are some of those with one of the lowest capacities to feel pain, suffering, distress, or lasting harm but still generate a suitable immune response with a sufficient amount of circulating serum. Usually rabbits would be preferred as a species with a larger serum

volume compared to alternative small animals, unless there is evidence to demonstrate a good immune response associated with a different species (i.e. in some circumstances Guinea pig). The increased serum volume in rats over mice does not have the magnitude to make it as useful an alternative as Rabbits and Guinea pigs, additionally rat antibodies are more likely to cross-react with mouse antibodies.
Traditionally, polyclonal antibodies would be generated in larger animals, such as donkeys or sheep. These are not used here as: **a)** that volume of serum is not required for the small scale amount of polyclonals we will use and **b)** smaller animals can be more easily kept in contained conditions.
Guinea pigs are utilised in protocol 1 as an excellent immune response has been demonstrated towards the relevant immunogen which will be used in this study. It is decided that due to the increased likelihood of getting a good immune response, Guinea pigs will be used.

Why can’t you use animals that are less sentient?

Animals less sentient than mice (e.g. insects, which lack the immune memory of mammals) are not suitable for monoclonal antibody production. A mouse is the least sentient animal model with a good chance of generating hybridomas.
A functional, mature immune system is required, with immune schedules taking place over months. This prevents use of animals in immature life stages, when they would have reduced sentience (e.g. prior to two thirds of the way through gestation) and under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

A less distressing form of administration of antigen will always be chosen first (e.g. subcutaneous in mice), unless it does not, or is reasonably expected not to, elicit a suitable immune response.
Where suitable, subcutaneous administration will utilise a "scruffguard" or similar device, whereby the mouse is placed on a spongy surface and the "scruffguard" is placed over the animal to allow easier scruffing and injection of the antigen. This avoids having to restrain the animal and scruff at the same time, which is more distressing on the animal.
For all animals, there will be vigilance for potential use of milder adjuvants which may decrease the adverse effects experienced by animals being immunised. There will be limits on the number of times an animal is immunised, and injection sites will be checked daily if any adverse effects are seen.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Available guidelines on the NC3Rs website regarding blood sampling will be followed. This references "A Good Practice Guide to the administration of substances and removal of blood, including routes and volumes" by Diehl et. al. This will also be followed regarding the administration of antigen.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Updates on advances in the 3Rs are regularly distributed by our Named Information Officer. The licence holder

is actively engaged in our establishments Animal Welfare and Ethical Review Body (AWERB). Any appropriate advances will be discussed with our veterinary staff and, where appropriate and compatible with the scientific aims of the project, these advances will be incorporated.
A watching brief will be kept in working towards adopting methods to replace and reduce animals.

Home Office

NON-TECHNICAL SUMMARY

67. Genes and essential nutrient influences on behaviour.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Methylation, Circadian rhythms, Methionine

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how essential nutrients and their metabolism can influence our physiology and behaviour, and in particular our biological rhythms.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We eat food to stay alive; our body needs energy to keep functioning. Beyond simply providing energy, some nutrients dramatically influence how our body functions. This is especially true for vitamin B9 and the essential amino acid methionine, whose deficiencies can cause many pathologies including aging, diabetes, and neurological problems. These deficiencies can either arise from a poor diet or from genetic mutations that are often undiscovered until severe symptoms occur. Yet, the mechanisms underlying how these diseases occur are poorly understood.
In our body, vitamin B9 and methionine are involved in the metabolism of methyl groups. Methyl is a small chemical group, composed of only one carbon atom linked to three hydrogen atoms, which can be attached to other molecules in the cell, including DNA, RNA or proteins. The addition of a methyl group, or *methylation*, is a mechanism by which our body can regulate the function of virtually every genes, depending on what the methyl is attached to. Low amount of methionine or vitamin B9 in our diet, or mutations in genes involved in their metabolism, will inhibit methylation reactions and cause wide-ranging disruptions.
Our research has previously revealed a link between methyl metabolism and the body clock in many organisms from bacteria to humans. However, this research was based on *in vitro* experiments, using cell cultures. The nature of this link and how it is regulated is unknown. Using mice, whose methyl metabolism is virtually identical to ours, we seek to define which methylations are linked to our body clock, and whether and how they are regulated by our diet.
In addition to further our fundamental understanding on how nutrients can affect our body, this research will also provide potential new targets for the treatment of diseases related to methionine deficiencies.

What outputs do you think you will see at the end of this project?

Discoveries made during this research will contribute to our understanding on how our bodies work at the fundamental level but will also provide insights into two clinically relevant themes: nutrients metabolism and the body clock.
The body clock is clinically relevant because our life-style and 24-h society have detrimental consequences on our biological rhythms, leading to poor general health and increased incidence of cancer, cardiovascular and metabolic diseases. Interestingly, deficiencies in essential nutrients when unnoticed cause similar pathologies. These deficiencies can be caused by a poor diet but can also originate from genetic mutations.
The evidence accumulated so far suggest that these two themes, clock and diet, are intimately linked in our body; understanding such a link will therefore increase our understanding on how our body functions and responds to stress, and provide potential new avenues for the treatment of related pathologies.

Who or what will benefit from these outputs, and how?

- **Academic beneficiaries**

At the local and (inter)national levels, results from this project will find beneficiaries in fundamental as well as in more applied academic fields.

- **Society**

This research seeks to understand the link between our diet and our body clock, how they regulate each other, and what pathologies occur when this link is disturbed.

How will you look to maximise the outputs of this work?

Positive and negative research results will be published in Open Access journals, and data produced by this research will be deposited in repositories (e.g. NCBI's Gene Expression Omnibus, EMBL's Proteomics Identifications database) when appropriate. Research results will be presented at (inter)national conferences and host laboratories. Scientific papers will be accompanied by media releases to reach the general public. Collaborations with (inter)national laboratories have already been set up and will develop further in the course of this research. When appropriate, tissues and data will be shared with direct collaborators.

Species and numbers of animals expected to be used

- Mice: 11500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In the first part of this research, the mice will be genetically modified but will develop and grow healthily just like normal mice. A drug called tamoxifen (used in the chemotherapy of breast cancer) can then be added to the food of these mice, usually at the adult stage, which will cause the inactivation of a selected gene. This allows the physiological role of that gene to be investigated, without risking potential negative consequences on the development of the animal.
In the second part of this research, animals used will be wild-type and healthy adult mice that will be given food lacking essential nutrients such as methionine and choline, whose insufficient intake has been associated with hepatitis in humans. However, how these nutrients are used in our body, and what processes they regulate, is not well understood.

Typically, what will be done to an animal used in your project?

A typical experiment in our project will involve monitoring mice in a cage containing various items to interact and play with, notably a running-wheel that is connected to a computer to measure the activity of the mouse, or a system that measures when and how much the animal eats and drinks. Since these behaviours are controlled by the mouse body clock, when the mouse is in complete darkness these rhythms in wheel running and drinking can be quantified and used to measure the internal biological rhythms of the mouse. The effects of gene inactivation and nutrients deficiency on these behaviours will be studied. In addition, some animals may be killed by a Schedule 1 method in order to identify the molecular mechanisms triggered by these nutrients, or lack thereof.
The precise procedures that will be performed on the animals in this project, will be the following.

Part 1:

1) Animals will be genetically modified.

2) Animals from 1) will be provided with a diet containing the drug tamoxifen, or may be given tamoxifen via gavage (direct administration into the stomach through a tube) or subcutaneous injections (only if the diet method does not yield the expected results).

3) Some animals from 1) and 2) will be single-housed and monitored for biological rhythms under normal light/dark cycles and constant darkness for up to 2 months.

4) Some animal from 1) and 2) other than the one used in 3) will be single-housed and undergo physiological monitoring and/or imaging using non-invasive specialist equipment for up to 6 weeks.

5) Animals may also have small blood samples collected (microsampling), and their ear may be notched for identification.

Part 2:

6) Animals will have the composition (decreased levels of essential nutrients) of their food changed for a duration of up to 3 months.

7) Animals from 6) will be single-housed and monitored for biological rhythms under normal light/dark cycles and constant darkness for up to 2 months.

8) Animal from 6) other than the one used in 7) will be single-housed and undergo physiological monitoring and/or imaging using non-invasive specialist equipment for up to 6 weeks.

9) Animals other than those used in 6) will be fasted for a maximum of 38 hours.

10) Animals may also have small blood samples collected (microsampling), and their ear may be notched for identification.

What are the expected impacts and/or adverse effects for the animals during your project?

Inactivation of candidate genes may cause chronic pathological consequences such as weight loss, anaemia and an inefficient immune system.
Single-housed mice can experience some level of stress and anxiety, that may be more pronounced when it is in constant darkness for 2 months.
The diets lacking methionine and choline, when given for a period of up to 3 months, are likely to cause health issues in mice as they do in humans, notably weight loss and hepatitis, although this will not be allowed in this project since healthy mice are needed.
Veterinary help will ensure mice showing these symptoms are treated appropriately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold: 50%
Mild: 40%
Moderate: 10%
Severe: 0%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

These studies are aimed at understanding how the metabolism of essential nutrients can influence our physiology and behaviour. Therefore, an animal showing a complex array of human-like behaviours is needed.

Which non-animal alternatives did you consider for use in this project?

Human and mouse cell cultures will precede all investigations involving animals.
We have also considered simpler organisms, including fish, flies and even plants and bacteria.

Why were they not suitable?

While cell cultures are key to study molecular mechanisms, investigating physiology and behaviour can only be done with a complete organism.
Less complex organisms do not exhibit the same array of human-like behaviour that mice do, and do not have the same dietary requirements.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

11,500 is the maximum number of animals estimated, but the actual number of animals used is likely to be lower. This number was estimated on the basis of the number of different genes that will be investigated, each of which requires a separate genetically-modified mouse line and respective controls. An independent statistician has been consulted on the number of animals required to achieve the objectives of our research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experimental designs were approved by an independent consulting service.

We are working with the NC3Rs experimental design assistant to help us ensure the experimental designs are appropriate.
Animals studied will have the same genetic make-up and age to reduce variability.
To avoid experimental bias, random allocation of mice to treatment groups or to cage number and position within the animal house will be carried out, and the investigators assessing the outcomes of experiments will be blind to the nature of the groups to be compared.
Animals of both sexes will be used, which ultimately will decrease the total number of animals used.
Typically, randomisation will be carried out using a computer's randomize function to avoid human bias.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When applicable, *in vitro* experiments using cell cultures will be carried out to first test the validity of our hypotheses before deciding whether *in vivo* experiments should go forward.
Pilot studies will be used; they will enable us to determine the most efficient and least stressful methods, as well as to obtain a first idea of the effects triggered by the procedures.
Another benefit of running pilot studies is that it will allow a more accurate estimation of the required number of animals.
Genetically modified animals expressing the luciferase gene as a reporter for molecular circadian rhythms *in vivo* will be measured longitudinally, at multiple time points, without the need for humane killing of different animals for every time point.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Tamoxifen-inducible gene inactivation allows the physiological role of a given gene to be investigated without risking any negative consequences on the development of the animal. Tamoxifen administration via food intake is the preferred method because it is not invasive and based on the animal's own volition.

Why can’t you use animals that are less sentient?

Immature life stages are not appropriate because inactivation of the genes studied here cause early developmental arrest, and less sentient animals do not show complex human-like metabolism and behaviour.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements throughout the project

In relation to how the welfare of the animals is affected by the procedures, monitoring may increase or decrease in frequency and details. Should the animals develop pathologies to a level that is more serious or earlier than anticipated, increased care, under the veterinary surgeon's supervision, will be provided and protocols will be updated accordingly.
As much as possible animals will be acclimatised when transferred to a new environment.
When animals are single-housed, environmental enrichment will be provided to alleviate potential anxiety due to social isolation.

Animals of both sexes will be used, which will increase the relevance of our research results.
Animals kept in constant darkness will be killed by a Schedule 1 method in the dark, using night-vision goggles, to prevent acute stress to the animal and avoid the effects of light exposure on the animals biological rhythms.

The licenced personnel will be trained to use the most refined methods of mouse handling and husbandry, providing environmental enrichment in the cages so that the animals can display an appropriate range of behaviour as in the wild.

Refinement specific to the first part of the project

Pilot studies have been set up to be able to determine the most refined methods in the administration of substance such as tamoxifen. A common problem of tamoxifen-containing diet is their low palatability, decreasing food intake, causing weight loss, and lacking efficiency. To refine this, the highly palatable sucrose will be added to the diet to promote food intake.

Refinement specific to the second part of the project

Pilot studies have been set up to be able to determine, with a view to stop or prevent, the effects of methionine/choline deficient diet on the animals' health.
Unfortunately, commercially available methionine/choline-deficient diets have been optimised to quickly induce fatty liver diseases, notably by adding sucrose and polyunsaturated fatty acids. However, we will not include these "improvements" in an attempt to prevent or delay the incidence of fatty liver diseases while still allowing the specific roles of methionine and choline to be detected.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The Code of Practice for the Housing and Care of Animals Bred, Supplied or Used for Scientific Purposes published by the Home Office (2014) will be followed.
The LASA guidelines for record keeping will be enforced to all personnel working on the project.
A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes (Diehl et al., 2001) will be followed whenever a procedure requires administration of substances and removal of blood.
The ARRIVE guidelines will be followed when reporting research results using animals.
These best practices will evolve whenever these guidelines are updated.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through discussions with colleagues and named persons at the institute, through keeping up to date with recent discoveries in the field, and through frequent visit to the NC3Rs website looking for resources. We have an account with the NC3Rs and receive frequent updates by email. The NC3Rs regional programme manager, available on site can be consulted about recent advances.

Home Office

NON-TECHNICAL SUMMARY

68. Genes and lineages in blood and immune cell generation

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Stem cells, Hemato-immune system, Lineages, Gene regulatory networks, Mouse development

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to breed and analyse genetically altered mice to further our understanding of the cell lineages and gene regulatory networks involved in the generation of blood and immune cells during embryonic development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood and immune cells are critical for the health and survival of an organism, with red blood cells transporting oxygen and white blood cells of the innate and adaptive immune system fighting invading microorganisms. The process by which blood stem cells and the layered immune system are generated during embryonic development is poorly understood. To understand this process in sufficient detail to develop and improve therapeutic applications for blood and immune disorders, it is important to understand how these cells are born during embryonic development. Indeed, the notion that all immune cells are derived from blood stem cells has recently been challenged. It has become increasingly clear that several types of immune cells that display specific functions later in life are generated independent from blood stem cells early in embryonic development. The precise cellular origin of these immune cells remains unclear. Here we aim to trace the origin and development of blood stem cells and immune progenitors in the mouse embryo, begin to map their respective contribution to the adult blood and immune system, and characterize the gene regulatory networks underlying their generation. Our studies are expected to contribute important new insights into blood stem cell biology and innate immune cells. **What outputs do you think you will see at the end of this project?**

The output of this project is new knowledge about the cellular and molecular mechanisms that underlie the initial generation, maintenance, and expansion of blood and immune cells in embryonic development. Within the current interest in regenerative medicine, it is important to obtain a thorough understanding of how adult stem cells and the organ systems they maintain are generated. The elucidation of the gene regulatory network and signals underlying blood stem cell emergence will form a valuable benchmark for future studies into how this network is perturbed in leukemia. In addition, the knowledge obtained from this project will be valuable for the future development of new protocols to generate blood and immune cells in vitro, such as from induced pluripotent stem cells (iPS) and embryonic stem (ES) cells. This would be valuable both for research purposes such as drug development and for the improvement of stem cell-based therapies in for example leukaemia. We expect the output route of this project will be primarily through publication in peer-reviewed journals, through presentations at international and national conferences, through collaborations, and through science events for the public.

Who or what will benefit from these outputs, and how?

Short term: The foreseeable short-term impact is the valuable insights obtained from this project for the field-specific scientific community, whereby data acquired here will form the basis for new lines of work.
Long term: The long-term impact may include the establishment of novel blood stem and progenitor culture and expansion methods/conditions as well as identification of critical genes/gene networks that can be therapeutically targeted.

How will you look to maximise the outputs of this work?

We have a history of successful collaborations all over the world. Through such collaborations we are exchanging project-related knowledge before it becomes public, allowing us to tweak experimental designs and revisit aims and questions of our projects and likewise inform the work of colleagues. In addition, we attend

conferences, symposia, meetings and talks to share our unpublished results.

Species and numbers of animals expected to be used

- Mice: 11600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The study of the development of blood and immune cells in embryonic development requires we use embryos as our experimental model, as the complex developmental processes we study cannot be replicated in the laboratory. We use the mouse as our model as this has many similarities with human for the processes we study. Most of our work involves isolating cells from embryos at different stages of development, that reflect discrete steps in the development of blood and immune cells, for experiments performed outside the animal in the laboratory. To obtain embryos of a particular developmental age we set up timed matings. For this we maintain mouse colonies that carry for example fluorescent reporter genes that mark our cells of interest, or that carry extra or fewer genes involved in the generation of blood and immune cells so we can test the role of these genes in developmental processes. At birth mice are less developed than human babies, so to study stages equivalent to late human development we also study newborn mice. As blood and immune cells still develop in early life, we also sometimes study cell obtained from juvenile and adult mice.

Typically, what will be done to an animal used in your project?

Typically this project involves breeding and maintenance of genetically altered mice and setting up timed matings for embryo analyses in the laboratory. Mice are marked for identification purposes. On some occasions need to perform experiments in the mice. This includes 1) testing the capacity of cells to regenerate the blood of irradiated mice in an assay similar to what happens in bone marrow transplants of patients with leukemia. These so called reconstitution assays take up to 6 months to be sure that the test cells contained blood stem cells. 2) In another assay we administer a gene inducing or deleting substance to a pregnant female. These assays typically need two inherited components to work. As the pregnant female only carries one of them (the other is provided by the father), genes are only induced/deleted in the embryos. The embryos are analysed in the laboratory. 3) Finally, we occasionally label the newly synthesized DNA of cells by administration of a DNA-base analogue that is incorporated in the DNA. As this only happens when cells divide, this assay gives us information about cell division so we can study how this is related to the processes underlying the generation of particular blood and immune cells.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of mice used on this licence will be bred and used for tissue harvest following Schedule 1 killing. For mice that undergo the experimental procedures in this licence are closely monitored for adverse effects (e.g. dehydration as a result of the irradiation, abortion due to the administration of gene

inducing/deleting substances), and killed if adverse effects arise, though these are rarely seen. The in vivo assays involve momentarily discomfort from the injection, but no other adverse effects are expected.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The large majority (approximately 90%) of the animals are only used for breeding and maintenance, including timed matings. The remaining approximately 10% undergoes an experimental procedure. Over 95% of the mice used for breeding/timed matings have an expected actual severity level that is sub-treshold; the remaining up to 5% are expected to experience a mild severity level. Of the mice undergoing an experimental protocol, approximately 45% is expected to experience an actual subthreshold severity level, approximately 20% an actual mild and approximately 35% an actual moderate severity level.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Blood and immune cell generation in the embryo is a complex process that so far cannot be reproduced in vitro. During embryonic development, blood stem cells and other progenitors of blood and immune cells are generated in asynchronous waves that take place at different locations in the embryo and surrounding membranes. The cells generated in these waves migrate to the fetal liver and bone marrow where they generate more blood and immune cells that are distributed over various other organs. Blood stem cells can currently not be robustly generated in the laboratory, and the migration of cells in the embryo can only be studied in situ. We use the mouse as a model organism, as this is the lowest mammalian species with clear similarities to the development of human blood and immune cells. It is not feasible to use human material to study the migration of cells over the embryo as this involved inherited labelling methods not possible in human. Also, the earliest stages we studied are seldomly available in human as they are equivalent to pregnancies of less than 1 month.

Which non-animal alternatives did you consider for use in this project?

We use mouse embryonic stem cell (ESC) cultures and/or human induced pluripotent cells (iPSCs), and cell lines for part of our assays. Overall, we make use of a large variety of in vitro/ex vivo assays wherever possible.

Why were they not suitable?

Although mouse ESCs and human iPSCs can be differentiated in vitro into blood progenitor cells, their maturation in the red and white blood cells found in the blood is often incomplete and importantly blood stem cells cannot be robustly generated in these cultures. The type of blood and immune cells obtained from these models is thought to reflect those found in the membranes surrounding the embryo (the so called yolk sac). So we use this model to study basis processes in yolk sac blood cell generation, in particularly when large cell

numbers are needed for the experiment, for which sometimes cell lines are useful too. Still we largely depend on embryo-derived material for our studies into blood and immune cell generation because of the dynamic changes in space and time that are associated with the generation of these cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is estimated based on the type and number of experiments that can be performed by the laboratory group over a period of 5 years, and the number of animals that needs to bred to perform these experiments. Most of the animals are used in a breeding protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments are carefully planned to avoid wastage, and the size of the mouse colony is continuously tailored to meet experimental needs, to avoid surplus. We freeze embryos/sperm to archive lines not in use.
We perform pilot experiments to explore new hypotheses and design the experimental series based on their outcome. We make sure to use the right number of mice to see an effect so it is clear when there is none and experiments can be ended.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use the minimum of stud males and females for timed matings, as we screen the females for estrous so they are likely to get pregnant after mating.
When a few mice of a specific strain are needed, we seek to obtain these from local colleagues to avoid duplicating the colony. This reduces mouse numbers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the best studied model for blood and immune cell generation in mammals. It has many similarities with human, a plethora of markers is available for the identification and isolation of different blood and immune cells, and many in vitro assays are available to test cell characteristics. In addition, blood stem cell transplantation assays have been pioneered in mice and are well established and there is a wealth of data to build our studies on. In addition, the multiparity of the mouse makes it feasible to obtain sufficient material for study.
We monitor mice in breeding protocols for aggression by either sex. This is rare, but if it happens aggressors are replaced.
Irradiation can cause temporary discomfort though it is rare in the type of mice we use. Where possible we use outbred strains as recipients, which are more robust than inbred strains. Irradiation occurs in a split dose to minimize adverse effects on e.g. the gut. Irradiated mice are closely monitored for adverse effects of irradiation.
With the administration of gene inducing/deleting agents rare adverse effects can occur which are mitigated by close monitoring. We choose the route of administration that causes least distress while meeting the specific requirements of the particular experiments.

Why can’t you use animals that are less sentient?

Most of our work is done with cells obtained from mouse embryos, which is the least sentient life stage in mice. For repopulation experiments to yield clinically relevant data on blood stem cells, experiments need to be performed in adults as this is the main life stage in humans that undergoes bone marrow transplants as therapy for severe blood-related disorders.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Most mice will not experience welfare issues during their lifetime, apart from occasional mild and transient discomfort or pain associated with marking, administration of substances, or blood sampling via a superficial vessel. Rarely, mice may experience moderate adverse effects that is mostly transient due to irradiation. To minimise this, animals will be closely monitored in the critical 2 week window after irradiation and any animal exhibiting more than moderate transient effects will be humanely killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow guidance from NC3Rs and local guidelines based on these. We will follow ARRIVE guidelines for the reporting of animal experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Dissemination of the 3Rs is through discussion at lab meetings, information from the NVS and NACWO, attendance of the termly departmental welfare group at our university and 3R days, the nc3rs.org.uk website. We also aim to find new ways to implement the 3Rs in discussions with animal technicians and colleagues.

Home Office

NON-TECHNICAL SUMMARY

69. Genetics of Down Syndrome

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Down syndrome, Congenital heart defects, Craniofacial development, Neuronal development, Cognitive function

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to identify genes that are needed in three copies to cause specific Down syndrome phenotypes and establish the mechanisms by which they cause pathology.

Potential benefits likely to derive from the project, for example how science might be advanced or how

humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Down syndrome is a human condition caused by an extra copy of chromosome 21. It is a complex disorder with many different phenotypes including leukaemia, autoimmunity, congenital heart defects, craniofacial changes, and cognitive deficits. It is not known which of the ~230 coding genes on chromosome 21 is required in three copies to cause these diverse phenotypes, and thus there are no effective treatments for any of these conditions. We aim to identify the causative genes and establish how an extra copy causes pathology. Knowing this will lay the foundations for the design of rational therapies for the phenotypes of this common genetic disorder.

What outputs do you think you will see at the end of this project?

The main outputs of this work will be knowledge about which genes cause DS phenotypes and the mechanisms by which they do so. This will be published in peer-reviewed journals, and the publications will always be open-access and thus available to all to read for free.

Who or what will benefit from these outputs, and how?

The first beneficiaries will be other researchers working on DS. More importantly, in the longer-term the work will benefit those who are working towards identifying rational therapeutic approaches to alleviate DS phenotypes. Ultimately, the beneficiaries will be people with DS who will have access to therapies that will be developed on the basis of this research.

How will you look to maximise the outputs of this work?

The main outputs from the work will be published in peer-reviewed journals, and the publications will always be open-access and thus available to all to read for free. We will also communicate our work through presentations, by giving seminars at other institutions or through seminars or poster presentations at conferences. Unsuccessful approaches will be discussed openly in appropriate venues, for example at internal meetings. We have an extensive track record of collaboration, helping other groups with more limited experience in these areas of research and sharing all our novel mouse strains, often before publication. We will continue to support such collaborative work. **Species and numbers of animals expected to be used**

- Mice: 24000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The project will use embryos, neonates or juveniles to study developmental processes, e.g. heart development to investigate congenital heart defects. Adults will be used to study physiological processes typical of adult mice, e.g. cognition, locomotor function.

Typically, what will be done to an animal used in your project?

The large majority of mice in this project will be bred and then killed and tissues analysed by, imaging, cell culture,

transcriptomics, proteomics flow cytometry, etc. Some mice may be treated with substances to induce gene deletion or to report cell proliferation. In some case adults will be analysed by in vivo imaging, or in tests of cognition or locomotor activity.

What are the expected impacts and/or adverse effects for the animals during your project?

For the vast majority of mice there will be no adverse effects. For some animals, there will be transient pain when being injected, but no lasting harm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild – 95%
Moderate – 5%

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The DS phenotypes we are studying – congenital heart defects, otitis media, craniofacial changes, learning and memory deficits, immune dysfunction and locomotor impairment – cannot be studied in vitro. These phenotypes can only be meaningfully studied in vivo.

Which non-animal alternatives did you consider for use in this project?

We considered using human IPSCs from DS people and differentiating these into relevant cell types.

Why were they not suitable?

The use of IPSCs is possible, but very limited – essentially only individual cell types can be studied and the complexity of tissue interactions cannot be replicated in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate is based on our current experience of carrying out similar studies under our current project licence, and the number of researchers working on this project which will remain around 5 individuals for the next 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The efficiency of animal usage will be maximised by careful control of breeding to meet research needs with respect to numbers, phenotypic uniformity and health. This has been greatly facilitated by a custom-built mouse database in which every breeding pair and every mouse born are recorded and through which we can readily monitor the numbers of mice we hold. Many experiments will require homozygous mutant animals. Littermates of these that are heterozygous or wild type will be used as age- and gender-matched controls. This allows optimal use of mouse numbers generated as well as being best scientific practice for the study of genetic alterations.

The experimental design is always based on using the smallest number of animals that are sufficient to answer the question being posed. We expect, from experience, that 6-8 animals per treatment group should be sufficient to obtain statistically robust results. For most of the quantitative experiments, sample sizes may be set using power analysis, generally using a significance level of 5%, a power of 80%, and a difference between groups of 20%. Otherwise, we will use the minimum number of animals to provide an adequate description, generally on the basis of previous experience (ours, or from the literature).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding strategies are always set up to maximise the number of useful mice from each litter. Wherever possible we will use multiple tissues and/or fluids from every animal, in order to maximise the data obtained from each mouse. Cryopreservation of gametes or zygotes will be used to preserve mouse strains, thereby obviating the need for continuous breeding and thus minimizing numbers of mice used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice since these are the mammal with the best studied developmental biology and cognition.

Why can’t you use animals that are less sentient?

Many of the mice we will use will be embryos – these are most suitable for the study of developmental processes, e.g. in the heart. Since we are modelling DS phenotypes, including cognitive deficits, less sentient animals would not be suitable as they are too far away from humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all manipulations, we will adhere to the relevant guidelines that aim to minimize suffering. We examine the animals for signs of pain and discomfort (such as grimacing), providing additional analgesia if appropriate, and

monitor body condition, killing the animals if the distress is likely to be more than temporary. Many of the genetic and physiological manipulations, as well as the administration of substances, including gene inducers and repressors are standard and previous refinements from the literature will be used and added to if possible. For novel types of manipulation, or where insufficient information is available, small-scale pilot experiments are conducted in order to determine the best conditions to obtain a sufficiently robust and meaningful response from the minimum dose, exposure time or treatment. These pilot experiments help to minimize any potential suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Publications from the NC3Rs and the Institute for Animal Technology, as well as relevant articles in scientific journals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay up to date via regular communication with animal facility staff at the host establishment, other scientists in our fields, via e-mail and other updates and publications from, and occasional attendance at meetings held by, the NC3Rs, the Institute for Animal Technology, and the International Society for Transgenic Technology, and through regular visits to their websites:

https://www.nc3rs.org.uk/3rs-resources

NON-TECHNICAL SUMMARY

70. Germ cell modification of birds

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (e) Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

No answer provided

Animal types	Life stages
Gallus Gallus	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to understand and modify chicken genes using the reproductive cells of chicken. The results from these studies will be useful for understanding bird fertility, poultry production traits, disease resistance, and for the safeguarding of breeds of chicken.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The chicken, a non-mammalian animal, is a valuable model for understanding the genes important to form a healthy embryo. As the most numerous agricultural animal with production reaching tens of billions of birds annually, understanding the genes that control growth, immunity, feeding and behaviour, and reproduction will help us to increase productivity and welfare in poultry farming. This project will also increase our basic understanding of development of reproductive cells in birds. The process of germ cell development is central to reproduction and procreation.
In fact, some of the genes we have investigated using genome editing have caused the sex of the chicken to reverse which shows the importance of the same genes in both birds and mammals.

The knowledge acquired in this project will help understand the reproductive problems that exist in commercial poultry production. Broiler chickens (raised for meat production) are required to be kept on a severely feed-restricted diet to maintain their normal cycle of egg laying. It is possible that understanding how normal reproductive cells form in chicken will help us discover how and why broiler chickens lay double yolked eggs if allowed to feed freely which will improve commercial welfare.

This project also has benefits for bird conservation and the management of poultry genetic resources. Breeds of chickens and specialised lines of chicken (transgenic chicken lines and naturally occurring breeds that have mutations that cause a loss of vision or polycystic kidney disease) are kept as living flocks of animals because no methods exists to bring back a pure breed of chickens from frozen material. This project will develop the methods to make breeds and transgenic lines of chickens from frozen reproductive cells using surrogate hosts. This will have many direct benefits i) lines and breeds of chickens can be protected against loss and from epidemics such as avian influenza; ii) breeding flocks do not need to be kept to maintain a chicken breed or line so the numbers of specialised chicken breeds with defined genetic mutations or transgenic lines can be frozen, 'biobanked', which will support the concept of the 3Rs, this will reduce the breeding numbers of chicken kept for research; iii) flocks and lines of chickens could also be efficiently managed for agricultural purposes, as specific breeds could be frozen then brought back at a later date when needed for food production. It is possible that the techniques developed in this project could be applied to all bird species to aid with their conservation.
What outputs do you think you will see at the end of this project?

The project will help identify the genes that are important for production traits such as rapid growth, increased muscle mass, a heathy gut and a proper feeding appetite. We will also identify the genes and genetic differences that are important during disease infection and for disease resistance to the many poultry diseases, such as avian influenza.

We will also identify genes that are important for the fertility of birds and for chicken egg production.
This project will also develop the methods to cryopreserve breeds of chickens and produce chicken using 'surrogate' host birds. This will reduce the breeding numbers of chicken kept for research. We will also be able to have the mother hens lay eggs containing embryos with genetic changes without the hens having to experience health issues from these genetic changes.

Our results will be published in scientific journals and communicated to poultry research laboratories worldwide.

Who or what will benefit from these outputs, and how?

The public will benefit from this work through safer sustainable food production. Commercial chicken are vaccinated to prevent disease. Our increased understanding of disease pathogenesis will help make poultry resistant to these diseases and improve vaccination programmes or eliminate the need for vaccination, increasing the health of poultry and of human communities that depend on these birds for their livelihoods.

This project also has benefits for poultry conservation and the management of poultry genetic resources. In the future this will also be a benefit for poultry through increased welfare by replacing the need to breed flocks of chicken. In the end, agricultural companies will benefit as their production costs will be reduced and their flocks can be protected from pandemics which can destroy both chicken flocks and chicken breeds.

How will you look to maximise the outputs of this work?

We collaborate internationally and communicate our scientific results at seminars, conferences, 3R conferences, and through scientific publications and poultry news journals. We communicate with other laboratories who are also developing poultry cryopreservation techniques and genome editing techniques and we also speak with regulators internationally at the USDA and FAO through our scientific collaborations. We seek to streamline the pathway to breeding genome edited birds and managing flocks of both normal breeds and special research breeds of poultry and post these results on institute webpages and through institute blog sites.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The chicken is an appropriate animal model to study avian development, embryology and agricultural traits. It may also prove to be useful in the re-establishment of other bird species from cryopreserved material. The chicken is very useful to study embryonic stages as a fertilised egg can be obtained without surgery on the mother. However, to study gene function, agricultural traits, and disease resistance, we need to use adult birds.

Typically, what will be done to an animal used in your project?

The animal will be blood sampled one to five times during its life. Its production traits will be measured and its behaviour observed. It may be assayed for disease resistance in challenge experiments carried out on other licences with appropriate authority. It may be treated with a drug to change gene expression or ablate cells in the animal. The animal will be humanely euthanised after which phenotypic and genotypic data will be obtained.

What are the expected impacts and/or adverse effects for the animals during your project?

There is a reduced hatching rate experienced for some of the lines of chicken and from manipulated eggs. Most of the chicken will lead a normal life. One of the GA chicken lines develop granulosa cell tumours as adult and must be humanely euthanised before tumours progress to affect the animal's welfare. A second line of chickens have misshaped eyelids and must be monitored for eye infections and appropriately treated and managed if their eyes become infected. There is the consistent problem to breed homozygous animals for a genetic locus

while avoiding the health deficits associated with inbreeding of chicken.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild severity: 95% of animals
Moderate severity 5% of animals
What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The chicken is an important agricultural animal and it is important to study the genes involved in the fertility, disease resistance, and productivity traits of this animal for sustaining and improving food production. The biology of reproduction of birds is of interest in terms of understanding reproductive mechanisms of all vertebrate animals (including humans). The use of embryos and animals is necessary to study the interaction of the germ cells and somatic cells in the reproductive organs. The interaction of the germ cells and the somatic cells is what determines the fertility over the lifespan of the adult animal. The fertility needs to be measured by the formation of functional eggs and sperm in the sexually mature animal. The need to investigate gene function in chickens and the genes important for growth and development and the genes governing pathogen interactions necessitate the generation of novel animal models containing genetic modifications

To develop new methods to freeze chicken breeds from frozen material and demonstrate the re-creation of chicken breeds used in research, commercial and rare chicken breeds from frozen material necessitates the use of surrogate chicken hosts to carry the reproductive cells.
Which non-animal alternatives did you consider for use in this project?

We considered trying to grow chicken stem cells to generate the different cell types and tissues that could then be studied in cell culture. We could change the genes in these cells to study gene function.
Why were they not suitable?

The number of chicken cell lines is extremely limited and the ability to culture and change chicken stem cells into different tissues is lacking. Our skill in culturing chicken reproductive cells allows us to carry out some experiments in cell culture without using animals. Our use of chicken embryos mostly involves injecting germ cells at unregulated young stages in eggs and many of the experiments will also be performed before hatching of the chick. The use of the chicken as a model species is an improvement over using mammals. In this instance, the chicken offers advantages over using a mouse models as the mother does not need to be killed to obtain the embryo and a surgical manipulation is not needed to introduce donor reproductive cells into an embryo. The majority of experiments will also be carried out at unregulated developmental stages (before day 14.5 of incubation) Meiosis (halving of the chromosome number) occurs in the chicken embryo at day 16 of incubation so early meiosis can be studied in embryos before hatching.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For chicken, we have estimated the total number of genome edited and transgenic lines we will establish over 5 years, the number of genome edited offspring that will be bred during that time period. For each genome edited line, we will need to generate surrogate host birds that will carry the genetic material. For each experimental genome edited line, we use a power calculation to determine the number of animals we need to breed in order to carry out the required experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The cell culture of reproductive cells enables us to carry out some experiments without using animals. The donor reproductive cell injections are carried out at unregulated developmental stages in eggs and many of the experiments will also be performed before the chick would hatch. The use of avian species as models offers advantages over mammalian species for the study of embryonic development. In this instance, the chicken offers advantages over using a mouse models as the mother does not need to be culled to obtain the embryo and a surgical manipulation is not needed to introduce donor reproductive cells into the embryo. The majority of experiments will also be carried out at unregulated developmental stages (before day 14.5 of incubation) in the egg. Meiosis (halving of the chromosomal number) occurs in the chicken embryo at day 16 of incubation so early differentiation can be studied in embryos before they would hatch.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have worked to improve the efficiency of hatching surrogate chicks carrying the donor genome edited reproductive cells. We have added a protocol to investigate the incubation conditions to improve the hatch rate of chicks. We have and are developing genome edited surrogate hosts that lay 100% of the offspring from the donor genome edited cells. We have improved our genetic modification of the donor genetic material to screen for the genetic modification before the genetic material is introduced into the surrogate host chick embryos. We are also developing methods to reduce breeding by directly mating the surrogate hosts to generate pure offspring in a single generation which greatly reduces the number of chicken bred in these experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use the chicken as a model to study the genetics of poultry and birds and the ability to freeze eggs and sperm from bird species. The use of cultured avian reproductive cells that can be genetically modified to disrupt gene function and used to produce genome modified birds is unique to the chicken and avian species. The

access of the fertilised avian egg also means the surrogate host chicken can be hatched without killing the mother to obtain the egg. The transfer of reproductive donor cells into surrogate hosts is done in the laid chicken egg at young ages (unregulated stages) before the formation of a nervous system. The surrogate hosts chickens will grow normally but make eggs and sperm from another chicken breed or potentially another bird species.

Why can’t you use animals that are less sentient?

The chicken is an important agricultural animal and it is important to study the genetics of this animal for sustaining and improving food production. The understanding of the genes involved in the major production traits of disease resistance, feeding, and production traits will lead to more efficient agriculture. The biology of reproduction of birds is of interest in terms of understanding reproductive mechanisms of all vertebrate animals (including humans).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have added a new protocol to investigate the incubation and manipulation of fertile eggs to increase our hatching rate from manipulated incubated eggs. We have instigated monitoring the weight of our newly hatched genome edited chicken to verify a normal growth curve for hatchlings.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work is undertaken in close collaboration with our Named Veterinary Surgeons. Study protocol forms must be completed and submitted to them prior to proceeding with any experimental work and animal unit staff are closely involved in experimental work and will offer advice on improvements to experimental protocols and monitoring/raising of the animals.

The group contains all the competencies required to perform the majority of techniques and procedures outlined in this project. Where additional expertise is required, staff will undergo appropriate training until competent.

Animals will be kept in accordance with annex III of Directive 2010/63 EU and/ or Home Office Codes of Practice, as appropriate.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We communicate with our NVS on current developments to enrich the environment of housed chicken. Our poultry workers are trained in proper welfare techniques for birds and we are strictly monitored by our veterinary scientists and the Home Office on current practices. We visit the NC3R website for new information on animal use in research. We hold annual conferences veterinary ethics and welfare.

Home Office

NON-TECHNICAL SUMMARY

71. Glucocorticoids and Vitamin B3 metabolism

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Glucocorticoids, NAD+, Metabolism, Cushing's syndrome

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to investigate glucocorticoid interactions with nicotinamide adenine dinucleotide (NAD^+) pathways to determine their combined effect on energy metabolism and the underlying mechanisms that facilitate the potential relationship between the two.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Glucocorticoids are stress response hormones that are released to meet changing metabolic demands and as such are key regulators of energy metabolism and homeostasis. An excess of glucocorticoids, often seen in Cushing's syndrome lead to metabolic dysfunction and disease. The role of NAD^+ as a signalling substrate or as a metabolic cofactor in redox reactions is well understood, and like glucocorticoids altered content levels can lead to metabolic dysfunction. We and others have shown that using NAD^+ precursors to augment the NAD^+ metabolome can modify metabolism and positively impact metabolic function. Glucocorticoids interact with the NAD^+ metabolome and synthetic pathways, but the nature and impact of their combined interactions on metabolic function, as well as dysregulation, has not been studied. We propose that interrogation of this new axis of metabolic regulation will illuminate novel biology and therapies in a range of disease processes.

What outputs do you think you will see at the end of this project?

The research project will lead to a better understanding of the relationship between glucocorticoids and the NAD^+ metabolome as well as the mechanisms behind their interactions. This will include how they might directly affect each other or how they might alter other metabolic functions to indirectly affect the other. For example, this project will reveal whether glucocorticoid treatment directly alters the synthesis of NAD^+ or the total content of it or whether it might indirectly affect it through regulation of another metabolic function. Additionally, this project will reveal if increasing availability of NAD^+ can alter or rescue the effects of glucocorticoid excess. These planned treatments will enable the identification of the mechanisms that underpin any potential relationship.

Who or what will benefit from these outputs, and how?

All knowledge gained from the project will be shared with the scientific and clinical community and published in peer reviewed journals (output expected during the project).

In the short term (within the timespan of this licence) knowledge of the mechanisms behind the relationship between glucocorticoids and the NAD^+ metabolome and their combined effect on energy metabolism and homeostasis will become known. This will include knowledge of how glucocorticoids might affect the NAD metabolome and alternatively whether NAD^+ might be able to help combat glucocorticoid excess. This knowledge will then be used to inform human experiments (beyond 5 years) that will test if the findings of this project translate into humans to combat issues caused by glucocorticoid excess.

How will you look to maximise the outputs of this work?

Discoveries as well as negative results will be shared with the wider scientific and clinical communities through presentation at national and international conferences and publication in highly ranked peer reviewed journals. We will also share best practice of new techniques and newly developed protocols with collaborators. We will engage with the public through events organised by the establishment to showcase our research.

Species and numbers of animals expected to be used

- Mice: 2400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The aim of animal studies in this project is to examine the relationship between glucocorticoids and the NAD^+ metabolome in order to understand their shared impact on energy metabolism and homeostasis. Mouse genetics and genome manipulation is uniquely advanced and there is a wealth of understanding of murine physiology making mice a most tractable mammalian model. The broad range of reagents and testing kits suitable for murine work makes them more suitable than other rodent models.
Young adult mice (3-6 months) were chosen to avoid developmental issues that can be seen when treating younger mice (<10 weeks) with glucocorticoids.

Typically, what will be done to an animal used in your project?

Animals will be treated with glucocorticoids to induce models of glucocorticoid excess which will lead to the development of a cushingoid phenotype. This phenotype will be characterised by an increase in adiposity, a reduction in muscle size, a reduced rate of weight gain or even weight loss. This model will be used to test the effect of glucocorticoids on the NAD^+ metabolome. Some mice will be treated with vitamin B3 (NAD^+) precursors during or after the development of this phenotype to test the therapeutic effect of NAD^+ in this model, as well as its effect on glucocorticoid metabolism. If not treated with glucocorticoids or NAD^+ (vitamin B3) precursors animals will instead be given a vehicle control or sham injection. Furthermore, the effect of glucocorticoids and vitamin B3 precursors on glucose homeostasis and energy metabolism will be investigated. Treatments will not exceed 4 weeks apart from vitamin B3 precursor supplementation in the drinking water. Mice will be humanely culled at the end of each experiment allowing for tissue collection and blood samples to be taken.

What are the expected impacts and/or adverse effects for the animals during your project?

Glucocorticoids are naturally occurring hormones, while they are not toxic, excess can lead to Cushing's syndrome which causes increased adiposity, muscle atrophy, hypertension and insulin resistance. Glucocorticoid treatment doses and duration in our project are carefully chosen to induce a cushingoid phenotype while minimising adverse effects for the animals. While animals will experience an asymptomatic muscle atrophy, it is not anticipated that animals will experience pain or discomfort from glucocorticoid treatment, other than the transient discomfort from subcutaneous injections. Body weight and body condition will be closely monitored to detect any deterioration in muscle mass as soon as possible.
Mice treated with just vitamin B3 precursors are unlikely to experience any adverse side effects as a large body of research already exists to support their use for increasing NAD^+, these compounds are well tolerated and have minimal effects on welfare, and in general promote metabolic health.
Glucose and insulin tolerance testing lead to transient pain during blood sampling (2min) when the initial tail incision is made and when subsequent blood samples are taken from the same incision over a period of up to 3

hours. To ameliorate this, a local anaesthetic will be applied before venesection. If tolerance measurements are repeated, mice will be resting for 2 weeks between measurements. For energy assessment in the TSE Phenomaster System mice have to adapt to the new environment, which might lead to slight weight loss in some animals. To ameliorate this an acclimatisation phase allows the mice to get used to the environment in their original litter groups before they are single housed during the isolation phase. The energy assessment itself is performed by measuring O_2 and CO_2 concentrations non-invasively while the mice live in their cages. Mice will rest between TSE measurements and tolerance testing for a week.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 80% of mice will undergo a combination of procedures, like glucocorticoid treatment, glucose and insulin tolerance testing and energy assessment or vitamin B3 precursor injection followed by glucose and insulin tolerance testing or mice will undergo glucose, insulin tolerance testing. This will be classed as moderate severity.
The remaining 20% of mice will not undergo a combination of procedures and will be classified as mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use non-animal methods to identify and validate the vitamin B3 precursors that can be used to influence glucocorticoid metabolism in cells. While these are important studies, these conditions are artificial and cannot give an accurate picture of glucocorticoids effects on different organs and the whole body in mice or humans. Glucocorticoids are produced in the adrenal cortex, but effect many different organs like muscle, liver and adipose tissue. Thus, we use mouse models to study how glucocorticoids and vitamin B3 precursors can influence energy and glucose metabolism in different organs.

Furthermore, in mouse models specific genes of the bio synthetic pathway from vitamin B3 precursors to NAD^+ can be inactivated to allow to examine their effect of biochemical pathways *in vivo*.

However, continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace *in vivo* animal use.

Which non-animal alternatives did you consider for use in this project?

In vitro data obtained from murine cell culture approaches has guided the proposed *in vivo* studies. We always conduct cell culture based experiments to justify the need to use animals.

Why were they not suitable?

Not all questions can be addressed in cell culture, there are no immortal cell lines available to study the complex interactions of glucocorticoid hormones with different organs. Organoid cultures are still technically challenging.

Reduction

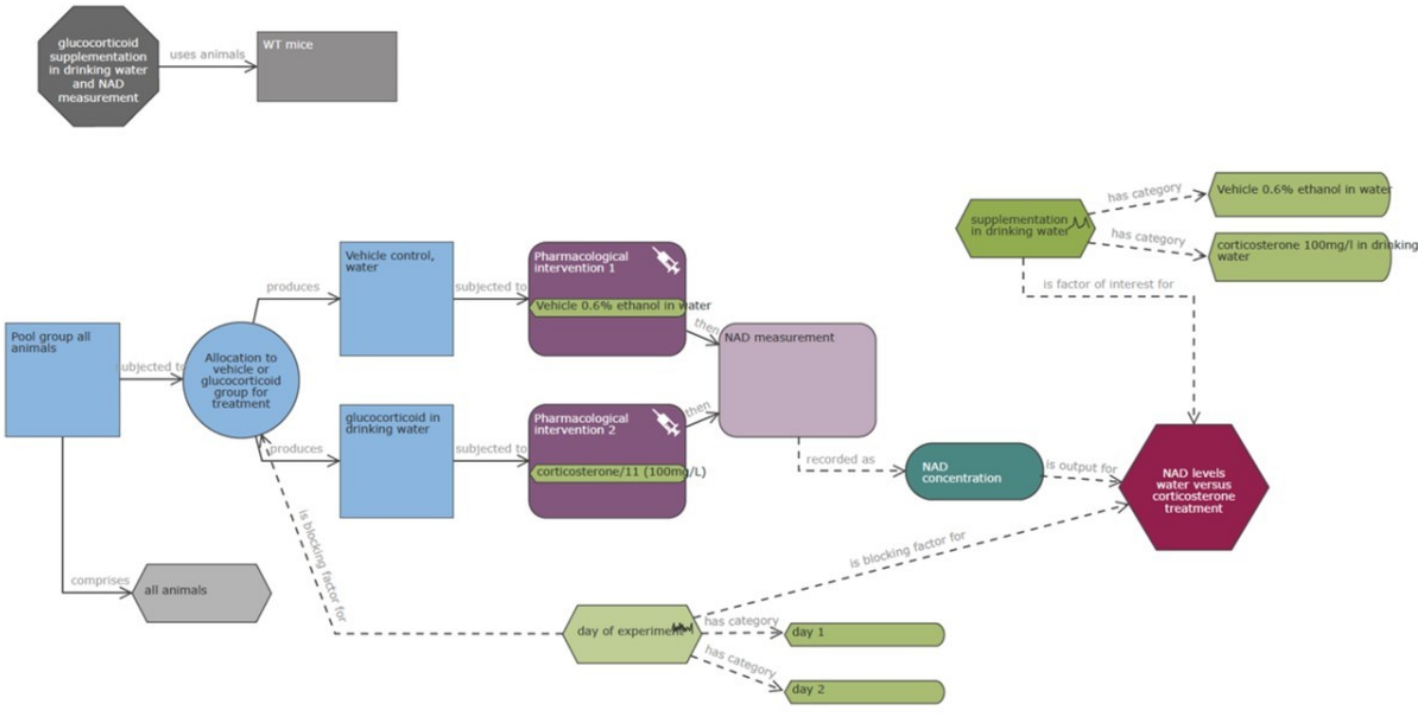
Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

When possible, we will always use power calculations to determine the number of animals that should be used. For most quantitative experiments, animal cohort size will be calculated via power analysis. Expected effect size will be determined through consultation of the literature, cell culture based *in vitro* analysis or through small pilot experiments when possible.
We have used statistical methods to calculate how many animals we need to get meaningful data, depending on the type of glucocorticoid used for treatment and the outcome measures of the NAD^+ metabolome we will look at. We will carefully consider which treatments and outcome measures will be tested sequentially, thus reducing the number of animals being used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3Rs' Experimental Design Assistant to design experiments (PROTOCOL 1,example) and taken advice from researchers who have performed similar research projects in the past.



We aim to reduce animal numbers, methods to reduce subjective bias, and appropriate statistical analysis

without compromising the scientific objectives. When possible, experiments will involve a factorial design that will maximise the information obtained from a minimal number of animals. Furthermore, non-invasive energy metabolism assessment and subsequent glucose or insulin tolerance testing can be performed on the same animal over a period of time, thus reducing the number of animals used. As importantly, at the end of all *in vivo* experiments, several tissues will be isolated and a large proportion of the scientific output in terms of NAD metabolism will be generated from these tissues in further *in vitro* experiments for example primary cell culture, protein analysis, metabolomics and genetic studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to estimate variability and perform power calculations to calculate sample sizes.
Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment. The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.
Even the most effective breeding strategies lead to some wastage of non-target animals. This can be avoided in our studies as we will be using WT animals to study physiology. If we are unable to estimate an effect size from our *in vitro* data, the literature, or our collaborators, we will conduct small pilot experiments.

All tissue surplus to requirement will be stored and made available to collaborators within the institution and beyond.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use WT mice to study how glucocorticoids effect the NAD^+ metabolome and how altered NAD^+ bioavailability (via vitamin B3 precursors) effects glucocorticoid activity.
Glucocorticoid treatment doses and duration in our project are carefully chosen to induce a cushingoid phenotype while minimising adverse effects for the animals. While animals will experience an asymptomatic muscle atrophy, it is not anticipated that animals will experience pain or discomfort from glucocorticoid treatment, other than the transient discomfort from subcutaneous injections if they are chosen as the appropriate route of administration. If possible administration in the drinking water will be used as a more refined route of glucocorticoid administration. Body weight and body condition will be closely monitored to detect any deterioration in muscle mass as soon as possible. Young adult mice (36 months) will be used to avoid developmental issues that can be seen when treating younger mice (<10 weeks) with glucocorticoids.
Even though vitamin B3 precursors are well tolerated and usually have no adverse effects, we will use pilot studies to help us to develop dosing regimens for vitamin B3 precursors if administration is not oral to further minimise risk of adverse effects.
To measure the energy metabolism of mice *in vivo* we employ the TSE Phenomaster System. While the mice live in their home cages, CO_2 production, O_2 consumption as well as food and drink intake can be monitored without any disturbance to the animals.
Other methods employed are considered the gold standard (ipGTT, ipITT, ipPTT) and as such are well

understood and practised, helping to minimise the risk and distress to the animal. These methods are designed to collect the minimal blood volumes required for glucose measurements, which again minimises both the risk and distress to the animal.

Why can't you use animals that are less sentient?

Mice are the least sentient species available to achieve our objectives. Using mice allows us to explore the relationship between glucocorticoids and the NAD^+ metabolome in a physiologically representative model, to produce data that can greatly inform treatments or further investigation within humans. Mice and humans share 97.5% of their DNA sequences, making mice preferential to using less sentient species such as zebra fish or drosophila.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Discussion with academics both internally and externally, as well as extensive review of the literature, ensures we are aware of, and continue to develop refined treatment doses and administration techniques. This combined with prior *in vitro* work ensures we have a strong understanding of the maximum tolerated dose, the minimum effective dose, and sub-optimal doses. This minimises the chances of an animal experiencing excessive adverse side effects.
Animal welfare is a key consideration in all of our protocols, and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.
We are fortunate to have excellent colleagues both in academic groups and within our animal facility with extensive, relevant animal procedure experience, from whom we can learn refined techniques. Our team will undergo extensive training on dead animals and require to be authorised by our animal facility before being allowed to perform a procedure on live mice.

Examples: The TSE phenomaster System allows to quantify energy metabolism by measuring O_2 and CO_2 concentrations, food and drink intake while the animal is living in an IVC cage without any disturbance. For glucose and insulin tolerance testing a single incision will be made on the tail to take small sequential blood samples rather than sequential cutting for blood sampling from tail vein. Cardboard tubes are used for refined handling and body condition charts for humane endpoints. Whenever scientifically possible the most refined route of administration will be used for vitamin B3 and glucocorticoids. This means administration in the drinking water will be the preferred to injection. To establish suitable doses and duration of vitamin B3 administration small pilot studies will be used, before larger more informative will be conducted.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will constantly consult the literature for experimental design, best practice, and humane endpoints for metabolic and diabetes research in animals, and we will publish in accordance with ARRIVE guidelines published by the NC3R's.

We will consult Simon Bate's book, The design and statistical analysis of animal experiments, for experimental design, statistical analysis, and sample size calculations.
Prior to all experiments we will also consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment (PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

The LASA giudlines: RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)
Jones HRP, Oates J, Trussel l BA (1999) An applied approach to assessment of severity. In: Humane End points in Animal Experiments for Biomedical Research (Hendriksen CFM, Morton DB, eds). London: Royal Society of Medicine Press, pp 40±7

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will perform literature searches, attend vendor's information sessions, seminars and conferences to find out about new technology and new approaches that we could implement.
We will comply with the ARRIVE guidelines 2.0 (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.
My Lab group twitter follows the NC3Rs and lab members are subscribed to the NC3Rs newsletter - helping us keep up with advances in the 3Rs which will be discussed and implemented through our lab meetings.

Home Office

NON-TECHNICAL SUMMARY

72. Hormone and genetic regulation of skeletal tissue maintenance and repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Osteoporosis, Osteoarthritis, Fracture, Thyroid hormones

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The project has two main aims:

1. To determine the role of thyroid hormones and their mechanisms of action in bone and joint tissue maintenance, injury and repair.

2. To identify the cellular and molecular mechanisms of disease onset and progression in osteoporosis and osteoarthritis.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Half of all adults are affected by bone and cartilage disorders. The two most common musculoskeletal disorders are osteoporosis and osteoarthritis.

Osteoporosis is a chronic condition characterised by loss of bone tissue and a decrease in its mineral or calcium content, resulting in decreased bone strength and an increased risk of fracture. Living with osteoporosis means that individuals are at a higher risk of breaking or fracturing a bone following a minor injury or a fall. The lifetime incidence of fracture for a 50-year-old in the UK is 40% for women and 13% for men, and osteoporosis already costs the NHS more than £1.7 billion per annum.

Osteoarthritis is a chronic condition that can affect any of the joints, but commonly involves weight bearing joints such as the hips or knees. It results from prolonged wear to the cartilage lining of the joint and when this happens all the tissues within the joint become more active than normal as the body tries to repair the damage. The repair processes may change the structure of the joint, but will often allow it to work normally and without any pain and stiffness. However, the repair processes don't always work so well and progressive changes to the joint structure can cause or contribute to pain, swelling or increasing difficulty with mobility. Osteoarthritis affects 15% of the population and its cost is estimated at 1% of gross national product. This financial burden will inevitably increase as our population ages and disease incidence rises.

The few available treatments for osteoporosis generally prevent bone loss but their effectiveness is limited by side effects and patient acceptability, whilst there are no effective drugs that prevent osteoarthritis or delay its onset and progression. Thus, there is urgent need to advance understanding of the mechanisms of bone and cartilage formation and repair in order to develop new treatments.

The basic cellular and molecular programmes that regulate development of bone and joints are also essential for tissue maintenance and its response to injury and chronic disease. Hormonal regulation of these processes is important. Osteoporosis and osteoarthritis each affect men and women to differing degrees but the mechanisms responsible for these sex differences are unknown. Exposure to thyroid hormone excess, due to thyrotoxicosis (an immune condition in which the thyroid gland produces and secretes too much hormone into the circulation) or following excessive thyroid hormone replacement in patients with hypothyroidism (deficiency of thyroid hormone in the circulation), is an important risk factor for osteoporosis and fracture. Furthermore, the local supply of thyroid hormones in the joint has been associated with susceptibility to osteoarthritis in large population studies, but it remains unknown how thyroid hormone actions in joint tissues modify disease risk.

The work in this project will identify new genes and pathways that underlie development of chronic tissue damage in the skeleton and will investigate how hormones, such as thyroid hormone, regulate these processes. This work will provide essential new understanding into the origins and development of skeletal diseases and will help to uncover new strategies for drug development in osteoporosis and osteoarthritis.

What outputs do you think you will see at the end of this project?

New knowledge

This work will provide a detailed understanding of the fundamental role of thyroid hormones in the maintenance and repair of bone and joint tissues. This new information is particularly applicable to the role of hormones in osteoporosis, fracture repair and osteoarthritis. The primary expected benefits will include publication of new scientific knowledge regarding the individual cell types in bone and joints that respond to thyroid hormones and the signalling pathways that are activated or repressed by hormone stimulation of these cells. The work will also identify new genes that specify bone and joint structure and function and new molecules and signalling pathways that regulate skeletal development, bone maintenance, cartilage degeneration and fracture repair. Publication of these findings will provide the research community with fundamental new knowledge, particularly relating to the identification of specific proteins that could be developed for measurement in the blood as new markers of disease, or which could be used to identify and understand the actions of new drugs. Such advances will ultimately help in the diagnosis, prevention and treatment of skeletal diseases such as osteoporosis and osteoarthritis.

New resources

A further benefit of this work will be the generation of new and specific genetically altered mice that will be made available to scientists working in the musculoskeletal and other fields. Furthermore, tissue samples from disease models used in these studies will be archived and stored so they can be provided to other scientists and collaborators for their studies.

Datasets

The data describing the characteristics of the joint in osteoarthritis, which are generated in these studies, are being made freely available for the benefit of the scientific community via the International Mouse Phenotyping Consortium website. Furthermore, datasets containing functional information on the genes that control joint characteristics will be uploaded onto the International Federation of Musculoskeletal Research Societies (IFMRS) Musculoskeletal Knowledge Portal, which is a new open-access integrated data mining platform aimed at accelerating discoveries for musculoskeletal traits and diseases.

Who or what will benefit from these outputs, and how?

Throughout the life of this project, data produced will be presented at national and international conferences and published in academic journals. The new information will provide a fundamental understanding of how hormones and newly identified disease susceptibility genes regulate cellular and tissue responses to chronic damage and injury in bone and joints. Protocols and methodological refinements or examples of best practice that we identify during this project will be published in scientific journals wherever possible and are being made available via the International Mouse
Phenotyping Consortium open-access website. We will archive and make post-mortem tissue available to collaborators and other scientists working in musculoskeletal research or other fields.
In the medium term the pharmaceutical industry will be interested in new knowledge that will help to understand the mechanisms of action of new drugs, which could be used to treat musculoskeletal diseases.
The long-term potential benefits of this study are that data generated may have far-reaching implications for the treatment of osteoporosis and osteoarthritis, benefitting patients and clinicians by contributing to the development of novel drugs that will ultimately reduce the economic and health burden caused by these common and chronic diseases.

How will you look to maximise the outputs of this work?

Findings from this work will be made available to other scientists through publication in open-access journals, presentations at scientific conferences and meetings, and via open-access websites to assist the research community. These routes of dissemination have already fostered collaborations outside the musculoskeletal

research arena, and we anticipate that the new knowledge gained in these studies will encourage further broad collaborations. New disease models and other transgenic mice developed in these studies, post-mortem tissue samples, and phenotype and genetic datasets will be valuable and made available to other scientists interested in therapeutic targeting and drug development for osteoporosis, fracture healing and osteoarthritis.

Species and numbers of animals expected to be used

- Mice: 10000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is critical to study disease mechanisms in an animal model that resembles the human condition as closely as possible. The mouse is the least sentient species, which can be used to obtain meaningful results that will both advance scientific understanding and be applicable to human disease. Many physiological processes in humans are the same and maintained in mice. Thus, skeletal disorders result from abnormalities that may occur during intra-uterine development, post-natal growth or adulthood in both species, whilst structural properties of bone and joints depend on movement and weight bearing. Furthermore, the same genes, hormones and regulatory factors that control; (i) bone and joint development and maintenance, (ii) the onset and progression of disease in osteoporosis and osteoarthritis, and (iii) the healing processes involved in fracture repair are also identical and maintained in both mice and humans.
Overall, mice are the most appropriate species for these studies as they allow developmental and temporal aspects of the mechanisms of skeletal disorders to be investigated using well established disease models.

Typically, what will be done to an animal used in your project?

Mice will undergo procedures to manipulate their hormonal status by giving hormones or inhibitors in the drinking water or, in some cases, by surgery to remove the ovaries and mimic the menopause. To study the effect of altered hormone responses in the skeleton, animals will also undergo surgery to provoke the onset of mild arthritis of the knee or create an internally splinted and stable fracture. Surgical procedures are shorter than 30 minutes in all cases, performed under aseptic conditions and animals are fully anaesthetised. Mice are monitored very closely and recover fully within a few minutes after surgery. They only experience a mild degree of lameness for a short period after procedures to provoke the onset of mild arthritis or generate a stable fracture, and this does not prevent free movement or normal eating and drinking. All animals routinely receive painkillers to prevent discomfort and they are housed for up to a maximum of 16 weeks with appropriate bedding, nesting material and cage toys within an enriched environment. At the end of the study animals will be killed humanely and their bone and joint tissues collected for analysis of samples using X-rays, microscopes and molecular techniques.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice will receive hormones or inhibitors of hormone production in their drinking water over several weeks to produce either thyroid hormone excess or deficiency. Thyroid hormone excess can result in increased activity,

weight loss despite good appetite and muscular weakness, whilst marked thyroid hormone deficiency may cause lethargy and weight gain. Such symptoms occur in severe and established chronic hormone disturbances and, in our experience, they are very unlikely to occur with the protocols used in these studies (less than 1% of mice develop problems). Nevertheless, animals will be monitored closely, examined at least every 5 days and weighed every week to ensure they do not experience any distress.
Some genetically altered mice may be given a hormone treatment by mouth in order to produce the genetic alteration in a single cell type within the skeleton but not in other parts of the body. The reason for doing this is to investigate the role of hormones in skeletal tissues without affecting their function in other organs or in the circulation. Such genetic alterations are mild and have no harmful
consequences. Nevertheless, tamoxifen treatment can rarely cause local inflammation, loss of appetite and hair loss, and may result in still births if given to pregnant dams. In our experience problems are highly unlikely as we have previously performed pilot studies to determine the safe effective dose and method of drug delivery that result in minimal side effects. Adverse reactions resulting in mortality due to tamoxifen administration can occur very rarely in less than 1% of animals. All animals will be checked and monitored for minor physical changes and signs of distress at least daily and will be weighed regularly.

Mice may also undergo minor surgery to either (i) remove the ovaries and mimic the menopause, (ii) provoke mild arthritis of the knee or (iii) create an internally splinted and stable fracture in the lower leg. After removal of the ovaries, mice will be given painkillers and post-operative care just like people receiving treatment in hospital and they recover quickly. Following arthritis or fracture surgery, mice are fully mobile and weight bear normally on the operated leg within a few minutes of recovery. Mild lameness can occur immediately after surgery in less that 10% of animals, but this does not prevent free movement and normal eating and it resolves rapidly. Nevertheless, all mice will be monitored carefully and given painkillers for an extended period of up to 3-4 days post-operatively if necessary. Some animals can scratch or pull sutures apart before the wound has healed and if this happens wounds will be cleaned are re-closed. Most animals have an uneventful recovery and will be housed in groups to encourage social integration. Together with regular gentle handling and cage enrichment these measures minimise distress and alleviate boredom.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

There are eight protocols in this licence.
The first four protocols include the procedures that are used to generate genetically altered animals; two of these protocols are of mild severity (we expect 5% of mice to experience mild severity and 95% to experience sub-threshold severity in these protocols) and two are of moderate severity (we expect 5% of mice to experience moderate severity and 95% to experience mild severity in these protocols).
The fifth protocol is used for the breeding and maintenance of genetically altered animals and is of mild severity (we expect 75% of mice to experience mild severity and 25% to experience sub-threshold severity in this protocol).
The sixth protocol includes the procedures that are used to alter hormone levels in mice and is of moderate severity (we expect 45% of mice to experience moderate severity and 55% to experience mild severity in this protocol).
The seventh protocol includes the procedure that is used to provoke osteoarthritis and is of moderate severity (we expect 100% of mice to experience moderate severity in this protocol).
Finally, the eighth protocol includes the procedure that is used to produce a stable fracture of the shin bone and is of moderate severity (we expect 100% of mice to experience moderate severity in this protocol).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals is essential for these investigations as other options that were considered in detail and discussed below are not able to deliver what is needed. Hormones and other regulatory factors act in the microenvironment of the skeleton and the bone marrow to control bone development and maintenance. Bone and joint diseases may result from abnormalities that arise during fetal development, post-natal growth or in adulthood, whilst maintenance of bone structure and strength is dependent on movement and weight bearing. Animals are similarly essential for studies of the onset and progression of osteoarthritis and fracture healing. These dynamic processes involve multiple cell types, recruitment of inflammatory cells from the circulation, formation of new blood vessels, and migration of bone-forming cells in order to maintain and repair the sites of injury. All these intricacies cannot be modelled ex vivo, and investigation of factors that initiate and modify disease progression must therefore involve whole animals.

Which non-animal alternatives did you consider for use in this project?

We contribute to and make extensive use of the Musculoskeletal Knowledge Portal (http://mskkp.org), which is curated by the International Federation of Musculoskeletal Research Societies (IFMRS) and contains genetic and gene function databases that aim to accelerate discoveries for musculoskeletal traits and diseases. Thus, we have access to cutting-edge information from genetic, studies in populations, bone cell culture and gene function studies in humans and several species of animal model. Computer modelling and bioinformatic analysis of these datasets enable us to focus our animal experiments to investigate the complex physiological regulation of gene functions in the skeleton using the whole organism and ensure our studies are relevant to human disease. It further allows us to test molecular mechanisms of hormone action and genetic control of skeletal cells in vitro, using primary cell cultures of bone forming osteoblasts, bone resorbing osteoclasts and cartilage forming chondrocytes.

Why were they not suitable?

The computer modelling, bioinformatics and cell culture models that we employ to investigate molecular mechanisms that underpin bone and joint abnormalities and diseases are extremely important and useful. They complement studies in live animals and give an overall much greater understanding of the onset and progression of skeletal disorders. On their own, however, they cannot provide a comprehensive understanding of skeletal tissue maintenance and repair in response to chronic disease or injury, and so animal studies remain essential.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used was determined using published information, previous experience and the biological variation encountered during analysis of bone and joint parameters relating to structure and strength. Our calculations account for different time points of study to investigate the onset and progression of disease, the use of complementary analytical methods to ensure robust outcome measures and give us assurance that our experimental approaches will detect biologically meaningful effects when they are present.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We follow the international PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines, have taken advice from statisticians and have planned the studies to enable them to be published according to the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines, which are intended to improve the reporting of research using animals and have been approved by the National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs). Furthermore, we have developed a tissue collection and storage strategy that enables us to maximise the use of tissue by employing sequential and complementary analytical techniques on the same sample in order to gain the most information possible from a single animal. This minimises animal numbers and prevents experimental duplication.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Primary bone cell culture will be used in place of animals to investigate molecular mechanisms wherever possible. Studies will include hormone manipulations to investigate cell maturation and examine gene regulatory responses. Data from these in vitro studies, and analyses of publicly available musculoskeletal datasets (http://mskkp.org), will be used to inform in vivo approaches and pilot studies. This strategy will provide preliminary data that will enable us to ensure the design of animal studies will be statistically robust and informative, relevant to human disease, and efficient. We have also developed an efficient breeding strategy to minimise animal numbers by using an osteoarthritis model only suitable in males, together with a fracture-healing model that is independent of gender and will be performed in females. This ensures all mice that are bred and maintained will be informative and can be used for experiments whenever possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use the least traumatic and most refined disease models; ensuring best practice by adhering to the Animal Research Reporting In Vivo Experiments (ARRIVE) guidelines; and ensuring the best possible animal husbandry is adopted according to LASA guidelines.
The osteoarthritis, stable tibia fracture and osteoporosis provocation (ovariectomy) models were established and validated in mice with predictable outcomes. They are the least traumatic of the published provocation models and represent the gold standard in the field, being internationally recognised by the Osteoarthritis Research Societies International (OARSI) and American Society for Bone and Mineral Research (ASBMR). We ensure that scientists working with animals have gained the highest surgical expertise, use the most-refined and adhere

to up-to-date aseptic techniques, and incorporate appropriate anaesthetic and adequate analgesia to minimise pain and facilitate rapid recovery and restoration of full-mobility following surgery.
In studies to manipulate thyroid status we adhere to the published “American Thyroid Association guide to investigating thyroid hormone economy and action in rodent and cell models” that contain the most up-to-date refinements for investigation of thyroid hormone action in rodent models.

Why can’t you use animals that are less sentient?

The mouse represents the least sentient species that can be used to model human musculoskeletal disease. Conserved mechanisms of skeletal development and skeletal regulation are well documented in mice and humans, and studies in mice have already led to the development of new drugs for the treatment of osteoporosis. Our studies, in collaboration with human geneticists, have established that genes associated with increased risk of osteoporosis and osteoarthritis in humans share similar functions between species, and we have shown that genetic alteration in the mouse faithfully reproduces human disease. In order to study disease onset and progression and understand the underlying pathological mechanisms, it is essential to study developing, juvenile and adult animals. Mice are the most appropriate species because genetic manipulation is well-established. Furthermore, many genetically altered strains are already available and validated and can be used by others without the need to generate them again.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have noted and incorporated a number of refinements to each of our protocols since we started to use mouse models over 25 years ago. We continue to monitor animals closely, and with the Veterinary Surgeon constantly assess possible improvements in husbandry, postoperative care, pain management, and animal environments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow international PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) guidelines, plan and conduct studies according to the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines and use National Centre for Replacement, Refinement and Reduction of Animals in Research (NC3Rs) guidelines to ensure our animal experiments are as robust and reproducible as possible. We follow research conduct, protocol and reporting guidelines from the Osteoarthritis Research Societies International (OARSI), American Society for Bone and Mineral Research (ASBMR) and American Thyroid Association (ATA) to ensure our studies on hormone regulation of the skeleton and joints are the most refined, up-to-date and relevant to understanding the mechanisms that underpin human musculoskeletal disease.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We read the monthly updates from the National Centre for Replacement, Refinement and Reduction of Animals in Research (NC3Rs) on their events and publications and their e-Learning resources. All of these detail advances in replacement, refinement and reduction techniques and best practice and provide information how to put these in place. Furthermore, I have extensive experience as member and chair of Animal Welfare Ethical Review Bodies, ensuring I am fully up-to-date and conversant with the principles and practices of the 3Rs.

Home Office

NON-TECHNICAL SUMMARY

73. Host-parasite dynamics in spatially structured host populations

Project duration

5 years 0 months
Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
voles	juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The work focuses on examining the impact of host spatial structure on parasite dynamics and diversity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Environmental change can increase the likelihood that diseases will transmit from wild animals to livestock or humans. By influencing the number and distribution of wild animals, land-use modification and the increasing fragmentation of natural habitats can have important impacts on the prevalence of different diseases. Such changes can also lead to the emergence of pathogen strains better suited to the new conditions. To understand these issues, we need information on the prevalence and strain diversity of pathogens infecting wild animal populations that inhabit fragmented natural habitats, as well as to what extent pathogens are shared between co-existing animal species.

What outputs do you think you will see at the end of this project?

By comparing the prevalence and diversity of different pathogen species and strains, we will achieve a better fundamental understanding of disease dynamics in fragmented wildlife populations. Our work will shed light on the relative importance of factors such as the ability to infect multiple wildlife species and infection length. Ultimately, this research will hopefully benefit the health of livestock and people by improving our understanding of how the increasing fragmentation of natural habitats may influence the risk posed by diseases that can be transmitted from wildlife populations

In addition, this research will also have direct benefits for water vole conservation. The species has suffered the largest decline of any British mammal in the last century, largely due to predation by feral American mink. One approach to the conservation of the water vole is the reintroduction and translocation of animals to form new populations. The research will provide further information for reintroduction and translocation programmes on (i) the parasites that can infect water voles and the other wildlife species that may transmit infections to water voles, (ii) how water voles move across landscapes between populations and (iii) the likely threat of disease spread between adjacent reintroduced populations.

Who or what will benefit from these outputs, and how?

At this stage, the principle beneficiaries will be other researchers working in the fields of disease ecology and pathogen evolution. Research findings will be disseminated to the research community through published articles and presentations at conferences.

In addition, we will use our close links with conservation practitioners involved in water vole translocation projects to ensure relevant information is effectively shared.

How will you look to maximise the outputs of this work?

In addition to primary scientific publications and conference presentations, we will seek to make the data available to other researchers. Our research team has a long history of collaboration with theoreticians and statisticians to ensure maximum gain from the datasets generated. For example, teams from Australia, France and the UK have used our wild rodent data to develop and test approaches and methods for analysing “real” disease data.

Species and numbers of animals expected to be used

- Other rodents: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We want to understand disease in natural, wild populations. Wild rodents are an ideal model system for this as they exhibit a range of population structures (e.g. large, relatively continuous populations; small, fragmented populations), are easy to catch, and are infected with a range of diseases. Sampling will include a range of life-stages. Animals are not caught in traps until they are weaned, and capture of animals < 1month old, heavily pregnant or > 12 months old is uncommon (<5%). It is important to sample a range of ages so that the relationship between age and infection status, and age and movement rates can be determined.
Typically, what will be done to an animal used in your project?

Animals will be caught in traps. They will be marked using appropriate methods for future individual identification (e.g. tags inserted under the skin, small ear biopsy). They will have a small blood sample collected from the end of the tail. Animals will typically be handled for <10 minutes before being released back into the wild at the place of initial capture.
What are the expected impacts and/or adverse effects for the animals during your project?

These procedures are not expected to result in more than momentary pain or distress and cause no lasting harm. The stresses placed on individual animals due to handling are minimised through good training and efficient field technique. Animals are expected to fully recover from the procedures within a few minutes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild (100%)
What will happen to animals at the end of this project?

- Set free
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of the work is to understand host-parasite dynamics in natural populations - hence the programme consists of observational studies, and must be based on the study of whole animals in their natural environment.

Which non-animal alternatives did you consider for use in this project?

Simulation modelling.
Why were they not suitable?

Simulation modelling will be used to understand likely disease dynamics under different scenarios. However,

ultimately these need to be tested with the field data, and therefore they are not sufficient to address the project objectives by themselves.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on our previous experience of rodent numbers in our study system, and are sufficient to detect key effects linked to our objectives (e.g. effect of the number of animals on infection rates).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To maximise the information that can be obtained from the studies, we will use advanced statistics to ensure that the natural variability in the data collected during studies of natural populations is properly accounted for. This helps ensure objectives can be met with fewer animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Each year specific objectives will be determined for the field season. Annual analyses of data will enable targeting of population sampling based on these objectives. For example, targeting sampling at large populations or populations that have naturally recolonised empty areas of habitat.

When expanding the studies to include additional populations we will conduct preliminary trapping prior to conducting any licensed procedures to ensure that sites with appropriate mixes of wildlife species are selected.

As the same samples are used to test for many diseases, overall this programme of research will use fewer animals than a similar research programme that focussed on one disease.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The water vole is probably the best available system for such a study due to the range of population structures that occur. The other species that will be sampled are the species that are most likely to share parasites and diseases with the water vole. Methods include inserting tags under the skin of animals, fur-clipping or taking an ear-punch for individual identification and taking a small blood sample from the animal for detection of

pathogens. All of the species can be easily handled, facilitating sample collection and minimising any distress.

Why can’t you use animals that are less sentient?

Sampling will include a range of life-stages. Animals are not caught in traps until they are weaned, and capture of animals < 1month old, heavily pregnant or > 12 months old is uncommon (<5%). It is important to sample a range of ages so that the relationship between age and infection status and age and dispersal rate can be determined.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The stresses placed on individual animals are minimised through good training and efficient field technique. This is essential for both ethical reasons and to ensure we have as little impact as possible on the natural processes under study. Trapping will always be performed by a competent person using a method which does not cause the animals avoidable pain, suffering, distress or lasting harm. Traps are calibrated to minimise the risk of catching smaller, non-target species and only baited with food attractive to the target species. Traps are regularly checked.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

2016 Guidelines of the American Society of Mammologists for the use of wild mammals in research and education

Journal of Mammalogy, Volume 97, Issue 3, 9 June 2016, Pages 663–688,

https://doi.org/10.1093/jmammal/gyw078 http://mammalogy.org/uploads/committee_files/CurrentGuidelines.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attend annual Licence holder refresher meetings, keep up to date with literature in field and collaborate with others in the same field.

Home Office

NON-TECHNICAL SUMMARY

74. How does metabolism affect the immune response in health and disease?

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Immunity, Autoimmunity, Lymphoma, Cancer, Metabolism

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We seek to understand how changes in metabolism can affect the immune system in health, autoimmunity, and cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our current understanding of the role of the immune system in causing autoimmune disease and in responding to cancer is very incomplete. This project will examine the effects of metabolism on the normal and abnormal immune systems, with the overall aim of identifying pathways which might represent novel therapeutic targets. This is important both to advance our knowledge of fundamental science in immunology, but also to guide new approaches to treatment, which are at present limited in efficacy and subject to significant toxicities. The idea that metabolic pathways might control the immune response has emerged as a result of *in vitro* investigation, but in order to determine if there is fidelity to normal physiology, both to inform science and to develop therapeutics, it is necessary to explore these pathways and their modification *in vivo*, in relevant and important disease models.

What outputs do you think you will see at the end of this project?

Key areas this project will examine include:

- The role of metabolic pathways (in particular amino acid synthesis and metabolism and mitochondrial metabolism) in the germinal centre reaction, and protective immunity in general (against infection and cancer)
    - *This work will uncover how immune cell metabolism influences the formation of protective antibodies which bind to their target with high affinity, and the development of immune memory, which occur in a process known as the germinal centre reaction (GC)*
- Whether cellular metabolic programmes determine progression from normal GC B cells to lymphoma
    - *This objective will help to understand if the specific metabolism B cell use in the GC reaction helps program the lymphoma cells which arise when this process goes wrong.*
- The metabolic dependencies of lymphoma *in vivo*
    - *This aim will help to understand if lymphoma cells have specific metabolic adaptations in vivo which can be targeted for therapy. Almost all previous work on lymphoma metabolism has been in cell culture, which has poor fidelity to in vivo and therefore poor translational potential.*
- How alteration of cell-intrinsic metabolism affects the function of regulatory T cells
    - *How regulatory T cells, which are essential for avoidance of intestinal inflammation in response to the microbiome, utilise metabolites is not clear. This aim will genetically alter these cells to understand the importance of key metabolic genes.*
- How autoimmunity (lupus, inflammatory bowel disease, and arthritis) affects immune cell metabolism
    - *This objective will identify how metabolism is deranged in autoimmune disease, providing new information about the drivers of pathology and revealing potential therapeutic targets.*

- The effect of modification of external metabolites through alteration of the diet on immune cell metabolism
    - *Very little is known about how changing the availability of nutrients or metabolites in the environment affects the metabolic phenotype of immune cells. In this aim, we will uncover the effect his has on the cellular level.*

This project will lead to new scientific knowledge, including the potential identification of novel therapeutic targets. The primary output will be peer-reviewed scientific papers, presentations at scientific conferences, and through a peer reviewed public engagement outlined in the supporting grants.

Who or what will benefit from these outputs, and how?

The scientific community will benefit from the experimental results of this work immediately following dissemination at conferences, and upon publication in peer-reviewed scientific journals, likely to take place within a year of its conclusion. In the longer term, patients may benefit from either repurposed existing therapies or from the development of new drugs which act the pathways this project will reveal. The overall aim therefore is to improve treatment for often fatal and severe disease, and to save human life.

How will you look to maximise the outputs of this work?

The results from this project will be initially communicated at scientific conferences and via publicly available pre-prints, and then in peer reviewed journals. The nature of the work is highly collaborative and will allow the building of new research teams to continue active investigation. There are peer reviewed public engagement plans in the grants supporting this project to maximise the overall sharing of the results and their impact.

Species and numbers of animals expected to be used

- Mice: 14000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used as the lowest vertebrate with an immune system which closely approximates that of humans. The experimental protocols are well-established and validated in mice, which increases the overall reproducibility of the work. There are highly validated tools for measuring the outcomes of the project in mice. We will predominantly use adult mice with a mature immune system.

Typically, what will be done to an animal used in your project?

Mice will typically receive injections of substances used to induce an immune response, and the effect of deletion of genes involved in metabolism measured by killing the mouse and analysing its immune tissues. The span of this will typically be 2-3 weeks. Some elements of the project will use mice which develop lymphoma or autoimmune disease, and measure the impact of the disease on the metabolism of immune cells. Mice will typically be killed before they develop clinically significant disease. Other experiments will look at the effect of treatment with drugs that modulate metabolism in healthy mice and in those with lymphoma or autoimmune

disease.
What are the expected impacts and/or adverse effects for the animals during your project?

The overwhelming majority of mice will undergo either subthreshold or mild experiences, typically associated with breeding or ear clipping for genotyping or identification, and which are highly transient.

For mice on moderate protocols, the expected impacts may include weight loss, pain, tumours, diarrhoea, arthritis, and lymph node enlargement. The majority of these symptoms are relatively short in duration (<3 weeks), as the affected mice will be killed at the earliest timepoint possible whilst still obtaining reproducible data.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The great majority of mice will experience subthreshold severity. Otherwise, the severities are from mild (75%) to moderate (25%).
What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune response cannot be completely modelled *in vitro* due to the complex interactions between immune cells in a specific microenvironment. The same is true for lymphoma, in which *in vitro* growth significantly disrupts normal metabolism. In order to fully understand, on a mechanistic basis, the impact of pathway manipulation in an immune cell it is necessary to genetically disrupt the cell using conditional knockout techniques, which again is only fully informative *in vivo*. Finally, to determine if potential treatments for lymphoma or autoimmunity are effective, this must be done *in vivo*.
Which non-animal alternatives did you consider for use in this project?

We considered (and use) *in vitro* culture systems to measure basic elements of the immune response, and to study of lymphoma in culture. We have also searched existing databases of results which we can apply to our research questions, without needing to repeat the experiments in animals ourselves.
Why were they not suitable?

They do not fully recapitulate the complete immune response, and in particular metabolism in cell culture systems is very different to that in vivo, due to differences in oxygen concentrations and nutrient availability.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimate of mouse numbers is based on experimental experience, aiming to balance reduction in use with producing robust, reproducible, and meaningful results. Statistical techniques have been used to estimate the number of mice included in each experimental group, to reduce the risk of false positive or negative results.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3R's Experimental Design Assistant, and employed statistical calculation using analysis software.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As a key element of the usage of mice is the breeding of genetically-altered animals, we will optimise breeding strategies to reduce surplus animals which would otherwise need to be culled. In situations where statistical calculation of group sizes are more difficult due to limited prior knowledge, we will employ pilot, preliminary experiments to reduce the risk of inadvertent harm to large groups. The same approach will be used when treating mice with therapies that have limited clinical experience. The experimental utility of each mouse will be optimised by maximising the number of measurements taken from each animal, and tissue will be shared when possible to reduce the need for mouse use by other groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experimental methods and models we will employ are all well established as techniques which provide robust and reproducible results carefully balanced against causing unnecessary harm.

Strains of mice are used that delete genes only in specific types of immune cells, reducing the harm that might occur if all cells were deficient. When mice are used to model human disease, we will select strains that reproduce human disease but with the least severe symptoms. For example, this includes breeding mice which develop lupus, with those that have protective genes, producing an overall much milder model. We will also use chemical 'triggers' to delete genes only when required, avoiding the adverse effects that would occur if this had been present from birth. Wherever possible we analyse mice at a minimal symptomatic stage of the intervention or disease model, and throughout mice are strictly subject to humane endpoints to prevent excessive suffering.

An essential part of this work is to understand immune responses, usually by immunisation or infection. In all cases, we will use immunisation techniques with the least adverse effects, and infection with the weakest strains of microorganisms and at the lowest doses we can. The same principle applies when using drugs to alter metabolism or as potential therapies: the lowest effective dose will be used to minimise side effects.
Why can’t you use animals that are less sentient?

Mice are the least sentient animals which have an immune system similar enough to humans to be able to begin to generalise results, and in which human immune disease and lymphoma can be modelled. The availability of disease models allow us to test whether new treatment might be effective in humans, and whether side effects are likely.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Central to our refinement efforts is questioning whether the same experimental results can be achieved with reductions in doses of substances, over shorter periods of time, and with earlier clinical or nonclinical endpoints, such as the use of biomarkers or by imaging techniques.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE, PREPARE, and FELASA guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We closely follow the immunology literature relevant to the project, continuously looking for techniques which will allow us the refine the animal work which we conduct. We also following NC3Rs initiatives closely, both on their website and as disseminated through the university.

Home Office

NON-TECHNICAL SUMMARY

75. How nutrition and ecology impact infection and immunity

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Wood mice	adult, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The central aim of this project is to better understand how natural ecological variation, including differences in nutrition, can impact parasite and pathogen dynamics and host immunity, in order to better understand the impact of infectious diseases in natural populations.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

To understand how parasites and pathogens impact the fitness and dynamics of their wild hosts, we need to recognise and investigate the ecological heterogeneities that are inherent in natural systems. Lab studies can, and do, generate invaluable information on how variation in nutrition, sex, age or past infections affect infection, immune responses and disease progression. However, there are many aspects of the controlled setting that don't capture the ecology of natural systems. Life in the wild is tough: individuals compete for food, mates and space; endure seasonal and spatial environmental variability; are exposed to a vast array of parasites; and also vary in their genetic composition. All of these factors will influence the likelihood of an individual being infected with a given parasite, the magnitude and efficacy of the immune response, and the clinical progression of disease. However, understanding the roles of each of these factors in isolation, and certainly in combination, is not logistically possible with lab studies alone; as such, we have a poor understanding of how these responses are affected by the simultaneous variation of these various factors, as happens in natural settings. If we are to understand disease progression, immunity and parasite transmission, we need to complement lab approaches with detailed studies of host-parasite interactions in their natural setting. This combined approach is essential to understand both the mechanisms driving parasite infection and immunity, and their implications for host health and population, or community, dynamics.

In our research, we complement our understanding of infection and immunity, as obtained from studies on lab mice, with experiments from wild rodent systems to provide a comprehensive understanding of what ecological factors determine infection and immunity.

What outputs do you think you will see at the end of this project?

This project will (a) advance our understanding of how the immune system operates in the wild in response to infection and coinfection, (b) determine what factors, with a specific focus on nutrition, drive individual variation in infection, disease, and treatment success, (c) strengthen the translation of immunology research to the development of medical interventions, especially in developing treatment strategies for variable host populations, and (d) better understand the patterns of cross-species transmission for multi-host parasites. By integrating field experiments with lab experiments using the same, naturally occurring, host-parasite combinations, our methods and results will have widespread benefit for health studies in non-laboratory settings, and for non-model species. Also by using genetically altered mouse strains, with known changes in their immunological phenotypes and expression, we aim to understand the mechanisms driving these important host-parasite interactions.

Thus the direct benefits of this project will be to:

- Improve current knowledge of how the immune system operates in wild populations and in controlled studies that better mimic natural ecological variation (e.g. different food quality, coinfection, etc)

- Understand how the immune system prioritises its response to different pathogens in wild, lab and GA mice;

- Understand the unintended consequences of disease intervention strategies (e.g. drug treatments, vaccination) for both host health and the dynamics of coinfecting parasites

- Better understand how different pathogens interact when body condition (sex, age, nutrition, etc.) varies across individuals and what the causes of these interactions are on host health;

- Detail how nutritional quality, availability and specific micro- and macro-nutrient quantities impact infection, immunity and response to disease control measures;

- Help identify priorities for medical intervention – for example, the proportion of individuals that should receive treatment/vaccination or how spatial movements can affect spread of disease.

- Help to test new technologies for measuring animal movement and behaviour in a UK habitat and on small rodents.

Who or what will benefit from these outputs, and how?

This project will be of most relevance to researchers working on infectious disease ecology; those interested in the spread and impact of parasites and pathogens within host populations (human, agricultural or wildlife). From an applied perspective we also see great interest to those involved in the design and outcomes of population-wide disease treatment programmes, e.g., mass drug administration, vaccination programmes, nutritional integration with mass drug administration programmes. Given that there is considerable debate on the wider benefits of both deworming and integrating deworming with nutritional supplements, and the constraints of assessing alternative treatment scenarios in human communities, we see experiments on natural mammalian host populations to be informative about the potential wider impacts of alternative treatment strategies. Furthermore, by taking wood mouse immunology into the natural setting, we envisage our work will be of great interest to immunologists in providing an opportunity to test many ideas of immune activation and action in the face of genuine parasitological and physiological challenges.

How will you look to maximise the outputs of this work?

Our regular contact with the academic research community greatly facilitate the rapid dissemination of our key findings to those working in similar areas. Beyond just publishing our results in interdisciplinary journals and giving talks we also aim to collaborate with different groups and share samples. Over the last 6 years we have provided wild rodent samples and data to >20 separate research groups and agencies (e.g., faecal samples to measure the wild mouse microbiome, blood samples to identify potential novel infections, host tissue to characterise immune diversity at key immune genes, parasite material to examine genetic diversity and for phylogenetic analyses, serum to find mRNAs as biomarkers of infection, components of the digestive tract to investigate microbiome–immune system interactions, oral swabs to assess oral disease and bone loss, ectoparasite samples to measure the incidence of Lyme disease in Scotland, etc.), which has led to a number of publications and aided the development of grant applications by several other groups. Our reputation as willing collaborators in the provision of material has grown rapidly, and we will continue to provide samples and data, benefitting the international research community and providing clear added value to our research.
We always disseminate our data and knowledge using traditional routes such as publishing the results of both

successful and unsuccessful work. We also strive to take part in many outreach activities with the public to engage adults and children in our research about infectious diseases. **Species and numbers of animals expected to be used**

- Mice: 1750
- Other rodents: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For our laboratory work we use inbred laboratory mice as they provide a range of reagents not available in other species. In addition, we also use a laboratory colony of wild-derived wood mice, as they are the primary natural hosts for several important parasites, and as such are more appropriate models for investigating the ecology of infection and immunity. Our laboratory research using mice involves both sexes of mice, and we focus our work on adults under 6 months of age to mitigate any risk of adverse effects with helminth infections.

Wild mice and voles are natural hosts of a number of medically-relevant parasites. These species, and their parasites, have been studied for decades in the UK, and this knowledge base makes them excellent species to address our aims. Our live-trapping protocols are standard, and have been optimized to be as minimally invasive as possible. (e.g. with protective shelters, bedding and food provided). We cannot discriminate what life stage of animal we catch in our traps, but we only carry out procedures on mice over 12g.
Typically, what will be done to an animal used in your project?

For lab studies: animals will typically be ear clipped for identification if grouped housed, housed in the same cage with a partition or single housed. Animals will be infected with one or more parasite orally (e.g. helminth, protozoa), or by injection (e.g. bacteria) or intranasally (e.g. virus). Animals may be given one or multiple doses of each of these pathogens. Alongside the inoculation of none, one or more pathogen/parasite the animal may be given an immunisation (e.g. antigen, attenuated parasite, DNA vaccine, cells). Immunisations may be given multiple time through the study. A blood sample may be taken regularly (e.g. weekly, fortnightly, etc.) for measuring host and parasite responses (e.g. immunological metrics, to confirm pathogen load, host gene expression, etc.). Faecal samples maybe taken regularly to confirm gastrointestinal pathogen burdens. Animals will be killed via schedule 1 methods at the end of experiments. The duration of experiments will vary.
For field studies: animals will be trapped using live traps in their natural habitat. On the first capture, each animal will be given a tag (subcutaneous), an ear notch will be taken for DNA (both host and pathogens), a blood sample taken to measuring host and parasite responses (e.g. immunological metrics, to test for parasite infection/coinfection using diagnostics, host gene expression, etc.), and a faecal sample will be collected for host and parasite information (e.g. gastrointestinal parasites, hormone analysis, immunological analysis, etc). The animal will be weighed, sexed, measured, aged, visually inspected for ectoparasite infection, and then released at sight of capture. If caught again within a 28-day window the animal may be subjected to a tail bleed or if caught after the 28-day period the animal could be sampled via a venepuncture. Faecal samples and demographic data will regularly collect from each capture. In some experiments, we may administer one or multiple doses of drug therapies and/or be given a safe, non-toxic vaccine to stimulate the immune responses. All animals will be release at sight of capture, but in a subset of experiments, we will use schedule 1 methods to cull animals in the wild.

What are the expected impacts and/or adverse effects for the animals during your project?

For lab studies: There are a few mild symptoms that can occur from infection with various pathogens (including bacteria and viruses) and or parasites (helminths, protozoans, etc). However mice show no negative effects, and those that due, recover quickly (within 2-3 weeks). Immunocompetent mice >5 weeks of age do not usually exhibit any clinical signs. Supportive care will be provided and veterinary advice maybe sought if an animal is showing weight loss of 10% or ill health (e.g. loss of condition, piloerection, hunched posture, staining around mouth and eyes, pallor, reduced activity). If no improvement is seen within 72 hours it will be promptly killed via a schedule 1 method. Blood sampling these animals may cause mild and transient pain but this is expected to be momentary. For drug administration adverse effects could include possible erythema (reddening of the skin) from topical applications, if it ever develops, should be short-lived.
From oral application/gavage momentary discomfort, with time allowed for the animal to swallow a small volume.
For field studies; most of the studies we conduct require good recapture rates and/or repeat sampling, and so it is essential the animals remain in good health. The stresses placed on individuals are minimised through good training and efficient field technique; our techniques have been established for >10 years across various projects and are optimised to minimise stress and reduce suffering. Rarely
(<1% of captures) an animal will exhibit signs of trauma by the sampling procedure, typically being in an inert rather than an alert and active state. In such cases, the animal would first be given an opportunity to recover and if it did so immediately release. If within several minutes it failed to recover, it would be immediately euthanised by a schedule 1 method. Blood sampling these animals may cause mild and transient pain but this is expected to be momentary. For drug administration adverse effects could include possible erythema (reddening of the skin) from topical applications, if it ever develops, should be short-lived.
From oral application/gavage momentary discomfort, with time allowed for the animal to swallow a small volume.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Wood mice: 95-100% mild
Mice: 95-100% mild
Field voles: 95-100% mild
Bank voles: 95-100% mild

What will happen to animals at the end of this project?

- Kept alive
- Killed
- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our goal is to provide insight into what determines the consequences of parasite infection under real- world scenarios. Our results will improve our current knowledge of how the immune system operates and prioritises its response to different parasites in wild populations, give us a better understanding of how parasites interact in

variable ecological conditions and help identify priorities for medical intervention. Because we are interested in how whole organisms deal with natural infections, our work needs to be performed in animals. However, wherever possible we adjust the numbers of animals needed to reach robust conclusions while minimising animal usage, replace with experiments that do not involve animals when possible, and continually strive to improve our methods.

Which non-animal alternatives did you consider for use in this project?

Most of our research addresses phenomena that occur at the whole organ (e.g. spleen) or organism (e.g. effect of sex, age, etc) levels, and up to the population/community levels (e.g. disease transmission across host communities). Therefore it is not possible to use non-animal alternatives to understand how a host will respond, for example to infection with a pathogen or immunisation. Part of this project, however, aims to use data generated in animals systems to build mathematical models that will help predict how the immune system/population will perform from much fewer samples or in other systems.

Why were they not suitable?

We can use build and use mathematical models to extrapolate our results and provide insight into infectious disease in other systems, such as to aid in the design and outcomes of disease treatment programmes (e.g. deworming). However, while these mathematical models extrapolate some of our results to other systems, they rely on conducting controlled experiments in both laboratory and wild animal populations in order to develop and parameterise these models, and so the models are not suitable without the paired animal work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In both the laboratory and wild, we are careful to use as few animals as possible, while maximising the amount of information collected from each animal. These numbers are based on annual returns from previous PPL's where we conducted similar numbers and sizes of experiments in the laboratory in combination with large-scale field experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use appropriately controlled, replicated experiments as they provide far greater power at detecting an effect, and so require far fewer animals, than the equivalent observational study. Furthermore, our experiments are designed to minimise the numbers of animals used while maximising statistical power; the experimental designs follow close consultation with our collaborators, including experts in ecological statistics. In laboratory mice, inbred/GA lines are chosen to answer specific questions about the effects of variation (e.g. coinfection). Experimental sizes and treatment numbers will be statistical analysis. All studies are designed to conform to the requirements for statistical analysis using ANOVA or generalised linear models while minimising random effects and the need for mixed effects models. However, all wild rodent studies require taking multiple sources of variation into account; for every animal and every trapping occasion, we record a range of variables of both the

individual and the environment, to ensure our ability to statistically control for potential confounding variables. Through this we can minimise the number of animals needed in order to test the specific hypotheses of each experiment. Since the procedures are carried out as part of field sampling, the number of animals cannot be predetermined. Here, collaboration with quantitative ecologists and regular monitoring of the variability of recently collected samples help define an appropriate compromise between numbers of animals to provide statistical power, avoiding excess animal usage, and time/manpower resources.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The data generated in wild rodents will also provide datasets for computationally more demanding analyses that will allow us to identify meaningful biomarkers of immunity and health within the whole dataset. In turn, this will help reduce the number of animals needed to reach robust conclusions about, for example, treatment efficacy. We will use pilot studies to inform any new lines of studies and any methods that we employ, we will optimise so that they can be done using small volumes of blood, tissue, or faecal samples so that we can use one sample for multiple tests. We also share tissues, blood, and faecal samples with many other lab groups to ensure that all samples that we collect can be used for several scientific pursuits.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most of the studies we conduct require good recapture rates and/or repeat sampling over time, and so it is essential the animals remain in good health. The stresses placed on individuals are minimised through good training and our efficient field techniques, which have been established for >10 years across various projects and are optimised to minimise stress and reduce suffering. Typically, >80% of resident wood mice and voles will be recaptured when trapping at 2-4 weekly intervals at the same location. Whenever treatments/procedures are administered, recapture rates of treated and control animals are compared to ensure the procedure causes no harm. In fact, both anti-parasitic treatment and nutritional supplementation are expected to improve health and survival. All participants on the project undergo rigorous training to ensure all techniques are carried out efficiently, to minimise handling and to maximise accuracy of data collection.
Wood mice and voles are natural hosts for a number of medically-relevant parasites, including *Heligomosomoides polygyrus*, a well-studied immunosuppressive helminth that is a model for human infections. These host species, and their diverse parasite and pathogen communities, have been studied for decades in the UK, and this knowledge base makes them excellent species to address our aims. We follow Natural England and Scottish Natural Heritage guidelines regarding the trapping of small mammals by setting traps as late as possible each day and checking them as early as possible the following morning, always within 16 hours of opening the traps. All traps are covered with semipermanent shelters (to reduce exposure to weather) and are provided with approved bedding material, grain, a source of moisture (e.g. vegetable/fruit) and, in areas where shrew captures are possible, a protein source (e.g. mealworms).
For our laboratory work we use a smaller number of inbred laboratory mice as they provide a range of reagents and GA animals not available in other species. Most mice used will be wild type, with occasional use of mice with alterations to genes suspected of affecting coinfection, nutrition, and/or immunity. *H. polygyrus* and *E. hungaryensis*, are two parasite species that we regularly study, are natural parasites of wood mice and have

been used as models of immunity and coinfection. Neither species is known to have an adverse effect on its host in the lab and so most of the animals undergoing these procedures, even with immunological manipulation, will typically not exhibit any discomfort. However, the majority of our experimental laboratory research will be focused on using our formerly wild now laboratory reared colony of wood mice.
In our research investigating treatments and vaccines against parasites (e.g. arthropods, helminths, protozoans, bacteria), we specifically choose drugs that are known to be effective with minimal dosing, ideally just a single dose. In all cases, the quantities administered follow recommended guidelines, have been carefully calculated to avoid toxicity, and the means of administration are both rapid and minimally invasive; favouring drugs that can be applied topically, second, orally and finally drugs applied by injection. As these treatments reduce parasite loads it is likely that such treatments are beneficial. However, in both the lab and field we closely monitor all treated and untreated animals, assessing body condition and behavioural responses immediately post-treatment and subsequently at each capture. If any animal shows any adverse response to treatment we cease treatment of that individual. If adverse reactions are extreme then the animal will be euthanised.

The criteria for their capture, manipulation and release are agreed upon with the local NVS. We are constantly refining and improving our methods, by assessing animal welfare following each procedure.

Why can’t you use animals that are less sentient?

Most of our research addresses phenomena that occur at the whole organ (e.g. spleen) or organism levels, and up to the population/community level. Because we are interested in how whole organisms deal with naturally-progressing infections, our work cannot be performed in animals that are less sentient or in cell cultures.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All experiments conducted on rodents in the laboratory will include continuous monitoring during experiments by taking their weight, fat scores and regular monitoring for changes in behaviour or appearance which would be indicative of ill health.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We use the PREPARE and ARRIVE guidelines to guide our experimental research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay informed about advances in 3Rs through constant communication with BVS, animal units, attending workshops or seminars on the 3Rs and by periodically checking the NC3Rs website.

Home Office

NON-TECHNICAL SUMMARY

76. Identification of processes involved in blood formation and the development of blood cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

blood stem cells, blood development, blood cancer

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how blood is formed during embryonic development and how these processes can go awry, resulting in blood cancer.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Blood cells are frequently used in the clinic for cell replacement therapies, with demand often outstripping supply. A lot of research has therefore been invested in ways of generating and expanding blood cells in culture; however, robust protocols are still lacking. It is essential to understand how blood formation takes place in the embryo in order to be able to recreate these processes in culture.

A common feature of cancer is the reactivation of developmental processes, and understanding these processes can therefore aid the development of new cancer therapies. In addition, some of these early blood cells produced during foetal development have unique properties not found in adult blood cells. It is important to understand these differences in the context of infant blood cancer which starts during foetal development and which differs from blood cancer in adult patients. By identifying the factors that specifically drive the infant disease, new and more effective treatments can be developed that will benefit these very young patients who currently have a dismal prognosis.

What outputs do you think you will see at the end of this project?

We expect to gain new insights into how blood develops in the embryo and on the origins and development of infant leukaemia. These will include the description of novel mechanisms and the identification of new regulators in both of these areas. We are also hoping that these novel findings may lead to new approaches for generating blood stem cells in culture and, in the case of the infant leukaemia studies, may even lead to pre-clinical studies aimed at establishing whether any of these newly identified mechanisms and regulators may serve as novel therapeutic targets.

We will always aim to publish our findings in peer-reviewed journals and make the studies open access. In publishing the findings from our animal studies, we will make sure to follow established guidelines on how to report animal studies as detailed in the ARRIVE guidelines (https://arriveguidelines.org/). Any data sets will be deposited in appropriate repositories and made publicly available upon publication of the manuscript. Findings will also be shared at meetings and conferences, public engagement opportunities and through the University's news channels. Any factors that have shown potential in the generation and expansion of blood cells and any drugs that have shown activity in the cancer mouse models will be further pursued and advice sought on their commercial exploitation and progression to pre-clinical trials.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries of our findings will be other researchers in the field who can make use of our data to progress their own research. Specifically, these will be researchers also interested in the generation and expansion of blood stem cells and those who are trying to generate blood stem cells from pluripotent stem cells in culture, which has immense clinical potential for the treatment of blood disorders. Our research may highlight new ways for them to modify their protocols, e.g. inclusion of any reagents, that could help to improve efficiency of these processes. Similarly, our studies on the origin and development of infant leukaemia, will help to drive

research forward in this field and help other researchers in putting their own findings in context with ours to gain a better understanding of the disease and identify the most promising strategies for drug development. In the long-term, we are hoping that our findings will lead to improvements in blood generation in culture and the treatment of cancer patients.

How will you look to maximise the outputs of this work?

We will always aim to make our findings open access and to make data freely accessible in repositories for the use of others. Any newly generated reagents will also be shared upon requests. We will always aim to publish all of the findings, including negative results, to avoid unnecessary duplications and to publicise the findings as much as possible through conferences and news channels.

Species and numbers of animals expected to be used

- Mice: 39700

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have been the chosen animal model for many decades as their blood system closely resembles that of humans. Many studies on blood development, regulation and cancer have been performed using mice, which will help us to compare our results with others and put our new findings into context. The most representative models for human blood cancer have been established in mice.
An important goal in blood research is the generation of blood stem cells in culture which has still eluded the community. To be able to recreate this process in the lab, it is essential to understand how the embryo achieves this during development. This stage is very difficult to study using human material, which is why we use mouse embryos to study this.
The gold standard assay for identifying blood stem cells is transplantation into and regeneration of the entire blood system in adult recipients, which is why we need to perform this assay. In some cases, we may perform transplantations into animals before or just after they are born in order to model the migration and maturation stages that these cells need to undergo. We will also have to perform transplantation assays in order to determine whether cells can cause blood cancer. Again, we would also like to perform these transplantations using foetal or neonatal recipients as a major question of our research is the origin and development of infant blood cancer, which originates pre-birth and where the foetal context is a known contributing factor.

Typically, what will be done to an animal used in your project?

Animals in which specific genes have been altered, will be generated and bred to be able to analyse how this affects blood production and the development of cancer. For our studies on the development of the blood system, most of these animals will be culled halfway during embryonic development and their tissues used for further experiments and analyses in the lab. They may be administered with genemodifying agents orally, in the food or water or via injection. Some of these mice will be allowed to be born to assess long-term effects on the blood system or to see whether they develop blood cancer. During that time, they may be injected with labelling agents (e.g. some that label proliferating cells), with disease-initiating factors (e.g. stimulators of the immune system) or drugs that may change the disease progression.
To determine whether a cell is a stem cell or whether a cell has the potential to cause cancer, they need to be

injected into an irradiated transplant recipient to demonstrate that they can regenerate the entire blood system or cause blood cancer, respectively. Therefore, some mice, that are serving as transplant recipients, will have their own blood system removed (usually through irradiation), injected (through the vein or the bone) with donor cells and regeneration of their blood system monitored through regular blood sampling. For normal transplantation experiments, the mice need to be monitored for at least 4 months, whereas for the cancer models it depends on how quickly the cancer develops, which can be more than a year. These animals may also be given (via the most appropriate route) disease-modifying agents or therapeutic drugs. To study stem cell development in the embryo or to model infantblood cancer, it may also be necessary to perform transplantations into newborns (via injections into the facial vein or the liver) or in utero transplantations, which would require temporary exposure of the uterus by surgery.

What are the expected impacts and/or adverse effects for the animals during your project?

It is expected that suffering will be kept at a minimum since we have clearly defined end-points and scoring systems. However, some of the animals will experience transient pain through injections and blood sampling. Whole-body irradiations also lead to a temporary weight loss, but the mice will recover their initial body weight within 2 weeks of irradiation. They will also be provided with antibiotics during that period to avoid infections. Any animals undergoing more substantial procedures such as intra-bone injections and surgery will be provided with pain killers. The greatest impact will be experienced by the cancer models, but daily monitoring, regular blood sampling and scoring of the animals according to well-defined symptoms will keep discomfort at a minimum and animals killed as soon as they reach a humane end-point.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

From experience, we can predict that the vast majority (>80%) of animals will experience discomfort classified as subthreshold. Only 14% of our animals last year experienced moderate levels of severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is necessary to use animals to achieve our aims for the following reasons:
(1) Blood stem cells can only be identified through their ability to regenerate the entire blood system on a long-term basis in irradiated recipients. We routinely perform cell culture assays first in order to test novel regulators and to determine optimal treatment doses. However, these assays cannot detect true stem cells. The results from these assays normally give a good indication as to the relevance of the tested substances, but the effect on true blood stem cells will ultimately have to be established through transplantation assays.

(2) It is currently not possible to maintain blood stem cells in the lab. One of the aims of this project is the definition of the environment in which blood stem cells reside and develop. This is a complex microenvironment of cells and molecules that control blood stem cell behaviour and that cannot currently be recreated in the lab;

however, one of our goals is to define the minimal components required to maintain and expand blood stem cells in culture, which would reduce animal numbers in the future.

(3) We have recently uncovered that the development of the blood system in the embryos is influenced by the co-developing sympathetic nervous system, thus demonstrating that these developmental processes need to be studied in the context of the intact individual to reveal complex interactions between neighbouring tissues.

(4) Blood cancers are complex diseases that affect numerous tissues and organs in an individual. Disease development and progression and possible treatment strategies therefore need to be studied in an animal model; however, the initial ability of a gene to change cells in a way that might eventually lead to cancer or of a compound to affect cancer cells will be tested through experiments that can be performed in the lab rather than in animals.

Which non-animal alternatives did you consider for use in this project?

We routinely consider cell culture assays as alternatives to transplantation or to model blood stem cell formation and how this may be influenced by external signals.
We also use blood cancer cell lines derived from patients that can be grown in the lab and cell culture assays to model cell changes that could lead to cancer.

Why were they not suitable?

While cell and tissue cultures can provide a useful initial indication as to the expected effect and can be a useful platform for dose determination, effects on true blood stem cells can only be determined in transplantation assays. In addition, while some signals from the stem cell environment can be simulated in cell culture, it is currently impossible to recreate the complex environment of an organism.
Similarly, while proliferation assays in culture can give an indication if a cell is becoming cancerous and can also test whether this can be prevented through drug treatment, the full cancer and its effects on the entire organism can only be modelled in a whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have based this number on previous experience and the number of projects that I estimate to undertake in the following 5 years. However, before starting a new experiment we will follow established guidelines on how to prepare animal experiments (https://norecopa.no/prepare).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When designing the experiments we perform statistical analysis to ensure that we use the minimum number of mice per group that will be informative. In addition, we consider published guidelines on how to prepare animal experiments (https://norecopa.no/prepare). The number of animals to be used is estimated based on previous experience and power calculations considering the number of experiments needed and number of mice per

experiment required to obtain the appropriate statistical power. Although statistical analysis may not be completely appropriate in the consideration of all cells behavioural phenotypes, we would like to be able to assess changes in blood cell behaviour in the range of 2-fold. Power calculations around these estimates indicate group sizes in the range of 3-5 experimental and control animals. We estimate that 2-fold changes (e.g. 50% vs 25%) with a standard deviation of 10 require a sample range of 3-5 animals to give significant results ($p<0.05$) with a power of 0.80-0.97). Allowing for failures in engraftment and three analysis regimes (1 to 2 animals/analysis), the initial starting group size is 6-8 animals. In the cases where the experimental outcome of mutant cells is unknown, it is more difficult to estimate the group size required. In the cases where the experimental outcome is the development of blood cancer, it is far harder to estimate the group size required. Cancer development may occur over a long period (12-24 months) and at a frequency that is a priori unpredictable. Publications in this field generally use group sizes in the range of 10-25 animals and based on our previous experience we would regard this as a prudent and scientifically sound starting point in cases where we have no additional information to guide our experimental design.
In order to reduce the number of breeding pairs, the mice will be kept as homozygous mice, provided that they do not have a harmful phenotype.
Wherever possible potential therapeutic agents will be pre-screened to obtain indication for the minimum dose that is likely to be effective thereby reducing the numbers of animals used in pilot studies.
Mouse lines no longer required will be kept as frozen stocks.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To maximise the information from a single animal, we will aim to take samples from multiple body sites and provide other affected tissues to appropriate scientists, so that they do not have to breed mice specifically for their experiments. If possible and appropriate we will try to obtain tissues from other researchers who have already developed relevant mouse models.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse has been selected for this work as it is an appropriate model for haematopoiesis studies and is the species in which reliable transgene technology is best established. Since the mouse is the most commonly used model for such studies, the results can be more easily incorporated with other groups' findings and we have a large amount of background scientific data to refer to relating to the mouse.
To generate transgenic mice, inducible constructs will be used wherever possible. The mice should not display a phenotype until candidate gene expression or deletion is induced. We will only use well established reagents and protocols to induce expression or deletion of the candidate gene.
When expressing or deleting a new candidate gene, animals will be bred and analysed as heterozygous animals first to avoid unexpected pain and suffering.
When exposing mice to irradiation for creating transplant recipients, this may be administered as a split dose to give improved recovery rates.

For protocols involving bone marrow transplantation and leukaemia a stringent scoring system which allows an immediate identification of mice with adverse effects has already been implemented in our facility. This system indicates clear endpoints and will allow us to efficiently minimise animal suffering.

Why can’t you use animals that are less sentient?

Of all experimental models available, the mouse has a blood system that most closely resembles the human system. Mice have so far generated the most representative model for human blood cancers.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As we gain experience with our leukaemia models, we can much better predict when animals will develop the disease phenotype and that way prevent unnecessary suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult the online resources provided by the National Centre for the Replacement, Refinement and Reduction of Animals in Research to obtain updated information on the best practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Throughout the project we will monitor the development of new techniques that may allow us to refine our current techniques. This information will be obtained from the literature, the veterinary service and events taking place at the University relating to the promotion of the 3R's. We have also subscribed to the monthly newsletter published by the National Centre for the Replacement, Refinement and Reduction of Animals in Research.

NON-TECHNICAL SUMMARY

77. Imaging biomarkers of normal and abnormal brain development and ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation, or modification of physiological conditions in man, animals, or plants

Key words neurodevelopment, neurodegeneration, ageing,

imaging, brain

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, embryo, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main aim of this project is to characterise changes in the brain that arise during normal and abnormal development and ageing. We will do this by using a battery of clinically relevant imaging and corroborative techniques, as we aim to improve the understanding of a variety of neurological disorders ranging from autism spectrum to Alzheimer's disease, in the way that matches and helps us interpret human brain imaging. Alongside this, we plan to test several novel treatments for their ability to ameliorate or halt the progression of neurodevelopment and/or neurodegeneration-related abnormalities.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to develop successful treatments for human neurological disorders it is important to not only model aspects of the disorders in a controlled way, but also to have the ability to detect and visualise these in a manner that is clinically translatable.

Animal models of brain disorders are a precious resource that enables us to learn more about the pathologies of the brain and the central nervous system (CNS), and how these affect the entire organism. Recent years have seen the development of sophisticated array of genetical tools with which the CNS can be manipulated in rodents that delivers a controlled and precise method for modelling pathologies, but with less overall suffering that would have been inflicted by the more traditional lesioning methods.

In this project we aim to characterise several animal models that have elements of pathologies arising from abnormal brain development and/or abnormal ageing including neural degeneration. We are particularly interested in the neurodevelopment/ageing continuum as there is a lot of evidence from clinical studies that these are connected. For example, mutations that interfere with neurodevelopment in mother's womb through childhood can be further involved in development of neurons and their connections (synaptogenesis and axon motility) eventually resulting in neurodegenerative processes later in life. In line with this it is well known there are disorders resulting from aberrant development that affect cognitive and physiological processes, and eventually progress into profound
neurodegeneration, such as for example Down's Syndrome. Ageing itself is a risk factor for developing neurodegeneration but accumulating evidence suggests there are a lot of factors influencing how well we age, which could be therapeutically modulated to ensure lifelong health and well-being. Finally, we are interested in neurodegeneration as an "accelerated ageing" process and how various abnormalities in specific proteins & neurotransmitters influence the rest of the brain and the body.

For our investigations we will use an array of non-invasive imaging methods, supplemented when appropriate by additional, corroborative techniques. Brain imaging methods, such as MRI and PET, are particularly important translational tools because of following reasons:

- They are largely non-invasive, and therefore can be employed longitudinally and without the need to sacrifice the animals and can be used to image the whole brain (not restricted to only one area) – thus ideal to monitor disease/pathology progression as well as effects of treatments.

- Multiple types of imaging markers can easily be obtained in the same session contributing toward refinement of techniques and reduction in overall animal numbers, and

- By and large, the same methods are already used in clinical (human) research, hence imaging is translational and the results from an animal study can be used to directly inform the results from a human

study.
Hence it is important to undertake this work in order to increase our understanding of the disorders that affect the brain during development and ageing, and to use the herein described methodology to test a number of experimental treatment strategies because they may lead to improved treatments for the human disorders.

What outputs do you think you will see at the end of this project?

We aim to publish all findings in quality peer-reviewed scientific journals in order to benefit the research community. In addition, the work will be presented at scientific conferences where it may be debated with and disseminated amongst other scientists working in the field of preclinical or clinical imaging and neuroscience. Ultimately, improving and validating imaging biomarkers will be possibly implemented in clinical research (early detection and monitoring of neurological diseases and their treatments), and will also have an impact on drug discovery, helping to expedite and facilitate development of new treatments for clinical disorders.

Who or what will benefit from these outputs, and how?

Short term: scientific community.
Longer term: patients undergoing imaging as part of their disease diagnosis or management.
Additionally, wider scientific imaging community may benefit through us publishing and sharing standardised protocols to avoid duplication, or obscure ‘in house’ development. As a start we have recently established such an online available platform.

How will you look to maximise the outputs of this work?

There is a drive to publish negative results across all aspects of neuroscience. Because imaging and corroborative methods are complex, time-consuming, and expensive, it is important to publish and disseminate negative results from such projects. We will endeavour to publish and disseminate these at all opportunities. Another important output strategy for our activities is via collaboration. For the same reasons outlined above (complexity, expense) most of the projects ongoing at our facility are collaborative. Our facility was created specifically to conduct collaborative projects as we have recognised that imaging experiments are multidisciplinary and must be conducted by highly experienced, often senior staff with relevant expertise, as training an inexperienced person adequately to acquire quality imaging data is a lengthy process. To this end, we strive to share our expertise in collaborative projects with neuroscientists seeking to answer questions and test hypotheses relevant to clinical scenarios using state-of-the-art translational methods.

Species and numbers of animals expected to be used

- Mice: 1450
- Rats: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will use genetically modified rats and mice, as well as normal (non-GA) animals and some animals will have brain lesion induced by a toxin. All the models herein selected were chosen to enable us to study aspects of normal and abnormal brain development and ageing, as well as neurodegeneration. We will use animal models of autism spectrum disorder and of learning disability in order to learn more about abnormal brain development; these will typically be studied while juveniles or young adults, alongside normal animal counterparts of the same age. Model of Down's syndrome will be important as an example of developmental abnormalities that propagates into neurodegeneration, as most humans with Down's syndrome eventually develop Alzheimer's disease as well. Finally, we will use models of dementia, Parkinson's as well as those with degenerating white matter in the brain, in order to study abnormalities linked to later age and to this end we will study most of those animals during adulthood and older age.

Typically, what will be done to an animal used in your project?

Typically animals will be tested behaviourally to confirm the functional consequence of abnormal development or ageing/neurodegeneration. Most of the time these behavioural tests will be of mild severity; occasionally we may probe behavioural signs further by using slightly more invasive tests that involve food deprivation, exposure to water or elevated platforms. We will undertake brain imaging in the majority of animals in this project: this will be done under anaesthesia using either MRI or PET scanners. Some animals may have their brain activity recorded by inserting EEG electrodes into the brain (implanted under anaesthesia). Approximately half of animals in this project will be given substances such as contrast agents for imaging or experimental treatment drugs. These may be administered orally or by injections or by osmotic pumps inserted under the skin.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals will be anaesthetised repeatedly for imaging. Repeated imaging sessions are not likely to impact adversely on animal welfare. Some animals will have electrodes inserted into their brains under surgical anaesthesia, and the electrodes may be kept for several weeks. In our experience these, when implanted properly, seldom pose welfare concerns. Any animals that show any unexpected or unacceptable adverse effects will be humanely killed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most protocols in this license are of moderate severity: this is because anaesthesia is classified as moderate. As almost all animals in this project will be anaesthetised at least once, they will undergo moderate severity procedures. Certain behavioural tests require exposure to water, or transient food restrictions which are also classified as moderate. Finally, implantation of brain electrodes and probes is also moderate. Approximately 50% of all animals in this project will undergo one anaesthesia, and approximately 50% will undergo one or more anaesthesias or one or more procedures with "moderate" severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For our work on animal models of disorders, the animals have to be used because it is not yet possible to model the complex central nervous system (CNS) disorders in question in vitro or in silico. This is because our knowledge about structure and function of the CNS, as well as of the pathological events in these disorders is not yet sufficiently advanced. Indeed, one of the main aims of this work is to help advance knowledge about CNS disorder pathways, which will eventually lead to improved non-animal modelling of diseases.
Secondly, as this project is largely concerned with the results of disturbing the normal function of the central nervous system of living organisms, little replacement is possible. For example, we aim to investigate effects of experimental compounds on parameters such as alterations in cerebral blood flow resulting from changes in neural activity and this cannot be replicated in vitro due to a lack of adequate models of cerebral circulation. Here we aim not only to quantify parameters such as cerebral blood flow, neural activity and metabolism in areas acutely affected by the disturbance, but also their “downstream” effects (e.g. in other neural pathways) and for this there are currently no appropriate in vitro/ ex vivo replacements. However, data generated here will help to directly corroborate similar results from neuroimaging in humans (e.g. fMRI), which are still not very well understood, particularly in applied pharmacological research.

It is hoped that as more research is conducted into the uses and benefits of neuroimaging in drug development, the utilisation of the technology to safely and effectively test novel compounds in humans may become a reality. It is of course important that any experimental and novel compounds first be characterised and tested in in vitro systems and/or computer libraries. While our own laboratory is not set up to perform such assays, we only work with the compounds for which these data already exist for example we use publicly-known (characterised) compounds or obtain information from collaborators about the compounds’ previous testing and results.

Which non-animal alternatives did you consider for use in this project?

The only possible non-animal alternatives in this project are human beings.

Why were they not suitable?

This is because it is not possible, safe or ethical to conduct experiments to fulfil our aims in human beings. For example, we seek to monitor progression of disease markers, from the earliest to the later stages. This is not possible to conduct in human beings as we do not have ability to detect most brain disorders at their early stage. We are also unable due to lack of safety and ethical permission to test all experimental therapy in human beings.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

We have carefully estimated the number of animals required based on our prior experience using similar methodology and similar models. We also estimated the number of animals needed based on usage in our prior work, under previous licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of in vivo neuroimaging techniques such as fMRI and EEG in drug development and disease characterisation experiments has the potential to reduce the number of animals used due to the continuous (longitudinal) monitoring, non-invasive nature, and ability to simultaneously acquire several different measurements.

We frequently measure multiple parameters in each animal. These may include behavioural assessment, physiological parameters, cerebral metabolism, protein synthesis, blood flow, metabolites, lesion volume, size of the brain and CNS structures. Whenever possible we acquire these measurements longitudinally whereby each animal serves as its own control and through this 'within subject' design we improve statistical power. In addition, a good experimental design frequently enables us to use one control group for comparison with several intervention groups. Altogether these interventions maximise the robustness of data and sensitivity to detect significant effects, while at the same time reducing animal numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use parametric and non-parametric tests for statistical analyses, as appropriate. We base our experimental design and analyses on our long-standing experience in these research methods.
Whenever necessary, we also consult statisticians and image analysts for advice regarding design prior to commencement of novel studies. Power calculations are always conducted prior to embarking on a new study, except when attempting to detect a novel biomarker for which there are no in-house pilot data available; in this case we conduct extensive literature searches and aim to achieve comparable group size to published reports of similar studies.
Additionally, one of the aims of the current project is to collect imaging data into a database of rodent brain images at differential stages and this will be publicly shared to enable other scientists to share these data digitally.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will only use rats and mice in this project; including genetically modified. We propose these are more humane, cause far less suffering and are more precise than the more traditional models induced by lesioning. Only a small fraction of mice and rats in this project will be lesioned by a toxin, using well known established protocols, to create a model of disorders such as Parkinson's disease for which there is no suitable genetic method at the moment.
The neuroanatomy, neurophysiology, and genetics of the rat and the mouse are well understood and validated. Our laboratory has extensive experience in the use of these animals for neuroimaging and behavioural experiments. The methodology we intend to use has mostly already been optimised and validated; although we aim to occasionally develop and validate novel, and improved techniques. By doing so in commonly used rodents, these can be easily shared between the scientific community, therefore contributing to the wider refinements.
Despite the use of multiple measurements, we will not cause unnecessary suffering to the animals. Majority of our imaging methods are performed under anaesthesia; thus it is possible to acquire multiple measures without causing additional discomfort.

Only those tests that are directly appropriate to the abnormality or the circuit in question will be undertaken, and only minimum number of sessions required to produce sufficient data will be conducted, so that each animal experiences minimum required testing.
Behavioural assessments will be undertaken in order to correlate this with the brain abnormality being studied. This also increases the statistical power and improves the characterisation (multimodality) and therefore validity of a given biomarker. These behavioural paradigms are all well established.
Treatment compounds will only be tested using relevant methodology, at appropriate doses and routes of administration, and only when it is predicted that the compound might be efficacious.
All instruments are routinely calibrated and quality controlled. Data are acquired and compared to positive and negative control values, as well as assessed against known values from literature and previous experience.

Why can't you use animals that are less sentient?

For our work in animal models of brain abnormalities, the animals have to be used because it is not yet possible to model the complex CNS disorders in question in vitro or in silico. This is because our knowledge about structure and function of the CNS, as well as of the pathological events in these disorders is not yet sufficiently advanced. Indeed, one of the main aims of this work is to help advance knowledge about CNS disorder pathways, which will eventually lead to improved non-animal modelling of diseases.
In terms of sentience, rodents are the lowest stage that can be used to model fully functioning brain, in order to translate the results to humans. Many of the disorders and age-related consequences are diagnosed based on behaviour, and rodents behave is similarly enough while lower species such as fish are too phylogenetically divergent – especially for brain cortex-controlled behaviours.
Because it is imperative that we connect our results to behavioural signs, as well as to measure effects of therapy, or disease progression over time (or the combination of progression and therapy) it is not sufficient to perform imaging or recordings only once in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely use monitoring and welfare scoring of experimental animals, analgesia, appropriate management of multiple anaesthetic sessions (e.g. administration of saline to prevent dehydration), additional environmental enrichment in cages. Post-operative care is achieved by appropriate pain management, soft bedding, liquid or soft easy-to reach food.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R and https://researchanimaltraining.com; also LASA guidance on dose selection

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Via the NC3R website and NTCO, as well as any locally or nationally organised courses. NC3R website provides information and multiple training resources as well as a newsletter. In addition I also have a beta access to the new website https://researchanimaltraining.com which provides a wealth of information and training videos.

NON-TECHNICAL SUMMARY

78. Imaging markers of brain structure, function and pharmacology

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

imaging, brain, functional circuits, drugs, behaviour

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main aim of the project is to characterise how the structure and function of the normal brain are affected by compounds acting on various neurotransmitters and their receptors. We aim to use clinically translatable imaging and corroborative methods to aid the interpretation of human imaging data of relevance to drug discovery in psychiatry and neurology. The project additionally aims to characterise the effects of direct and specific (opto- or chemo-genetic) manipulations of neural circuits and neurotransmitter pathways upon brain activity, to shed further light on the function of the brain and the CNS as an integrated network.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Most agents used to treat disorders of the central nervous system, as well as the disorders themselves, alter normal brain activity via direct or indirect interactions with neurotransmitter receptors or their cellular transporters. These interactions manifest as either immediate (acute) or prolonged (chronic) alterations of not only brain function, but also of brain structure (e.g. microstructural tissue changes from rearrangements of neurons, glia, or vasculature), and these effects can be visualised by state-of-the-art neuroimaging methods such as MRI and PET.
Characterising how drugs affect the brain is important for several reasons: prolonged alterations may be detrimental and present cause of concern for a particular clinical treatment (e.g. prolonged use of antipsychotics has been shown to cause microstructural brain changes), the knowledge about where and how a drug acts helps us to better understand its mode of action and the proposed clinical efficacy. Characterising downstream effects of a drug acting on a particular neurotransmitter system increases our understanding of that system, and comparing the profile of action of novel compounds to the well known “gold standard” compounds enables us to ascertain their relative pharmacological similarities. All these help to improve drug discovery programs aiming to develop new and better treatments for various human neurological and psychiatric disorders.
Because this project is concerned only with compounds that are already reasonably well characterised, and that are either already used in the clinic or are close to being clinically tested, we need to test them in living organisms as this final stage of research and development. To this end, experimental animals, and rodents in particular, represent the most appropriate systems for such testing; their brains are very well characterised and the array of methods we intend to use (imaging, behaviour, neural activity recordings, autoradiography) are widely available, standardised and translatable to the clinic.
To fulfil the aims of this project we will mostly use an array of non-invasive imaging methods, supplemented when appropriate by additional, corroborative techniques. Brain imaging methods, such as MRI and PET, are particularly important translational tools because of following reasons:

- They are largely non-invasive, and therefore can be employed longitudinally and without the need to sacrifice the animals, and can be used to image the whole brain (not restricted to only one area).
- Multiple types of imaging markers can easily be obtained in the same session contributing toward refinement of techniques and reduction in overall animal numbers.
- By and large, the same methods are already used in clinical (human) research, hence imaging is

translational and the results from an animal study can be used to directly inform the results from a human study.

The primary advantage of testing and characterising the effects of compounds, and manipulation of neural circuits in animals is that additional information can be obtained that is currently not possible to collect from human beings. To this end, we aim not only to collect an array of imaging markers from characterising the drugs in animals, but also to combine and correlate those with the more invasive in vivo measurements (EEG, microdialysis, behaviour) and with post-mortem examinations in order to gain better understanding of the cellular and molecular correlates of imaging results.

What outputs do you think you will see at the end of this project?

We aim to publish all findings in quality peer-reviewed scientific articles in order to benefit the research community. In addition, the work will be presented at scientific conferences where it may be debated with and disseminated amongst other scientists working in the field of preclinical or clinical imaging and neuroscience. Ultimately, improving and validating imaging biomarkers will be possibly implemented in clinical research and should have an impact on drug discovery, helping to expedite and facilitate development of new treatments for clinical disorders.

Who or what will benefit from these outputs, and how?

Short term: scientific community and pharmaceutical industry (drug discovery).
Longer term: patients undergoing imaging as part of their disease diagnosis or management.
Additionally, wider scientific imaging community may benefit through us publishing and sharing standardised protocols to avoid duplication, or obscure ‘in house’ development, as a start we have recently established such an online available platform.

How will you look to maximise the outputs of this work?

There is a drive to publish negative results across all aspects of neuroscience. Because imaging and corroborative methods are complex, time-consuming and expensive, it is important to publish and disseminate negative results from such projects. We will endeavour to publish and disseminate these at all opportunities.

Another important output strategy for our activities is via collaboration. For the same reasons outlined above (complexity, expense) most of the projects ongoing at our facility are collaborative. Our facility was created specifically to conduct collaborative projects as we have recognised that imaging experiments are multidisciplinary and must be conducted by highly experienced, often senior staff with relevant expertise, as training an inexperienced person adequately to acquire quality imaging data is a lengthy process. To this end, we strive to share our expertise in collaborative projects with neuroscientists seeking to answer questions and test hypotheses relevant to clinical scenarios using state-of-the-art translational methods.

Species and numbers of animals expected to be used

- Mice: 500
- Rats: 900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will only use normal adult rodents (rats and mice). This is because we are primarily concerned with studying the normal brain and how drugs, e.g. therapeutic or novel compounds, interact with the function and structure of the brain. Rodents are suitable for this project because their brains are already very well characterised and a lot is already known about the relevant circuits and pathways. To this end, normal adult rodents represent the best system for us to test these compounds in the final stages before they are potentially used in human beings.

Typically, what will be done to an animal used in your project?

Typically, the animals will be administered with a drug of interest (by injections or by food or water) and their brains will be scanned by MRI or PET which will be done under anaesthesia. We may also perform some behavioural testing to see how the relevant drugs affect their cognition, mood, general and fine movement. Occasionally, in order to delve deeper in the brain and neural circuits, we may study the animals conscious by measuring their brain activity via EEG electrodes, or by injecting them with radioactive probes, and sacrificing, then examining the brain in detail.

What are the expected impacts and/or adverse effects for the animals during your project?

Most drugs we will study will not cause any adverse effects. Occasionally, they may make animals mildly lethargic, drowsy or hyperactive. This is not expected to cause any lasting suffering. Repeated imaging sessions will not impact adversely on animal welfare except that they will be repeatedly anaesthetised. Some animals will have electrodes inserted into their brains under surgical anaesthesia, and the electrodes may be kept for several weeks. In our experience these, when implanted properly, seldom pose welfare concerns. Any animals that show any unexpected or unacceptable adverse effects will be humanely killed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All protocols in this license are of moderate severity: this is because anaesthesia is classified as moderate. As almost all animals in this project will be anaesthetised at least once, they will all undergo moderate severity procedures. Certain behavioural tests require exposure to water, or transient food restrictions which are also classified as moderate. Finally, implantation of brain electrodes and probes is also moderate. Approximately 50% of all animals in this project will undergo one anaesthesia, and approximately 50% will undergo one or more anaesthesias or one or more procedures with "moderate" severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For our work on imaging the normal brain and characterisation of the compounds, animals have to be used because it is not yet possible to model the complexity of the CNS in vitro or in silico. This is because our

knowledge about structure and function of the CNS is not yet sufficiently advanced. It is important to note that all compounds we intend to use in this project have already been tested and characterised using various computer-based and in vitro methods. This particular stage of preclinical in vivo imaging and behaviour/brain activity recording typically represents the final phase before such experiments are performed in human beings.
As this project is largely concerned with characterising the changes in normal function of the central nervous system of living organisms, little replacement is possible. For example, we aim to investigate effects of experimental compounds on parameters such as alterations in cerebral blood flow resulting from changes in neural activity and this cannot be replicated in vitro due to a lack of adequate models of cerebral circulation. Here we aim not only to quantify parameters such as cerebral blood flow, neural activity and metabolism in areas acutely affected by the disturbance, but also their "downstream" effects
(e.g. in other neural pathways) and for this there are currently no appropriate in vitro/ex vivo replacements. However, data generated here will help to directly corroborate similar results from neuroimaging in humans (e.g. fMRI), which are still not very well understood, particularly in applied pharmacological research.

It is hoped that as more research is conducted into the uses and benefits of neuroimaging in drug development, the utilisation of the technology to safely and effectively test novel compounds in humans may become a reality. It is of course important that any experimental and novel compounds first be characterised and tested in in vitro systems and/or computer libraries. While our own laboratory is not set up to perform such assays, we only work with the compounds for which these data already exist for example we use publicly-known (characterised) compounds or obtain information from collaborators about the compounds' previous testing and results.

Which non-animal alternatives did you consider for use in this project?

It is not possible to use non-animal alternatives for this project.

Why were they not suitable?

This is because there are no model systems that can adequately model the living brain for imaging biomarker development. Human beings are being used to some extent, but we cannot perform invasive investigations or take brain samples preventing us from being able to determine underlying biological correlates of imaging results.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have carefully estimated the number of animals required based on prior experience using similar methodology. We also estimated the number of animals needed based on usage in our prior work, under previous PPL.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of in vivo neuroimaging techniques such as fMRI and EEG in drug development and brain

function/structure characterisation experiments has the potential to reduce the number of animals used due to the continuous (longitudinal) monitoring, non-invasive nature, and ability to simultaneously acquire several different measurements.
We frequently measure multiple parameters in each animal. These may include behavioural assessment, physiological parameters, cerebral metabolism, protein synthesis, blood flow, metabolites, size of the brain and CNS structures. Whenever appropriate we acquire these measurements longitudinally whereby each animal serves as its own control and through this 'within subject' design we improve statistical power. In addition, a good experimental design frequently enables us to use one control group for comparison with several intervention groups. Altogether these interventions maximise the robustness of data and sensitivity to detect significant effects, while at the same time reducing animal numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use parametric and non-parametric tests for statistical analyses, as appropriate. We base our experimental design and analyses on our long-standing experience in these research methods.
Whenever necessary, we also consult statisticians and image analysts for advice regarding design prior to commencement of novel studies. Power calculations are always conducted prior to embarking on a new study, except when attempting to detect a novel biomarker for which there are no in-house pilot data available; in this case we conduct extensive literature searches and aim to achieve comparable group size to published reports of similar studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will only use normal adult rats and mice in this project.
The neuroanatomy, neurophysiology, and genetics of the rat and the mouse are well understood and validated. Our laboratory has extensive experience in the use of these animals for neuroimaging and behavioural experiments. The methodology we intend to use has mostly already been optimised and validated; although we aim to occasionally develop and validate novel, and improved techniques. By doing so in commonly used rodents, these can be easily shared between the scientific community, therefore contributing to the wider refinements.
Despite the use of multiple measurements, we will not cause unnecessary suffering to the animals. Majority of our imaging methods are performed under anaesthesia; thus it is possible to acquire multiple measures without causing additional discomfort.
Only those tests that are directly appropriate to the compound or the circuit in question will be undertaken, and only minimum number of sessions required to produce sufficient data will be conducted, so that each animal experiences minimum required testing.
Behavioural assessments will be undertaken when there is unsatisfactory existing data characterising a given compound or intervention, or when we need to correlate it with imaging or neural recording data, thus increasing the statistical power or improving the characterisation (multimodality) and therefore validity of a given biomarker. These behavioural paradigms are all well established.
Compounds will only be tested using relevant methodology, at appropriate doses and routes of administration, and only when it is predicted that the compound might be efficacious.

All instruments are routinely calibrated and quality controlled. Data are acquired and compared to positive and negative control values, as well as assessed against known values from literature and previous experience.

Why can’t you use animals that are less sentient?

For our work on normal and altered brain structure and function, and how the changes relate to behaviour, the animals have to be used because it is not yet possible to model the complexity of CNS in vitro or in silico. This is because our knowledge about structure and function of the CNS is not yet sufficiently advanced.
In terms of sentience, rodents are the lowest stage that can be used to model a fully functioning brain, in order to translate the results to humans. Because it is often important that we connect our results to behavioural signs, as well as to measure effects of therapy, or intervention over time it is not always sufficient to perform imaging or recordings only once in terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We routinely use monitoring and welfare scoring of experimental animals, analgesia, appropriate management of multiple anaesthetic sessions (e.g. administration of saline to prevent dehydration), additional environmental enrichment in cages. Post operative care is achieved by appropriate pain management, soft bedding, liquid or soft easy-to reach food.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

NC3R and https://researchanimaltraining.com; also LASA guidance on dose selection.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Via the NC3R website and NTCO, as well as any locally or nationally organised courses. NC3R website provides information and multiple training resources as well as a newsletter. In addition I also have a beta access to the new website https://researchanimaltraining.com which provides a wealth of information and training videos.

Home Office

NON-TECHNICAL SUMMARY

79. Immune cell migration in health, age and inflammatory arthritis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

inflammation, leukocyte trafficking, ageing, arthritis, therapy

Animal types	Life stages
Mice	juvenile, adult, pregnant, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project explores the processes controlling the movement of immune cells from the blood into tissue in health, how these goes wrong in age and inflammatory arthritis; and it also tests the ability of new chemical and cell-based therapies to restore normal immune cell movement.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Immune cell movement from the blood into tissues is an important protective response to infection and injury. It is very tightly controlled, like security checkpoints, to prevent unwanted inflammatory responses. However, many of these security checkpoints are lost in chronic diseases such as rheumatoid arthritis and cancer, but also as we age. Our work aims to provide more detailed knowledge on the factors responsible for maintaining these security checkpoints; exactly how the security checkpoints are altered during the ageing process and in chronic disease, and if certain new chemical or cell-based therapies can restore the normal function of these checkpoints. Ultimately our aim is to use this knowledge to develop a new type of treatment that treats the cause of abnormal immune cell movement, rather than treating the symptoms that arise from unwanted inflammatory responses.

What outputs do you think you will see at the end of this project?

Project outputs will include:

- advances in scientific knowledge on the processes controlling immune cell movement in health, with age and in disease; scientific and lay publications of our findings and methodology;
- presentation of our data and/or methodology to the wider scientific community through conference oral and poster presentations;
-
- identification of novel targets or agents that alter immune cell movement, which can be take forward to develop new therapies.

Who or what will benefit from these outputs, and how?

This project has a wide range of academic beneficiaries.

Short-medium term

Scientists and innovations in analysing immune cell movement in health, ageing and chronic disease described in this licence will have an immediate impact on the ongoing projects at the host organisation, and also further afield upon dissemination. Moreover, this project aims to improve our understanding the processes driving pathology in ageing and chronic disease, specifically linked to the loss of an endogenous regulatory pathway, an area of intense research interest worldwide. The impact of this is likely to occur in the short-to medium term, during the lifetime of this project and beyond as all publications are released.

Medium-long term

Collaborations – We intend to invite external seminar speakers who have an interest in immune cell movement, ageing and chronic inflammatory diseases to our organisation, with the view of fostering further collaborations based on the concepts and ideas incorporated in this proposal. We envisage that these collaborations will occur

during and following the completion of this project, and therefore represent a medium to long-term impact of this work.

Long term

Clinical Academics and pharmaceutical companies will benefit from advances in our understanding of disease pathology and premature ageing, along with our identification of new targets for drug development. We are in continual conversations with these collaborators and view the translational of our findings into new drugs over the subsequent 10-15 years following the completion of this project representing the long-term impact of this project.

How will you look to maximise the outputs of this work?

Dissemination of information

We will work with the relevant teams at our Institute to facilitate communications and resulting impact. We plan to use several routes to disseminate our findings to the wider scientific community, industry and the public that will facilitate end-user engagement:

(a) Peer-reviewed publication. We aim to publish high impact papers based on the findings generated from the research grants funding this project licence. In addition, our group has a strong tradition of publishing methodology papers; and negative data to ensure that groups do not unnecessarily repeat experiments that either technically are flawed or biologically yield the null hypothesis.

(b) Presentations. We and our collaborators will present data at internal seminars along with national and international conferences, such as British Society of Immunology (BSI); BSR; Society of Leukocyte Biology (SLB); Society of Cell Biology Research.

(c) Dissemination via international societies. We and our collaborators are active members of various scientific societies, such as BSI; BSR; SLB; European Workshop for Rheumatology Research; British Society for Ageing Research, allowing our findings to be disseminated to the wider scientific community in societal magazines and training workshops.

Enhancement of public understanding and engagement with research

We will take advantage of several events organised by the Public Engagement Working Group at our organisation and local charities to facilitate the public's awareness our research:

(a) Science "pop-up" activities. We will give at least three research talks at student recruitment days and will be participate in "Meet the Scientist" tours. We will aim to host at least 1 stall at the Annual Community Awareness Day and host an event local Science Festivals.

(b) Lay Resources. We would develop lay resources, in collaboration with our patient/public research partners (PRP), for publication of Atlas of Science. Additionally, we will continue to involve patients and the public in the delivery and dissemination of research generated from this project.

Clinical Collaboration.

My team and I are active members of several multi-institute research centres and will be able to present our findings at least twice annually at ongoing Centre seminars. We will also attend clinical conferences [e.g. European League Against Rheumatism (EULAR), American College of Rheumatology (ACR), British Society of Rheumatology (BSR)], where we will present our data and foster

collaborative opportunities for translational research across the fields of rheumatology, ageing and chronic inflammatory diseases.

Species and numbers of animals expected to be used

- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have chosen the types of animals and their age based on our need to model a mammalian musculoskeletal aging and disease that occurs in adult humans. As such, adult mice represent the lowest mammalian option available with a musculoskeletal system in which we can study immune cell movement in health, with age and in disease, and to test potential drugs for human use.

Typically, what will be done to an animal used in your project?

Animals will have either have arthritis induced (~70%) or ovaries removed (~30%). Test agents that might limit the movement of immune cells into tissues (e.g. the joints) will be given, and the tissues monitored during the inflammatory response.

For arthritis models, the majority of animals (80%) will undergo general anaesthesia (up to 30 minutes), daily handling for scoring and caliper measurements of joints and limbs; administration of an agent (typically x15 injections), dynamic weight bearing analysis (optional for monoarthritis) and will be killed up to week 8 via Schedule 1 method or non-schedule 1 for withdrawal of fluids (e.g. blood).

Alternatively, animals (100%) will undergo general anaesthesia (up to 60 minutes), ovariectomy surgery; administration of an agent (typically x15 injections) and will be killed up to week 6 via Schedule 1 method or non-schedule 1 for withdrawal of fluids (e.g. blood).

What are the expected impacts and/or adverse effects for the animals during your project?

All forms of arthritis cause joint stiffness, pain and some degree of disability. Animals may also lose weight or show signs of abnormal subdued behaviour. Arthritis, weight and behaviour will be monitored carefully using a scoring system that details when humane endpoints need to be actioned. Pain will be managed with pre-emptive pain relief.

For the age-related musculoskeletal model it is expects that animals will experience a low level of pain shortly after the surgical procedures which will be managed with pain relief. Breathing problems may occur following inhalation anaesthesia and leading to listlessness and laboured respiration. Such impacts/adverse effects will be addressed as described for up to 24 hours before humane endpoints are actioned.

We anticipate no adverse effects of the administered agents beyond those experienced during the administration step.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity to approximately 95% of animals Mild

severity to approximately 5% of animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The steps leading to the development of the state of chronic inflammation are poorly understood and it is likely that multiple physiological processes are involved, including proliferation of precursor cells, activation of lymphocytes and recruitment of inflammatory cells to the site of inflammation. Age-related musculoskeletal diseases, such as rheumatoid arthritis, are not static diseases confined to a single tissue or time point and hence modelling the effects of specific regulatory processes and new therapies inevitably involves the use of whole organisms and, in particular, the use of animal models of inflammation. However, where possible, cells from patients will be used to address questions relating to the mechanisms of action of therapeutic targets (see below in vitro models).

Which non-animal alternatives did you consider for use in this project?

We have pioneered a range of in vitro multi-cellular 3D constructs, incorporating primary human cells/tissues from healthy subjects and patients with different types of inflammatory arthritis. This has allowed us to further our understanding of the mechanisms regulating leukocyte recruitment. Indeed, for the majority of our work to date, we have used these in vitro tissue culture techniques to provide information about molecular and cellular mechanism(s) involved in the pathogenesis of disease or therapeutic effects. These cell culture assays will continued to be used throughout this licence to assess potential therapeutic molecules in functional assays such as expression, activation, proliferation and cytotoxicity. Molecules shown to be inactive in these assays will not be examined further in vivo. This utilisation of in vitro assays is an important replacement of in vivo experiments. Moreover, key molecules and/or processes identified using human and patient material will be used to inform the in vivo studies, focusing on those aspects relevant to the disease setting we are modelling.

Why were they not suitable?

Our in vitro models are unable to fully recapitulate the blood and lymphatic vasculature, and the movement of cells through complex organs, Moreover, they must be validated in licensing authority approved animal models before they enter clinical trials and are tested on patients. In some cases, this work represents preclinical therapeutic (drug and/or cell) efficacy studies required prior to embarking on toxicology studies and human clinical trials. There are no other in vitro or in vivo alternatives to this work. We will continue to collect as much in vitro evidence as possible before embarking on animal experiments, using it to inform and refine experimental design.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used specific mathematical calculations based upon previous studies and the likelihood of our interventions producing positive results, to estimate the number of animals we will use in our study. For all experimentation, the lowest possible number of animals will be tested whilst ensuring that the experimental result is robust.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used statistical analysis to calculate the minimum number of animals necessary for this project.
We will continue to use the NC3R's experimental design tool to aid experimental design and consult trained statisticians before using any new protocols.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have used statistical analysis to calculate the minimum number of animals necessary for each experiment within this project.
New interventions will first be tested for efficacy using in vitro models prior to use in vivo. Where new routes of administration or new interventions are being examined, pilot studies will first be established in 2-3 mice prior to full experiments. Subsequently these pilot data will used in the specific mathematical calculations described above to ensure that we use the minimum number of animals needed to obtain statistically significant results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used in arthritis models affecting either one joint, or multiple joints, and also in an age-related musculoskeletal model associated with age-related changes in immune cell movement. The single joint arthritic model offers the opportunity to significantly reduce the suffering and harm to the animal induced by inflammation in many joints. This is the preferred model of choice unless the model fails to recapitulate what we have already observed using the multiple joint arthritic model. This species and procedures have been chosen as they represent the lowest animal models with a musculoskeletal system in which it is possible to study immune cell

movement in health, with age and in disease, and the effects of a human protein have on this.

Why can’t you use animals that are less sentient?

Less sentient animals do not possess the same sort of skeletal structure that composes the joints, and often their vascular tree and immune system do not fully represent that of humans. Small rodents are the lowest mammals that can be used to recapitulate the human immune systems response to joint inflammation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Each experimental model will be monitored daily following intervention and mice will be assessed for any signs of distress such as pain and inability to feed. Wet food will be given for mice with diarrhoea and barrier cream will be used prophylactically to prevent skin irritation. Surgical interventions will be undertaken using the most appropriate anaesthetic and analgesia will be given. The mode of substance administration will be chosen to cause the least harm and distress to the animal. Any new substances or route of administration will be tested in a small pilot study and the mice monitored daily for signs of distress. Humane endpoints will be strictly adhered to at all times.
We have extensively refined the scoring system for each individual polyarthritis model to capture the specific aspects of each arthritis phenotype, ensuring clear and consistent analgesia and humane endpoints. We have also made refinements to the housing of the animals to cater for any disability arising from arthritis - including soft flooring, non-tangling nesting material, long spouts on water bottles, food on the cage floor.
We will also systemically review each experiment on completion to see what lessons can be learned from the study in terms of endpoints (scientific and humane) and any animal welfare issues that may have arisen during the experiment that could then guide the subsequent experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Animal welfare is a key consideration in all of our protocols, and we will be guided by our NACWOs and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. Following every experiment and regularly during group meetings we will review our procedures from a welfare standpoint to identify any potential for refinement.
We will also follow the published literature on arthritic models - for example the case for using different arthritis models to model the different aspects of inflammatory pathogenesis is extremely well made and described in Vincent et al. 2012. Moreover, refinement of the CIA injections has been described in Hawkins et al. (2015) and we have implemented these in our work to date and will continue to do so in this project.
If undertaking a systematic review, we will use SyRF, the free online platform for researchers, to perform a systematic review and meta-analysis of animal studies. This will allow us to keep up to date with any improvements in protocols and techniques which may reduce or replace the use of animals.
Finally, we will follow the LASA guidelines Guiding Principles for Preparing for and Undertaking Aseptic Surgery (www.lasa.co.uk/wp-content/uploads/2018/05/Aseptic-Surgery.pdf) and by the Home Office Minimum Standards for Aseptic Surgery (www.procedureswithcare.org.uk/ASMS2012.pdf) when undertaking aseptic surgery and providing analgesia.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

We will continue to engage with Institutional efforts to promote the 3Rs and workshops; and receive the NC3Rs newsletter.

Home Office

NON-TECHNICAL SUMMARY

80. Immune mediated disease and immunomodulation by parasites

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Helminth, Allergy, Inflammation, Obesity, IL-33

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to determine how immune responses are controlled in parasitic infection and immune-mediated disease, by the host and by immunomodulatory products released by the parasite. We will identify, characterise and develop parasite immunomodulatory molecules for potential use as therapeutic agents in human allergic, inflammatory and metabolic disease, with a particular focus on the IL-33 pathway.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Helminth parasites (parasitic worms) infect more than a quarter of the world's population, and have significant economic impacts on livestock rearing. The immune system is capable of ejection and killing of helminths parasites, however these parasites have developed very sophisticated techniques for suppressing immune responses against them, allowing them to survive in the host. In this project, we will investigate how the immune system ejects parasitic worms, how parasitic worms suppress the immune response, how parasitic immuno-suppression could be used to treat allergic and inflammatory diseases, and how the anti-parasite immune response could prevent weight gain in obesity.

Human population which have high levels of parasitic infections tend to have low levels of diseases caused by a hyperactive immune response such as allergies, autoimmunities and inflammatory diseases, as well as lower levels of obesity. We believe that this is due to the parasite releasing products into the host which suppress the immune response - over the past 5 years we have identified several individual proteins secreted by the parasite and shown that these can suppress inflammation in mouse models of asthma.

We now plan to identify further products released by the parasite which reduce disease in models of asthma, as well as showing that previously- and newly-identified products also suppress disease in models of asthma, inflammation, pneumonia, and obesity.

Much of our work will focus on the IL-33 pathway. IL-33 is an important messenger molecule in the immune system, and our previous work shows that it is the target of a series of immunosuppressive products from a parasitic worm. IL-33 is released on tissue damage, and initiates immune responses. IL-33 is important in a wide range of diseases, including allergies, asthma, pneumonia and obesity (amongst many others). However, we will not limit our research to the IL-33 pathway, but also assess the effects of parasite products on other relevant immune pathways.

What outputs do you think you will see at the end of this project?

The main output from this project will be better scientific understanding of how parasitic worms control (and are controlled by) the immune system. We will also investigate the role of blocking parasite interactions with the host immune system, as a proof of principle that this could be used as a vaccination strategy - if successful, this could ultimately lead to the development of new vaccines against parasitic worms which affect millions of people, as well as livestock and companion animals. We will investigate the products that parasites secrete to control the immune system - we plan to use this knowledge to develop new treatments for human immune-mediated diseases, including asthma, allergies, acute lung injury, pneumonia and obesity.

Who or what will benefit from these outputs, and how?

Ultimately, this project could benefit the many millions of people infected with parasitic worms in the world, through the development of vaccines. It could also benefit society economically, as parasitic infections of livestock have a large economic impact on meat and dairy production. Development of new treatments for asthma could benefit the 1 in 11 people in the UK who live with asthma, while better treatments are required for acute lung injury and pneumonia, diseases with high mortality rates which kill millions of people around the world every year. The obesity epidemic in the western world continues to increase, and hundreds of millions of people around the world are now classed as obese - better understanding of the biological processes that control obesity could have enormous health and economic benefits.

How will you look to maximise the outputs of this work?

We will at all times seek the best collaborations available. We currently have collaborations with leaders in the fields of parasite immunomodulation, anti-parasite immune responses and immune responses in fatty tissue. As further avenues of research become available, we will seek out collaborations to further this work.
Our main outputs from our research will be in the form of peer-reviewed publications in scientific journals, and we will seek to publish all data, positive or negative. However we have also always, and will continue to seek public engagement opportunities and to produce press releases for general news publications.

Species and numbers of animals expected to be used

- Mice: 10000
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will focus on how the immune system kills parasitic worms, and how parasitic worms suppress the immune system, and suppress diseases caused by the immune system such as allergic asthma. We will also assess how immune responses to parasites prevent obesity. To investigate this, we will use mouse models of parasitic infection, asthma, acute lung injury, pneumonia and obesity.
Mice are the best model of the human immune system - we understand the mouse immune system better than any other mammal, and a huge number of genetically modified mouse strains are available which allow us to remove certain parts of the immune response, to see how this affects infection, allergies and inflammation. We have already discovered a lot about the interaction between parasites and the immune system by using mouse models, and our lab has found several proteins secreted by parasites which could be developed as treatments for human diseases.
We will use young adult mice (6-14 weeks old) as the immune system is mature in mice of this age, and is highly responsive to stimuli.

Typically, what will be done to an animal used in your project?

Mice will be infected with parasitic worms: these parasites (depending on species) infect either directly by being swallowed, or by travelling through the skin, blood and lung, before maturing in the intestine. These infections can take between 1 week and 4 weeks. We will identify molecules which parasites secrete to suppress the immune response, and determine the effects of these by blocking their effects during infection.
We will also administer particular chemicals that cause specific types of inflammation into the lungs of mice to produce a response similar to that seen in asthma: these chemicals are that come from allergens from mould or dust, which result in the development of an allergic response. We will use parasitic infections, or injection of individual products which we have identified from parasites, to try to treat or prevent the asthma-like disease.
We will also introduce a material that comes from bacteria into the lungs of mice to cause pneumonia, or chemical agents to injure the lung (as is seen when people inhale stomach contents, potentially fatally injuring their lungs). Again, we will use parasites or their products to try and prevent or treat these responses.
Finally, we will provide mice with a high-fat diet to induce obesity. We will then infect these mice with parasites to see whether the immune response to the parasite has the side-effect of reducing weight gain.
In all of the systems above, we will use genetically-modified mice to remove or change the immune response, and see how this affects the interaction between parasites and their host.

What are the expected impacts and/or adverse effects for the animals during your project?

Parasitic infections generally do cause ill-health in infected mammals - most mice in the wild are constantly exposed to the parasites we will use, and around a billion people in the world are exposed to similar parasites, with comparatively low levels of illness caused. In some cases, however, especially when the immune response has been altered, we may see excess inflammation in the intestine or in other sites where the parasite has damaged. This can cause some weight loss and probably abdominal pain in these mice, however this is rare and short-lived - generally if we see these effects they are only for 2-3 days of the infection.
Models of asthma cause inflammation in the lung, however this is generally very mild and it is not possible to tell when a mouse has "asthma". The allergens used to cause asthma can be damaging to the lung, and so mice can have difficulty breathing immediately after receiving these but they don't appear distressed by this. These effects are short-lived however, and by the following day mice are always fully recovered.
Models of lung injury can also cause either immediate damage to the lung, or progressive inflammation during bacterial infections. Lung infections can eventually prove fatal to the mouse, however we will only be looking at the very earliest phase of infection, using a part of the bacteria rather than a bacteria that can multiply and spread, long before severe ill-health has been caused.
Finally, we will use a high-fat diet to cause obesity in mice. Although the mice will become significantly overweight, they should suffer no other ill-effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1: None of the genetically modified mice we are breeding on this protocol have harmful phenotypes, therefore we expect 99% of mice on this protocol to have a sub-threshold severity.
Protocol 2: Parasitic infections in mice and rats have a moderate severity limit. We estimate that around 10% of mice infected will reach moderate severity, the remainder showing mild severity. We estimate that <1% of rats on this protocol will reach moderate severity, the remainder showing mild severit**y.**
Protocol 3: Models of asthma, acute lung injury and pneumonia have a moderate severity limit, and due to the

pathology caused by administration of the Alternaria (asthma causing) allergen, HCl treatment (mimicking stomach content inhalation) and bacterial pneumonia, we expect around 40% of mice on this protocol to reach moderate severity, the remainder showing mild severity.
Protocol 4: Models of obesity have a moderate severity limit. We do not expect any ill-effects due to diet-induced obesity, but in combination with parasitic infection and immunomodulatory blockade, we expect that up to 5% of mice may show moderate severity, the remainder showing mild severity.
Overall, we expect the following severity categories:
Rats: Mild 99%, moderate 1%.
Mice: Sub-threshold 90%, mild 8%, moderate 2%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project will assess how parasitic worms suppress the host immune response, and how the immune response ejects parasitic helminths. It will also investigate the use of parasitic infection and molecules identified from helminths to treat diseases caused by an aberrant immune response including allergic asthma, acute lung injury, pneumonia and obesity. These systems all depend on a fundamental understanding of the immune system, which cannot be fully recapitulated outside of a mammalian organism. Therefore, as we break new ground in our understanding, we must use animals as a model of our own immune response.

Which non-animal alternatives did you consider for use in this project?

We will use in vitro systems wherever possible, however these systems are necessarily reductionist, only modelling specific individual pathways of the immune response. Therefore we can use these only when we have specific questions about a specific pathway. As we develop new and improved forms of the parasite immunomodulators, for development towards human therapeutic agents, these in vitro assays will be extremely useful for testing. However for testing factors such as immunogenicity and duration of action, these must again be tested in vivo.

Why were they not suitable?

As described above, when a system is incompletely understood (as is the case in the immune system) it cannot be fully modelled in reductionist in vitro assays. Therefore our hypotheses must be tested in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are estimates based on the number of experiments on planned projects and those already underway. The vast majority of mice will be from transgenic breeding, and the extent of these experiments will depend on success of current funding applications.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power calculations were carried out to find the lowest numbers of animals that can be used to achieve statistical significance. Of note, we will always pool data from repeat experiments to achieve significance: many journals in the field of immunology will not publish data taken from single experiments, therefore carrying out 2 pooled repeats is the most efficient way to achieve significance.
When we have multiple treatments to test, we will try wherever possible to trial multiple treatments in the same experiments: this has the advantage that these can then be compared to the same control groups, again reducing mouse numbers used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding of transgenic mice will be kept to the minimum numbers possible, however due to complex breeding regimens of genetically-engineered mice, not all mice bred will be of a usable genetic makeup – these mice will be screened and mice which cannot be used for experimentation will be culled at the earliest possible timepoint. Wherever possible, we will investigate hypotheses in lab experiments that do not involve procedures in live mice. We have developed a series of assays which replicate key parts of the mouse models we use, which we can now use to screen molecules and test hypotheses in the lab, without the use of live mice. We will continue to develop these assays wherever possible to minimise our animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use models of parasitic infection, asthma, acute lung injury, pneumonia and obesity in this project. These models have been selected to best replicate the immune response seen in human diseases, and thus results we obtain can be most readily translated to human treatments. Sometimes this means that models are used which cause greater distress to animals than some other available models, but which are more clinically

relevant. An example of this are models of asthma. A simple model of asthma is the OVA-alum model, where a single intraperitoneal injection of OVA protein in an alum adjuvant induces an allergic immune response which can be recalled in the lungs - this model causes minimal pain and suffering to animals. However, this is entirely non-physiological and is not how asthma occurs in humans. We instead will use models where clinically relevant allergens (moulds, dust) or chemicals that cause types of inflammation are introduced directly into the lungs, causing some damage and pain to the animal, but inducing an allergic or inflammatory immune response via the same pathways that are known to be important in human disease.
Wherever possible, we will use techniques that cause the least distress to animals as they are carried out. An example of this is administration of substances to the airways: previously, intratracheal administration (involving introducing a tube down the airway of an anaesthetised animal) was used which caused some inflammation in the airways, presumably with some discomfort for the animal. In all experiments involving airway administration, other than direct damage, we have now changed to using either intranasal or oropharyngeal administration: these techniques use very rapid inhalational anaesthesia, followed by administration of substances to the nostrils of the throat, and inhalation through normal respiration. This process takes less than 1 minute, is easy to master, and results in mice which have recovered fully within 5 minutes.
Models of acute lung injury by definition cause some injury to the lungs of mice. However we will assess responses over the earliest timepoints after injury, to minimise suffering. In some of these models, pathology is progressive and could ultimately lead to the death of mice from day 2 onwards if responses were left unchecked. In all of the experiments on this project, we will cull mice at a maximum of 48h after administration, at which point animals will experience only moderate ill-health. The majority of these experiments are planned to take place within 6h of administration, when the least suffering has been experienced.

Why can’t you use animals that are less sentient?

These experiments depend on a functional mammalian immune system - there are no less sentient model species available that recapitulate the human immune response to the extent that the mouse does, and where the responses are understood to the extent that the mouse's is. Likewise, we cannot use less mature life stages as the mouse's immune system is not fully formed until after wean (around 4 weeks of age). We are modelling immune responses in adult humans, therefore we must use adult mice.
Lung function measurements, which involve exposing the trachea and mechanically ventilating the lungs, will be carried out under an anaesthesia from which the animal doesn’t recover so that the animal is not aware of what is happening. Apart from this procedure, all other procedures require too long a time to cause an effect to allow these to be carried out under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be carefully monitored throughout procedures, especially procedures which have the potential to cause harm. For instance, in parasitic infections, animals will be monitored very carefully during the period of infection when pathology may occur - the first 4 days of *N. brasiliensis* and *S. ratti* infection, and days 7-10 of *H. polygyrus* infection. In models of acute lung injury and asthma, peak illhealth can occur immediately after administration of allergens/chemicals, therefore animals will be carefully monitored at these times after administration, kept warm and supplied with supplemental oxygen if required, and culled if their health status does not improve.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines and webinars available at the NC3Rs website: https://www.nc3rs.org.uk/experimentaldesign

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through participating in the local animal users group, interaction with vets and NACWOs, and NC3Rs information that is shared around the department.

Home Office

NON-TECHNICAL SUMMARY

81.Immune responses in murine models of cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Immunotherapy, Cancer treatments, T cell responses, Checkpoint receptors, Biomarkers

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

1) To understand how immune responses and disease progression are altered by immunotherapies in different models of human cancer.

2) To identify markers that predict T cell responsiveness to immunotherapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project seeks to explore how regulatory pathways activated during tolerance may also account for the exhaustion of immune responses in cancer. Given that most patients do not respond to immune checkpoint blockade therapy, there is an unmet need to understand the complex immunological consequences of checkpoint blockade. Furthermore, identifying early biomarkers of responders to these drugs would greatly aid in clinical management. For instance immune checkpoints "PD1" and "Lag3" are current targets for immunotherapy in cancers, however the majority of patients fail to respond to them. How they re-calibrate T cell activation thresholds and the exact phenotypic changes they impart are unclear. Thus, there is a need for greater insight into their effects on T cells and to identify biomarkers of successful responders. I aim to identify early T cell phenotypic biomarkers for responsivity to blockade of these pathways in vivo and gain insight into regulators of checkpoint expression. Thus, this work will not only lead to a better understanding of the mechanism of action of immunotherapies but will also identify priority biomarker candidates for future clinical studies.

What outputs do you think you will see at the end of this project?

We hope to identify a panel of markers that predict whether T cells are receptive to a given immunotherapy. These 'biomarkers' could then be used in future studies into human patient samples

We will generate new information on how different murine models of human cancer respond to immunotherapy, giving insight as to how these drugs work and how they might be further optimised in the future.

We envisage that this work will lead to several publications in reputable open access journals in the immunology/life sciences field.

We believe that the information generated over the project lifetime will support funding applications to begin human studies.

Who or what will benefit from these outputs, and how?

The project will deliver benefit to immunology and immunotherapy researchers in the short-term through the generation of new knowledge and understanding of important drugs (called immune checkpoint inhibitors) that are used to manipulate immune responses. It will identify similarities and differences between different immune regulatory pathways improving our understanding of the immune system and how to manipulate it.

In the medium term, the work here will be the first of its kind to perform a detailed investigation of how these different 'checkpoint inhibitors' work in distinct models of human cancer. Importantly, we will investigate responses to therapy in models of cancer that are either good or bad responders in the clinic to understand what may cause the differences immunologically.

In the longer-term, we envisage that the work may lead to the identification of biomarkers that can be used to decide whether a patient will respond to an immunotherapy thus helping to guide the treatment of cancer patients that receive immunotherapies.

How will you look to maximise the outputs of this work?

In order to maximise the outputs of this work we have identified two other groups within our establishment who work on similar models. These collaborations will enable sharing of expertise and optimisation of our experimental models. It will also maximise the chance of success of the project.

We will disseminate knowledge through publications, and for important data these may be released early into the public domain through non-peer reviewed pre-print servers such as bioRxiv.

We will promote our research through both internal and external presentations (e.g. seminars, conferences).

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are used in these studies because: (i) the main components of their immune system are shared by humans; this is essential where immune responses as opposed to the function of individual genes is being studied. Other animals provide an inadequate model of the immune system; (ii) a wide range of wild type and genetically manipulated strains of defined genetic makeup are available; (iii) an extensive range of reagents is available, enabling the best possible analysis of

the cellular and molecular interactions occurring during immune responses. In addition, we are using a unique T cell activation monitoring system, which has been established in transgenic mouse lines.

We will typically use adult mice for experiments, since by then the immune system is fully developed.

Typically, what will be done to an animal used in your project?

We will study immune responses in several murine models of human cancer.

1) **Engrafted tumours:** in these models cells from tumours are injected under the skin of mice (called 'engraftment'). This will allow the establishment of a tumour to grow. We will then inject drugs that target immune checkpoints. We will monitor the tumour size in response to the treatment using non-invasive calipers. Drugs may be injected several times in order to optimise the therapeutic effect. Typically these experiments will last 2-6 weeks.

2) **Inflammation associated cancer model:** we will utilise a model of human colorectal cancer. In this model, mice receive injection of a drug that induces DNA damage. Mice then will be put on 2 weekly cycles on and off of a water containing an irritant that causes inflammation of the colon. By 8 weeks tumour development has occurred. We will then inject drugs that target immune checkpoints. We will monitor the tumour size in response to the treatment (through non-invasive imaging). Drugs may be injected several times in order to optimise the therapeutic effect. Typically these experiments will last 10-14 weeks.

3) **Spontaneous tumour model:** we will utilise a mouse model of human tumours (called familial adenomatous polyposis). These mice have a mutation in a gene important for regulating growth of intestinal cells. These mice spontaneously develop tumours around 6 weeks of age. We will then inject drugs that target immune checkpoints. We will monitor the tumour size in response to the treatment (through non-invasive imaging). Drugs may be injected several times in order to optimise the therapeutic effect. Typically these experiments will last 6-12 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

In all models tumours will develop, which can lead to weight loss, pain and changes in behaviour. Our protocols have been optimised to limit the adverse effects experience (e.g. preventing weight loss below 15% of starting weight). Tumours are typically present for between 2-10 weeks of the experiments.

In the inflammation associated cancer models, some animals may experience diarrhoea and rectal bleeding. This typically occurs during the on cycle of the water containing an intestinal irritant. Mice are carefully monitored and water containing intestinal irritants is removed when these signs occur, so these side effects are anticipated to be episodic and short lived.

For injections, mice will experience momentary pain, which is expected to be mild and short-lived.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

As these models lead to tumour development. It is therefore anticipated that the majority (two-thirds) of control mice will experience moderate severity. This reflects tumour burden and weight loss that may be induced. However it is anticipated that one third of mice who receive immunotherapies will likely experience milder symptoms.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Growth of tumours and the tumour microenvironment is highly complex, involving numerous cell types including the tumour cell itself, infiltrating immune cells, stromal cells and vasculature. There is also the biophysical properties of tumour masses to be considered, such as the fact that some tumour will be wholly or partially
anaerobic and poorly perfused with nutrients. Three mouse models of colorectal cancer will be used in this research. One is the engraftment model, this model allows us to test T-cell responses in tumour models that are known to provoke vigorous immune responses. This is important as a positive control. We will also use a model of human colitis-associated
cancer, and is induced by giving mice carcinogen (AOM) followed by repeated exposure to an intestinal irritant
(DSS) to induce colitis. The third model is the Apcmin/+ mouse model of familial adenomatous polyposis, which is caused by inheritance of a dysfunctional APC (adenomatous polyposis coli) gene. Mice lacking one copy of this gene develop multiple intestinal neoplasia. Both of these mouse models are considered to be highly contiguous with human colorectal cancer development and progression. Furthermore as human colorectal cancer is generally considered a poor responder to immunotherapy, we will be able to compare immune responses in both good and bad responder models. This would not be possible with any in vitro or in silico approaches.

Which non-animal alternatives did you consider for use in this project?

Organoids, in vitro and in silico methods.

Why were they not suitable?

Growth of tumours and the tumour microenvironment is highly complex, involving numerous cell types including the tumour cell itself, infiltrating immune cells, stromal cells and vasculature. Whilst organoids can form 3D structures, they are not wired to vasculature which is how immune cells enter and exit tumour environments. Therefore understanding the complex consequences of drugs that target immune cells within cancer would not be possible. Furthermore interactions between multiple

cell types as well as the 3- dimensional structure makes it very difficult to truly replicate in vitro or in silico.
We will work with collaborators to further explore the option of using Organoid models for pathways that we identify in vivo. We will employ in silico methods to refine our biomarker datasets by intersecting our markers with published ones in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The project requires the breeding and maintenance of mice. In order to maintain colonies not all mice are subjected to further experimental procedures. We will utilise many different strains of mice to explore immune responses in cancer models. Typically we envisage breeding 500-700 mice per annum. This is based on us utilising 5-7 different mouse strains, with approximately one hundred of each strain used per year. Of these we envisage that up to 2000 will undergo procedures (the remaining 1500 mice are used to breed and maintain the colonies). This is based on 200 mice per year for engrafted tumour models, and 64 mice per year for colorectal and 64 mice for spontaneous tumour models. These are calculated based on 4 groups of 8 for each model being repeated on two independent occasions.

Pilot data suggest that n=5 is sufficient for engrafted models. However we will utilise more mice here to screen multiple checkpoint pathways, therefore we anticipate using more in this protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have consulted with the NC3R's Experimental Design Assistant tool. This helps to design optimal experiments. Typically we aim to use what is known as a "randomised block design" which permits us to detect differences even when we introduce variables such as different sex and age. This approach controls for these differences by randomly assigning them to control and treatment groups. In this way we can maximise use of mice bred for the licence.

By using pilot experiments we will be able to determine the minimum number of mice to be used - typically we have determined that 6 mice per group will allow us to detect a reasonable treatment effect in most circumstances. However these calculations will be continually updated and improved throughout the life of the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. **Pilot experiments**

Small numbers of animals will be used in pilot experiments for each new type of study performed to assess intra- and inter-group variation. For most models in this project, optimal group sizes and variation are already well established by collaborators.

2. **Inbred strains**

The use of inbred strains (matched for age and gender) will reduce the amount of intra-group variation thus increasing the power of each experiment and reducing the group size needed to achieve statistical significance.

3. **Sensible breeding of transgenic lines**

Where possible mice will be bred as heterozygous x homozygous KO to enable usage of the whole litter.

4. **Multiple read-outs from same animal**

Multiple read-outs taken post-mortem from experimental animals will further reduce the number of animals required. For example, a single animal can be used for the analysis of bacterial CFU, activation of organ-resident cells/recruitment of peripheral immune cells (using large panels for multi-colour flow cytometry analysis), histopathological analyses, metabolic and cytokine profiling from frozen tissues.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

1: Engrafted tumour models

Engrafted tumour models require a single injection of tumour cells under the skin, minimising the pain and suffering mice experience. These models allow faster tumour development, tumours are visible, which allows easy non-invasive monitoring and ensuring tumours do not grow beyond 1.25cm3 in size.

2: Colitis associated colorectal model (CAC)

Azoxymethane (AOM) and Dextran sulphate sodium (DSS)-induced CAC is considered to be one of the most reliable models of human colitis-associated cancer. It has 100% incidence, which reduces animal numbers, while recapitulating disease progression seen in human from aberrant crypt formation, through polyp, adenoma
– adenocarcinoma development. Other CAC models that involve gene-deficient animal, usually coupled with an infectious trigger, are less reliable (varying from 20 – 80% penetrance), and

some involve severe immunocompromised animals which can increase pain, suffering and distress of animals.

The AOM/DSS model involves giving one injection of AOM. This induces DNA damage and DNA mutation. The day after AOM, DSS is given in the drinking water for 5 to 7 days. This induces colitis as DSS irritates the epithelial lining of the colon. Our collaborators within the establishment have refined the model and identified that 3% DSS is sufficient to induce tumour development whilst minimising adverse effects. Mice lose weight, develop diarrhoea and rectal bleeding, which resolves from 1 to 2 days following replacement with normal water. The DSS treatment is repeated twice more, after 2 weeks rest on normal water. Therefore by careful monitoring the suffering of mice can be minimised and symptoms eased through replacement with normal drinking water. Therefore whilst some unavoidable adverse effects occur we have made the above refinements to support the animals.

3: Spontaneous tumour model

We will utilise the APCmin/+ model, which is a model in which a gene important in regulating intestinal growth is deleted. This leads to spontaneous tumour development in the intestine. Therefore mice do not need to be administered substances such as carcinogens for tumour establishment, therefore minimising pain, suffering and distress.

Why can't you use animals that are less sentient?

This work has to be conducted in mammalian species, mice in our case, because the immune system, and therefore role in tumour development/treatment, in mammals is much more complex than that seen in invertebrates or other vertebrates. Hence, studying rudimentary immune systems will not lead to a significant increase in our understanding of the regulation of the immune system in health and disease. The mouse is the worldwide standard laboratory animal model and its immune system has been the most intensely investigated and for which there are the most reagents and information available. This, in addition to the availability of GA mouse stains, allows much more rapid progress to be made.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

CAC model

In terms of refining the model, we aim to use the least amount of intestinal irritant required and ideally aim for an initial
weight loss of not more 15%, although the humane endpoint is 20% we try and avoid reaching that, as a consistent 15% weight loss can still yield the desired results. We will achieve this by doing an initial pilot study to determine the sensitivity of mice to DSS, and use the lowest dose. We will be using a 4 point scoring system for assessing the severity of colitis in protocol 4. This takes weight loss, stool consistency, with a score of 0 being no effect and a score of 4 indicating the humane endpoint. We will utilise smallest gauge needle for administration and will explore water sweeteners for improving DSS palatability. We will follow LASA dosing guidelines.

Monitoring of mice

Mice will be typically monitored and weighed daily, therefore if any issues arise these can be dealt with as soon as possible to minimis mouse distress and discomfort.

Planning and revision

It is often not possible to always predict outcomes, and future experimental design is dependent upon the results of previous experiments and upon in vitro data derived from ongoing experiments. The data generated feeds back
into the experimental planning for improvement and refinement. Pilot experiments are often performed using small numbers of animals to assess variability and outcome. Thus, I will be continually revising the experimental plan and will continuously monitor the literature for refinements and the most up to date methodology to perform the outlined experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult LASA guidelines on the handling and administration of substances.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the NC3Rs website (www.nc3rs.org) and new staff will be directed to these web pages. Where new 3R advances occur we shall work with staff in our facility to adapt protocols or techniques. We will also seek advice and latest information through our Named Information Officer (NIO).

NON-TECHNICAL SUMMARY

82. Immune responses to Marek’s Disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Marek's disease virus, lymphocytes, vaccine, chicken

Animal types	Life stages
chicken	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to have a better understanding of immune responses to an infectious disease which causes cancer and suppression of immune response in chickens.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Marek's disease (MD), which causes cancer and suppression of immune responses in chickens, is associated with huge economic losses to the poultry industry and causes major welfare problems for the infected birds. As more virulent Marek's disease virus (MDV) are emerging, the control of the disease remains a major challenge to the industry. In this project, we will investigate the effectiveness of a novel form of vaccine "so called cell-free" and compare that with the conventional cell-associated vaccine. In the medium term, the results from this research will open a new avenue to develop more effective control measures. In the long term, this project should ultimately lead to control of virus and improved animal welfare and productivity in meat and eggs. The development of effective cell-free vaccines will remove the need for a cold chain for both storage and transportation of current conventional vaccines against this virus. Therefore, the development of a cell-free vaccine will reduce the cost associated with conventional vaccines for poultry farms and allow poor farmers in developing countries to have access to cheap vaccines.

The proposed project will also investigate the role of the immune response in the control of the disease in both resistant and susceptible chicken lines and identify those parts of viral proteins that can induce protective immune responses. Moreover, the results will provide information on whether infection impairs functions of immune cells which are important for the control of the disease in chickens. We will investigate and identify the factors released by infected cells or cancer cells which can impair the function of the immune response. Identification of novel biological pathways involved in causing the disease and the development of specific assays to study the immune response against Marek's disease virus are the short-term benefits of this study which could be used by other researchers in the field. However, in the long term, results could be used to design control strategies by blocking the effects of those factors released from infected or cancer cells which suppress immune responses.

Another important benefit is the development of tools and techniques to study functions of chicken immune cells which will be an important resource for other researchers to study immune responses to other viral or bacterial infections such as avian influenza virus, infectious Bronchitis virus and infectious bursa disease in chickens. Therefore, the benefits of this project could extend to improve the control of economically important infectious diseases in chickens.

What outputs do you think you will see at the end of this project?

- This work is expected to generate new information about the role of chicken immune cells in providing protection against cancer which is induced by Marek's disease virus. This information will be published in peer-reviewed scientific journals.

- Novel biological pathways, involved in suppression of immune response, are expected to be identified. This information will be published in peer-reviewed scientific journals.

- The effectiveness of a novel vaccine which does not require cold chain for storage and transportation will be examined. This information may lead to the development of novel vaccine product and the results will be published in peer-reviewed scientific journals.

Who or what will benefit from these outputs, and how?

Marek's disease, which causes cancer and suppression of immune response in chickens, is associated with huge economic loss (1-2 billion US dollars losses annually) to the poultry industry and causes major welfare problems for the infected birds. As more virulent Marek's disease virus (MDV) are emerging, the control of the disease remains a major challenge to the industry. In this project, we will investigate the effectiveness of a novel form of vaccine and compare that with conventional vaccine. In the medium term, the results from this research will open a new avenue to develop more effective control measures. In the long term, this project should ultimately lead to control of virus and improved animal welfare and productivity in meat and eggs. The development of the novel vaccine, which does not need cold chain for storage and transportation, will reduce the cost associated with vaccination and allow poor farmers in developing countries to have access to cheap vaccines.
The proposed project will also investigate the role of the immune response in the control of the disease and these results will provide information on how the virus can escape immune control. In the long term, results could be used to design control strategies by blocking the effects of the identified biological pathway to suppress immune responses.
Another important benefit is the development of tools and techniques to study functions of chicken immune cells which will be an important resource for other researchers to study immune responses to other viral or bacterial infections such as avian influenza virus, infectious Bronchitis virus and infectious bursa disease in chickens. Therefore, the benefits of this project could extend to improve the control of economically important infectious diseases in chickens.

How will you look to maximise the outputs of this work?

The results from this study will be published in peer-reviewed open-access scientific journals and presentations at scientific conferences and meetings.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Marek's disease is an economically important disease in chickens, and thus chickens are the appropriate type of animals to study immune response to this disease. Vaccines against Marek's disease could be administered during embryonic stage or after hatching, and infection occurs after hatching.

Typically, what will be done to an animal used in your project?

Embryo and/or chicks will be vaccinated against the disease via various routes including subcutaneous and intra-abdominal routes and these birds may be re-vaccinated or infected with the virus at different time post vaccination.

Alternatively, unvaccinated chicks will be infected with the virus via different routes including intraabdominal or intra-tracheal routes and some of these birds may be administered with various substances, which modulate immune responses, via various routes including oral, intramuscular, intravenous and/or intra-abdominal routes. Blood samples or feathers will be isolated from the vaccinated/infected animals.
Duration of each experiment is approximately four months. Three different procedures used during the experiments are administration (e.g. subcutaneous, intra-abdominal, intramuscular, intravenous, oral), collection of blood samples from superficial veins and collection of feather samples.

What are the expected impacts and/or adverse effects for the animals during your project?

Injection causes a minor discomfort, and animals will recover very rapidly. Infection of unvaccinated chickens causes Marek's disease with clinical signs associated with formation of cancer and/or transient or permanent neurological signs. Some unvaccinated susceptible chickens may die from the infection without showing any obvious clinical signs or gross pathological lesions. The infected birds showing the clinical signs of the disease will be immediately culled. Infection of vaccinated chickens does not induce the disease, and the birds are protected from the disease.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Injection caused a minor discomfort, and animals will recover very rapidly (mild severity). Infection of unvaccinated chickens causes Marek's disease with clinical signs associated with Marek's disease (moderate severity). The infected birds showing the clinical disease will be immediately culled.

In approximately 75% of the animals which will be included in our experiments, we will use vaccinated chickens, or the birds will be administered with substances which increase the immune responses against the disease. Vaccinated chickens will be protected against the disease and they will show no clinical signs and they will not suffer from the disease. It is also expected that immune enhancing substances increase immune response against the disease and many of those birds will not show clinical signs or if the disease are induced a lower level of lesions are induced (moderate severity).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project is aiming to investigate immune responses to Marek's disease virus, the causative agent of Marek's disease, an important viral disease in the chicken.

Which non-animal alternatives did you consider for use in this project?

Alternatives to animal procedures will be used in the proposed project where possible. For example, cell culture techniques will be used to assess the cytotoxicity of chemical inhibitors on chicken cell lines and primary cells for regulatory pathways.

Why were they not suitable?

The biological complexity of the immune system means that there is no alternative to the use of animals to study cell mediated immune response to virus infection and tumour development. Moreover, the efficacy of vaccines can only be tested in vivo and there are no in vitro or ex vivo alternative models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on our previous results and results published by other researchers, we have calculated the numbers of birds in each experimental group which can give us statistically significant results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Advice was taken from statistician and we used online tools such as NC3R's Experimental design assistant

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Tissues will be collected and stored and shared with other projects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In many experiments, we will increasingly infect vaccinated chickens or chickens with maternal antibodies, when it is possible. These birds will have some resistance to the disease.

Why can’t you use animals that are less sentient?

MDV only infects and causes disease in poultry, therefore it is not possible to use any other animals to investigate the immune response to MDV and develop improved disease control strategies

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In those birds that sudden death could occur after infection with the virus, the frequencies of inspection will increase to three times a day to identify any early clinical signs associated with the disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Published guidelines from NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend workshop, seminars on 3Rs and follow latest information on new development about 3Rs in online sources.

Home Office

NON-TECHNICAL SUMMARY

83. Immunity to ectoparasites of ruminants

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

vaccines, ectoparasite, livestock, ruminants, immunity

Animal types	Life stages
Sheep	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The specific aims of the project are:

1) To understand the nature of the protective immune response which is induced by exposure to, or administration of vaccines against, the ectoparasitic mite, Psoroptes ovis in sheep.

2) To use this information to improve the effectiveness of vaccines such that they will provide an important tool in the control of infestation with Psoroptes ovis (sheep scab or psoroptic mange).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The vaccine that is being developed in the project will directly benefit livestock by protecting them from parasitic disease. This benefits both the welfare and productivity of the vaccinated animal but also reduces reliance on synthetic chemicals, adding to global food security and reducing environmental contamination. In addition, the parasite which is being investigated here has close relatives, which have negative health impacts on humans and other animals. i.e. scabies mites (Sarcoptes scabiei) and the house dust mite (Dermatophagoides farinae).

What outputs do you think you will see at the end of this project?

1) New prototype vaccine for further development to commercial products
2) New information on the host:parasite interaction
3) New information on vaccine and adjuvant effects on the immune system
4) Multiple scientific publications and lay articles on livestock vaccines

Who or what will benefit from these outputs, and how?

Short term beneficiaries will be researchers working in the fields of vaccinology and ruminant immunology through the availability of new information on the host:parasite interaction, immunology and vaccinology which will accelerate their own research programmes. Longer term beneficiaries include stakeholders in the vaccine and livestock industries through the production of new commercialisable tools for animal health and welfare. Societal benefits can also be seen through the reduction on reliance of injectable macrocyclic lactones and organophosphate dips with the attendant environmental and safety concerns that these bring.

How will you look to maximise the outputs of this work?

The applicant has a long track record of collaboration and effective knowledge exchange and outputs will be maximised through the following approaches:

Scientific Audiences: The results of our investigations will be published in open access journals appropriate for subject matter, 3Rs and scientific impact. All manuscripts will follow the ARRIVE guidelines [Kilkenny et al., 2010. PLoS Biol 8(6): e1000412] to promote accurate reporting appropriate for 3Rs initiatives.

During the course of the project we will attend scientific conferences (e.g. the World Association for the Advancement of Veterinary Parasitology Conference in Dublin, Republic of Ireland, 2021) to communicate progress and to emphasise the focus on scientific excellence in this project, highlighting crossovers in disciplines. The licence holder will attend the British Society for Parasitology Annual
Spring meeting each year to communicate these aspects. The licence holder is an active member of the BBSRC's International Veterinary Vaccinology Network and will attend their annual meetings to disseminate the approach and results (both successful and unsuccessful) to this community. The licence holder interacts with a large number of researchers through formal networks, which promote cooperation and multidisciplinary networking between scientists and stakeholders. In addition, as objectives are successfully completed we will directly communicate the emerging technology by email and/or Microsoft Teams meetings to the research groups most likely to benefit from it.

Educational and Public: The licence holder teaches undergraduate and postgraduate students in parasitology and will use these opportunities to promote the outputs and principles of this project. For dissemination to the wider public, the applicant will attend the Royal Highland Show in each year of the project, to communicate our results, their impact and context to members of the general public. The impact of the project will be made available on the host institution website as a resource for the public, policymakers and Government stakeholders in the food, animal health, environment and rural sectors.

Species and numbers of animals expected to be used

- Sheep: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in these protocols are the natural hosts for the parasite under study. The life stages of the ruminants used are the most susceptible to this parasite and also the stages for which the economic impact of infestation is the highest.

Typically, what will be done to an animal used in your project?

Animals in this project will be administered vaccines by the most appropriate route (this may be injections or sprays for example) and then infested with Psoroptes ovis mites using our standard challenge infestation. Typically, animals would receive 3 injections of the vaccine, 2 weeks apart and would then be challenged with the mites for a maximum period of 6 weeks in experimental settings.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects on the animals are expected to be moderate. Infestation of the skin with Psoroptes ovis is characterized by exuberant yellowish scabs, additional signs include restlessness, pruritus, scratching, yellow-stained fleece, wool-loss, head tossing, bleeding wounds and loss of condition. In particular, the disease can cause considerable irritation or pain, or both. Typically, these effects would be for the duration of the infestation, so a maximum period of 6 weeks in an experimental setting. However, we have extensive experience on the course of infestation following experimental challenge and, at termination of the experiment the area of lesion is expected to be less than 20% of total body surface area. The injection of recombinant P. ovis proteins as part of the vaccine is considered unlikely to cause any adverse reaction, although animals will be carefully monitored during and immediately following these injections. Quil A adjuvant has been widely employed by ourselves and others in vaccines in sheep, without any adverse reaction. Infestation of sheep scab mites will be monitored closely.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals infested with *Psoroptes ovis* would be expected to suffer a maximum of a moderate degree of severity. This will be controlled by limiting the number of mites used for each application to ~100 mixed stage mites. Animals will be monitored, and infestations will only be allowed to proceed until a maximum of 20% of the body surface is affected or for a maximum of 6 weeks duration.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The parasites being studied in the project are "obligate" parasites. This means that they can only survive on a host animal. We must therefore use host animals (sheep) to maintain these parasites before and during vaccine trials.

Which non-animal alternatives did you consider for use in this project?

Currently there are none as the mite *Psoroptes ovis* cannot be maintained off of the live ovine host

Why were they not suitable?

Currently no suitable alternatives exist

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimates are based on the numbers of animals used in previous studies over the last ~10 years and have been optimised through collaboration with statisticians reviewing data from our previous experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to each experiment, we review data from previous similar experiments, estimate the levels of effect of any treatment that we want to be able to record and collaborate with expert statisticians to determine the minimum numbers of animals required to accurately determine treatment/vaccine efficacy

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Maintaining good animal health throughout every experiment to avoid animal numbers reducing from disease which is not related to the disease under study. In addition, wherever possible we will make samples taken from live animals and any tissues from any euthanased animals available to other researchers for their use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The species being used (sheep) is the natural host for Psoroptes ovis and also the target species for the vaccine being developed, so are the most appropriate model species to be employed here. Vaccination and challenge of sheep consists of 3 immunisations with the candidate antigen(s) in adjuvant (QuilA) two weeks apart and animals are then experimentally challenged with a carefully controlled mite infestation. During infestation and vaccine testing, sheep are routinely monitored by veterinary staff and are treated with veterinary medicines if required, based on clinical symptoms.

Why can't you use animals that are less sentient?

The mite, *Psoroptes ovis* has adapted to surviving on lambs and ewes and has a relatively long-lasting lifecycle (several weeks) and as such the use of terminally anaesthetised animals would not be practical. In addition, as previous infestations can result in a degree of protective immunity, we need to ensure that the animals used in the trials are naive for sheep scab with no history of infestation, which is easier to guarantee in younger animals with a known history.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring, post procedures, will identify any areas which require refinement. For example, animals are closely monitored following vaccination and, if any of the compounds administered cause pain, appropriate analgesia will be administered

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where appropriate, the World Association for the Advancement of Veterinary Parasitology guidelines for best practise will be followed https://www.waavp.org. In addition, the ARRIVE guidelines 2.0 will be followed to allow the experiments to be performed in the most refined way and the publication of the data in the most appropriate form. https://arriveguidelines.org/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The host Establishment has had involvement in numerous NC3R research initiatives and has regular contacts with this body. In addition, we have an active 3Rs committee, which provides advice both to project and personal licence holders and the local AWERB. Any relevant advances in the 3Rs will be implemented into any of the protocols where appropriate.

NON-TECHNICAL SUMMARY

84. Immunity to ruminant endoparasites

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

vaccines, parasites, livestock, ruminants, immunity

Animal types	Life stages
Cattle	juvenile, adult
Sheep	juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The specific aims of the project are:

1) To understand the nature of the protective immune response which is induced by exposure to, or administration of vaccines against, parasites in ruminants.

2) To use this information to improve the effectiveness of vaccines such that they will provide an important tool in the control of production and welfare-limiting parasitic diseases of livestock.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The vaccines that are being developed in the project will directly benefit livestock by protecting them from parasitic disease. This benefits both the welfare and productivity of the vaccinated animal but also reduces reliance on synthetic chemicals, adding to global food security and reducing environmental contamination. In addition, the parasites which are being investigated here have close relatives which parasitise humans. The large-scale programmes which exist to produce vaccines against parasites of humans (e.g. the human hookworm vaccine initiative) may also benefit from the vaccine development and discovery work in this project.

What outputs do you think you will see at the end of this project?

1) New prototype vaccines for further development to commercial products
2) New information on host:parasite interactions
3) New information on vaccine and adjuvant effects on the immune system
4) Multiple scientific publications and lay articles on livestock vaccines

Who or what will benefit from these outputs, and how?

Short term beneficiaries will be researchers working in the fields of vaccinology and ruminant immunology through the availability of new information on host:parasite interactions, immunology and vaccinology which will accelerate their own research programmes. Longer term beneficiaries include stakeholders in the vaccine and livestock industries through the production of new commercial sable tools for animal health and welfare. Societal benefits can also be seen through the reduction on reliance of synthetic anthelmintics with the attendant environmental and safety concerns that these bring.

How will you look to maximise the outputs of this work?

We have a long track record of collaboration and effective knowledge exchange and outputs will be maximised through the following approaches:

Scientific Audiences: The results of our investigations will be published in open access journals appropriate for subject matter, 3Rs and scientific impact. All manuscripts will follow the ARRIVE guidelines [Kilkenny et al., 2010. PLoS Biol 8(6): e1000412] to promote accurate reporting appropriate for 3Rs initiatives.

During the course of the project we will attend scientific conferences (e.g. the World Association for the Advancement of Veterinary Parasitology Conference in Dublin, Republic of Ireland) to communicate progress and to emphasise the focus on scientific excellence in this project, highlighting crossovers in disciplines. The licence holder will attend the British Society for Parasitology Annual Spring meeting each year to communicate these aspects. The licence holder is an active member of the BBSRC's International Veterinary Vaccinology Network and will attend their annual meetings to disseminate the approach and results (both successful and unsuccessful) to this community. The licence holder interacts with a large number of researchers through formal networks which promote co-operation and multidisciplinary networking between scientists and stakeholders from EU member states. In addition, as objectives are successfully completed we will directly communicate the emerging technology by email and/or Microsoft Teams meetings to the research groups most likely to benefit from it.

Stakeholders and policymakers: The host Establishment has an established Communications Team through which we will attend the UK-wide Animal Health Roadshows each year to report on our progress and to promote the principles to both stakeholders and policymakers. The Licence holder will attend an annual Press Day in December each year to promote the findings of our project and to outline the benefits achievable with the outcomes. We have close interactions with many relevant stakeholders and lay updates on the research will be sent to these stakeholders through newsletters, website content and regular interactions at agricultural events and road shows.

Educational and Public: The licence holder teaches undergraduate veterinarians, scientists and public health students in parasitology and will use these opportunities to promote the outputs and principles of this project. For dissemination to the wider public, we will attend the Royal Highland Show in each year of the grant to communicate our results, their impact and context to members of the general public. The impact of the project will be made available on specific pages of the host Establishment website as a resource for the public, policymakers and Government stakeholders in the food, animal health, environment and rural sectors.

Species and numbers of animals expected to be used

- Cattle: 290
- Sheep: 1,130

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in these protocols are the natural hosts for the parasites under study. The life stages of the ruminants used are the most susceptible to the parasites and also the stages for which the economic impact of infection is the highest.

Typically, what will be done to an animal used in your project?

Animals in this project will be administered vaccines by the most appropriate route (this may be injections or sprays for example) and then infected with parasites which the animals would normally encounter in the field. Typically, animals would receive 2-3 injections of the vaccine, 3 weeks apart and would then be challenged with the parasites for 4-12 weeks in experimental settings, though these figures may increase in field experiments.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects on the animals may be loss of appetite, diarrhoea, reduced weight gain. Typically, these effects would be for 4-6 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate severity: <10% of animals infected with gastrointestinal worms

Mild severity: ~90% of animals infested with gastrointestinal worms

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The parasites being studied in this project are "obligate" parasites. This means that they cannot survive outside of a host animal. We must therefore use host animals (sheep and cattle) to maintain these parasites before and during vaccine trials.

Which non-animal alternatives did you consider for use in this project?

Currently there are none.

Why were they not suitable?

There are none.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These estimates are based on the numbers of animals used in previous studies on previous versions of this licence and have been optimised through collaboration with statisticians reviewing data from our previous experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Prior to each experiment, we review data from previous similar experiments, estimate the levels of effect of any treatment that we want to be able to record and collaborate with expert statisticians to determine the minimum numbers of animals required to accurately determine treatment efficacy.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Maintaining good animal health throughout every experiment to avoid animal numbers reducing from disease which is not related to the disease under study. In addition, wherever possible we will make samples taken from live animals and any tissues from any euthanased animals available to other researchers for their use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Cattle and sheep: gastrointestinal nematode infection models. Methods include blood and mucus sampling and faecal sampling, none of which cause anything more than transient pain or discomfort to the animal.

Why can’t you use animals that are less sentient?

These parasites are adapted to living in lambs, ewes, calves and cows and have relatively long-lasting lifecycles (several weeks) so the use of terminally anaesthetised animals would not be practical.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Monitoring, post procedures, will identify any areas which require refinement. For example, animals are closely monitored following vaccination and, if any of the compounds administered cause pain, appropriate analgesia will be administered.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where appropriate, the World Association for the Advancement of Veterinary Parasitology guidelines for best practise will be followed https://www.waavp.org

In addition, the ARRIVE guidelines 2.0 will be followed to allow the experiments to be performed in the most refined way and the publication of the data in the most appropriate form. https://arriveguidelines.org/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The project licence holder is the recipient of several NC3Rs grants and has regular contact with this funding body for reciprocal updates. in addition, the host Establishment has an active 3Rs committee which provides advice to both project and personal licence holders, the local AWERB and actively liaises with the Animal Technicians looking after the animals. Any relevant advances in the 3Rs will be implemented into any of the protocols where appropriate.

  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words rumen, microbiome, feeds,

supplements

Animal types	Life stages
Cattle	adult
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will determine the impacts of diet or supplements on rumen function in cattle to help improve their overall health, welfare and productivity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Farm animals can be affected by a whole manner of diseases that can be related to diet, and they can have a significant impact on the animal's health and wellbeing, in addition to its production characteristics such as milk production. By investigating the effects of diets or supplements or rumen digestion, metabolism, the rumen (the fermentation chamber of the ruminant gut that degrades fibre) microbiome (the beneficial microbes that live in the gut) and rumen function, it will be possible to develop new feeding or supplementation strategies that will maintain or enhance animal productivity, while not compromising animal health or welfare, and in fact should hopefully improve animal health and welfare. As part of these studies we may use rumen instrumentation boluses (electronic devices that reside in the rumen that transmit data to a computer) to gather real-time data on rumen pH and motility to further enhance our understanding of the effects of diet or supplementation on rumen function.

What outputs do you think you will see at the end of this project?

The outputs at the end of this project should be improved feeding or supplementation strategies that should maintain or improve dairy production parameters (e.g. reduction in incidence of metabolic disease), and importantly rumen health and overall animal health and welfare status should be enhanced. Given the financial impact of metabolic disease on the dairy industry, reducing the incidence of these diseases via novel feeding or supplementation strategies will be of considerable benefit. It is anticipated that by the end of this project we will be able to develop guidance or fact-sheets for dissemination to farmer groups/organisations for extension and knowledge transfer purposes.

Academic outputs will also include peer-reviewed publications, undergraduate or postgraduate theses.

Who or what will benefit from these outputs, and how?

These studies are directly applicable to cattle being maintained in typical production systems, where improved feeding or supplementation strategies will maintain or improve animal productivity, without compromising animal health, wellbeing or welfare.

More specifically:

- Individual animals or an individual herd may benefit from a reduction in the incidence of metabolic diseases through our development of novel feeding or supplementation strategies.
- From a business perspective farm businesses and the wider industry should see a reduction in the financial cost to the business from metabolic diseases.
- Adoption of novel feeding strategies with positive outcomes of lower disease incidence will lead to more efficient (nutritional and financial) management of the animal/herd, improving animal productivity and gross margin outcomes.
- Gaining a better understanding of the microbiome population and how it dynamically changes in response to diet, feed processing (e.g. rolled grains) or supplementation strategies will allow us to consider how best to 'support' the beneficial microbes within the gut via these strategies in order to help maintain a more stable microbial population that meets the challenges of rapid dietary changes that occur when animals are going from the dry period into peak lactation, into late lactation. Furthermore, we are aware of how the quality of milk changes throughout the season (spring grass versus summer/autumn grass), and again our studies in this project on the microbes within the gut will lead to further studies in the medium to longer term determining how fluctuations in milk composition could be reduced through a better understanding of the role that gut microbes play in rumen function.

How will you look to maximise the outputs of this work?

In addition to disseminating to the wider academic community through peer-review papers etc., we aim to disseminate the knowledge obtained from this project to the wider farming community via their community organisations, knowledge transfer events and social media. For example, we may be able to represent our results via seminars at various agricultural shows or similar farming events. We also aim to set up webinars later in the project to update farmer groups (e.g. DairyCo, young farmers clubs) on the dietary or supplementation strategies we've developed that may improve animal productivity, efficiency, health and welfare of their animals.

Species and numbers of animals expected to be used

- Cattle: 18

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These studies are relevant to commercially reared and maintained cattle, therefore it is entirely appropriate to use adult animals of these species for these studies.

Typically, what will be done to an animal used in your project?

For animals in this project they will be subjected to surgical modification through the creation of a permanent rumen fistula, which is the creation of a hole in the side of the cow to allow direct access to the rumen. A precise cannula is fitted in to this area, which is in the form of a specially fitted covering with a removable plug, to keep it maintained and to keep oxygen out of the rumen. This modification is essentially the same as that created in human patients with a stoma. Having an opening into the rumen from the outside is essential for us to monitor in real-time fluctuations in pH, digestion, metabolism and gut microbes in response to diet or supplement administration. This principally involves sampling digesta, faeces, or taking peripheral blood samples or samples of the lining of the gut. Rumen-fistulated animals can remain healthy for many years, and it is anticipated that on average these animals often live for over 10 years with the permanent fistula, which is much longer than a 'typical' commercial animal.

What are the expected impacts and/or adverse effects for the animals during your project?

The main impacts with creating an artificial opening into the gut of cattle is mild to moderate pain and discomfort for a brief period of time following surgery. Once animals have fully recovered from the surgery then tend to have minimal discomfort and can lead long lives on these studies. All other procedures used in this project are classified as having mild and transient adverse effects (e.g. from blood sampling).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of cattle undergoing this surgery will experience moderate pain in the immediate post-operative period, but this is transient and resolves over a few days typically. Animals are permitted at least 6 weeks to fully recover to ensure there is no pain or discomfort during their use for subsequent nutritional studies.

All other procedures in cattle are a mild severity for a transient period during sampling.

What will happen to animals at the end of this project?

- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of live animals is necessary as it is not possible to model in laboratory conditions the complex nature of rumen function, rumen contractions, feed interactions, gut microbes and effects of the production cycle, such as pregnancy or lactation.

Which non-animal alternatives did you consider for use in this project?

There are systems and equipment available in the laboratory that can simulate the rumen of cattle by investigating the rate and extent of how feeds are digested through measuring how much fermentation is going on, which is the process by which beneficial rumen microbes degrade fibre.

For the within animal inter-batch testing of rumen vitamin and mineral boluses (devices that reside in the rumen and slowly release vitamins and minerals) we aim to develop a parallel programme of work to develop a novel laboratory process that can mimic, to an extent, digestion in the gut of cattle, such that ultimately animal testing may not be required in the future.

Why were they not suitable?

While the laboratory systems can give some insights into feed digestibility by measure fermentation as a proxy measure, it does not adequately model the complexity of rumen function, and cannot simulate rumination (chewing the cud) or the complexities of the microbial community in the rumen compared to the live animal.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated based on over 30 years of experience conducting these studies, and by the number of studies planned over the lifetime of this project. It also includes the animals to be transferred from the previous PPL. Experiments will be designed taking into account biological

variation of parameters to be tested, in order to use the minimum number of animals required to establish statistically significant outcomes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of surgically-modified cattle for these studies vastly reduces the numbers of animals required for these studies as a result of them being able to be reused, including through utilising experimental designs such as cross-over studies. If we were to use 'normal' cattle then there would be a marked increase (in to the hundreds) in the numbers required to fulfil the work on this project. Their use is well validated in the literature. In addition, the continued use of surgically-modified animals for another protocol on rumen function studies in this project also minimises the overall number of animals required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where appropriate these studies we will utilise pilot studies to initially 'screen' diets or supplements that are to be taken forward to a full experiment. To a large extent pilot/screening studies will be completed in the laboratory using the simulated gut equipment to investigate digestion. This will allow us to screen a large number of feedstuffs (including those developed using novel processing techniques) and/or dietary supplements (e.g. probiotics) to see initially how they affect digestion. Only those feedstuffs or supplements that appear to significantly affect digestion parameters in the laboratory will be selected for further study in the animals. Together, these measures will optimise and minimise the number of animals utilised in this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project we will surgically prepare cattle to have a rumen fistula. The rumen is the largest part of the digestive system in cattle (functionally similar to the human colon) and it is where fibrous foods are degraded by a complex microbial community living in the rumen. The creation of a rumen fistula is very similar to the creation of a stoma in human patients who require it due to various diseases, such as bowel cancer or Crohn's disease. Cattle who get this surgery cope very well and this type of surgical modification has been used extensively since the 1950s, hence we are very well aware of how cattle live with this modification. It does not require a general anaesthetic and following initial periods of recovery with painkillers, these cattle can go on to live a very long life with this fistula without the need for painkillers, and in most cases these cattle are able to live much longer lives in relative luxury in comparison to commercial cattle. In order to minimise any harms in the medium to longer term, the

cattle undergo a strict regime of health monitoring and maintenance/cleaning of the opening to the gut. For example, in addition to daily health care assessment, once cattle are fully recovered from their surgery we physically monitor their fistula site regularly (at least weekly) for signs of irritation or ulceration. In addition, the cannula we use to maintain the access point to the gut is replaced at least annually, or as soon as needs be if upon inspection the material becomes brittle. We use an objective scoring system to ensure the overall animal's health status is maintained, and their fistula site is healthy.

From a scientific standpoint this model is entirely appropriate as it allows the frequent access required to the rumen to complete the objectives of individual experiments, such as inserting small porous bags containing test feed or supplement materials or instrumentation (data-transmitting) boluses. It is not possible to use normal animals and pass feed materials via stomach tube for these types of study, as we need to recover these feed materials at time points over the course of the study, and instrumentation boluses at the end of a study, and this would not be possible by stomach tube. If we used normal animals without a fistula we would have to use vastly greater numbers and slaughter them at the time points throughout different studies.

Why can’t you use animals that are less sentient?

These studies are aimed at examining gut function and microbiome parameters in adult dairy cattle, therefore we are required to use adult animals in these studies. There are no less sentient ruminant species, hence why adult cattle are required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal suffering will be minimised by using experienced licensees for all procedures. In addition, feed products, supplements or boluses are produced under strict regulatory frameworks and are not anticipated to have any adverse effects as most are already available on the open market. Animals are managed by trained personnel to ensure they are managed and trained/habituated to the sampling procedure process. For rumen fistulation surgery we have well developed protocols in place for the procedure itself, plus the post-surgical monitoring of the animal and fistulation site. This includes pain management during the procedure and post-procedure. We also have protocols for continued monitoring and scoring (lesions) of the fistula site, with inspections formally undertaken weekly and monthly. Following recovery from surgery, the cannula, which is the covering that sits within the site of the fistula to keep it clean and to ensure oxygen does not get into the rumen, is changed at least annually, or beforehand if the material becomes brittle.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For the studies included in this project we will follow published best practice as laid out in PREPARE (published by Norecopa, a Norwegian platform for the advancement of the 3Rs) and ARRIVE (published by the UK's NC3Rs) guidelines. When conducting scientific studies within this project we

will utilise and be conscious of the principles laid out in the PREPARE guidelines, to ensure that the experiment is designed and conducted in a manner that is scientifically valid and reproducible. The ARRIVE guidelines are a complementary set of guidelines to PREPARE that will be used to inform us of best practice in the preparation of reporting the outcomes of this project for dissemination/publication to scientific or other groups (e.g. farming community groups).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a member of AWERB, and routinely attend events/meetings organised by the establishment specifically focused on the 3Rs. This culminates in an annual group meeting of staff involved in ASPA activities where we review the year's activity and discuss examples of best practice in relation to the 3Rs. Furthermore, I collaborate with colleagues nationally and internationally who also have fistulated animals and we share resources and protocols (including health monitoring protocols) as necessary.

Home Office

NON-TECHNICAL SUMMARY

86. Implications of therapeutic inhibition of the complement system on infectious and noninfectious inflammatory diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Complement System, Kidney injury, Bacterial infection, Fungal infection, Immunotherapy

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

This project aims to validate the utility and efficacy of a novel therapeutic technology to reduce kidney injury in some diseases. We will also look for possible side effects that may result from using this technology like an increase in the risk of infection with microbial pathogens and how to reduce this risk.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

The complement system (a group of circulating proteins in the blood) is an important component of the immune system that participates in recognition and killing of invading microbial organisms. Activation of the complement system also triggers the inflammatory response. Uncontrolled activation can cause tissue injury and the development of some inflammatory diseases. Development of inhibitors that block the complement system in the blood will open a new avenue for novel approaches and strategies for the treatment of inflammatory disorders. Unfortunately, the use of complement inhibitors may increase the risk of microbial infection in patients and hence it is important to address the fundamental interactions between the host immune system and different pathogens during the course of active infection. Understanding the underlying mechanisms and pathways involved in the immune defence will also help to develop novel approaches for the treatment of bacterial and fungal infections.

What outputs do you think you will see at the end of this project?

Our research in the next five years will provide novel findings that will help to identify novel therapeutic approaches that will help to alleviate complement-mediated tissue injury especially in case of haemolytic uremic syndrome (HUS) and lupus nephritis. In addition, our results will provide a better understanding of how the immune system behaves towards invading pathogens especially in case of complement deficiency. This will help to develop new strategies for the treatment of bacterial and fungal infection. We always publish our new findings in high impact factor scientific journals to disseminate it to the scientific community. Unsuccessful approaches will also be highlighted in our publications and discussed with our collaborators.

Who or what will benefit from these outputs, and how?

In the short term the outputs will be communicated to academics working in the field of immunology, where we will assess both the benefits and the harmful effects results from complement activation and address the delicate balance between complement activation and down-regulation in health and disease.
In the long term we will introduce a new and well-defined study in the field of complement immunology during infection that will help to better understand how the immune system fights microbes, and how to avoid the harmful effects resulting from uncontrolled activation of the immune system. This work might also introduce new therapeutic approaches that will help to reduce kidney injury in lupus nephritis and HUS and improve the outcome in these patients.

How will you look to maximise the outputs of this work?

Our group has a close collaboration with experienced Senior Scientists in our field, who have established track records in mouse models of experimentally induced infectious disease, stretching over several decades whom I meet on a regular basis to discuss results and future experiments. A complete survey on the published data has already been done and we know exactly what is published in our area of study. We will use the most refined and the most reliable models for our infection studies as well as for HUS and lupus nephritis models. We always publish our new findings in high impact factor scientific journals to introduce it to the scientific community. Unsuccessful approaches will also be discussed with our collaborators and will be mentioned in our publications. Sharing of animal tissue from our well-designed experiment with our collaborators will help to maximise the benefits.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use adult wild type and adult complement deficient mice that lack one or more of the essential components of the immune system. Using these mice will give a clear overview of how the absence of these immune components will affect the infectivity and pathogenicity of different pathogens included in this project. We will also use adult MRL-lpr/lpr (Lupus) mouse, a strain that is known to spontaneously develop lupus nephritis and kidney injury after 14 weeks of birth. This model will help us to validate how inhibition of the complement system will improve kidney function in such mouse model.
We will use adult mice in our models of diseases because the immune response at that stage captures the essential traits of many bacterial infections and tissue injury in humans.
Typically, what will be done to an animal used in your project?

In our mouse models of microbial infections:

- Mice will be infected with bacteria or fungi via intranasal or oral administration as well as by injection.
- Mice will be observed for disease progression.
- Immunomodulatory and/or complement inhibitors therapeutics could be injected at any time either before or after the infection.

- Blood samples will be taken at different time points post-infection to assess the bacterial load in blood to avoid any complications that may increase the severity of disease progression beyond the expected severity limit.

- Our experience shows that the infection study in protocol 1 will last for 3 weeks while other infection models in protocol 2 will last for 7 to 14 days.

In case of lupus nephritis model:

- Mice at the age of 14 weeks will start to develop signs and symptoms of renal injury.
  At that age we will treat mice with immunomodulatory and/or complement therapeutics that will reduce
- complement-mediated kidney injury.

- In some experiments, mice will be treated with complement inhibitors therapeutics/immunomodulatory compounds at earlier ages (10 -12 weeks).

- This study will continue for 8 to 10 weeks

All animal experiments will be randomised and people who are assessing the animal will not be aware of whether they are assessing control or treated mice.

What are the expected impacts and/or adverse effects for the animals during your project?

In mouse models of infection, mice will show signs and symptoms of moderate severity limit including reduction in their activity within the cage and decrease in body weight. Animals will be closely observed as frequently as necessary and at least every 6 hours to ensure that these symptoms would not last for more than 12 hours. If these signs persist for over 12 hours or if an animal begins to deteriorate at any time, it will be immediately killed.
Lupus nephritis is inflammation of the kidney due to an auto-immune disease known as systemic lupus erythematous. With lupus, the body's immune system targets its own body tissues including kidney causing kidney inflammation and kidney injury. In a mouse model of lupus nephritis, mice will start to show some complications depending on the stage of the disease progression and the age of the mouse. From 14-16 weeks old, mice will show symptoms of mild disease severity such as a decrease in body weight (5-10%) and a slight increase in some biological markers that reflect how kidneys are functioning such as blood urea nitrogen (BUN) and creatinine levels in the blood. Older mice will show a moderate decrease in body weight (10-15%) and significantly elevated levels of BUN and creatinine levels.
Becuase the strain of mice that we will use in this protocol spontaneously develop auto-immune disorders, mice will also show some other side effects such as enlarged lymph nodes and skin lesions that will be considered during the course of our experiment.
Animals will be humanely killed by once they reach predetermined end-point for this protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

1. In protocols 1 we will use 500 adult mice at moderate severity limit
2. In protocols 2 we will use 1000 adult mice at moderate severity limit
3. In protocols 3 we will use 500 adult mice at moderate severity limit
4. In protocol 4 we are expecting mild severity limit (All animal).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will study how the immune response mediates tissue injury in some auto-immune diseases such as Haemolytic Uremic Syndrome (HUS) and lupus nephritis. In addition, we need to study the complex interaction between the innate immune response and different pathogens. These processes involve a complex interaction between immune cells, plasma proteins, the blood vessel walls (vascular endothelium) and organ-specific cells that cannot be modelled using ex vivo (using animal tissues in cell culture) or in vitro (in test tubes rather than in animals) systems.

Which non-animal alternatives did you consider for use in this project?

Prior to animal experimentation extensive in vitro studies using different techniques to assess the ability of different proteins from the immune system to bind bacteria such as (ELISA and FACS analysis techniques). Opsonophagocytosis assays (engulfment of bacteria by white blood cells isolated from human blood) will be performed to identify which strains/serotypes of the pathogen will stimulate the targeted pathway of the complement system. Assessment of the functional activities of the complement inhibitors will be completed first in-vitro using ELISA and FACS analysis to evaluate the specificity and efficacy of these complement inhibitors. We considered the possibility of limiting the infection experiments to ex-vivo studies using blood from human volunteers as a source of complement and cells. Ex-vivo studies do not reproduce the course of the infection in multi-organ model (i.e. in animals)

Why were they not suitable?

It is necessary to study microbial interaction with the immune system in a whole mammalian organism to appreciate the impact of medical treatments on:

a) The spread of the bacteria between different organs in the body

b) Tissue pathology in various organs

c) The effects of the progressive escalation of immune responses

In addition, we need to assess the degree of kidney injury as a result of uncontrolled complement activation in some autoimmune disorders such as lupus nephritis and HUS. This study requires the tissue to be exposed to different complement components and recognition molecules for a prolonged period of time to achieve tissue injury and there is no available ex-vivo model for such complications.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our long-term experience in animal work, using good experimental design helped us to give the estimated numbers of animals that we will need to use in each experiment. We also consulted with experienced scientists in our field and within our group. In addition, we consulted a departmental statistician who gave us advice and help whenever needed. Our previously similar animal models published in high impact factor scientific journals were also a useful guide to estimate the number of animals that will be used in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Whenever possible we perform preliminary studies using smaller numbers of animals. We also try to adjust our work to use only one control group that can be used for different experiments. We use the smallest possible experimental number of animals for each experiment being very careful that this does not affect the accuracy of the results. To calculate the smallest number of animals that we can use, calculations based on advanced statistics and mathematics in addition to other published results were taken into considerations. Online tools such as experimental design assistant (EDA) from NC3Rs website were used to perform sample size calculations. To increase the quality, reproducibility and translatability of our animal studies we will follow PREPARE guidelines (Adrian et al., 2018). Animal tissues from different experiments will be kept frozen and/or embedded in paraffin blocks that can be used later if more tissue analysis is required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We always run pilot experiments using a small number of animals to assess the feasibility of the study.
In some experiments we will use bacterial toxins instead of using the bacteria. This will help to minimise the side effects where mice will recieve only the calculated dose of the bacterial toxins that show the symptoms and the signs of disease without exposing animals to the bacteria. We will run pilot experiments to test the potency of the bacterial toxins and so large stock of bacterial toxins will be purchased to avoid repeating this step every time we buy a new batch.
We would not start any animal work in large groups until we have preliminary positive and encouraging data.
Tissues from pilot experiments and major experiments will be kept frozen or fixed in paraffin blocks for future use. For genetically modified mice, we will follow a breeding protocol that gives us only our gene-targeted mice by breeding deficient mice whenever possible to avoid the production of unnecessary mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs

(harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All animal models in this study are designed to cause less pain, stress and suffering. All the necessary procedures will be taken to achieve high levels of welfare to the animal starting from good husbandry and animal care before starting the experimental procedures. We will use the most refined mouse model of infection for each pathogen. During the experimental procedures in the infection study (Protocols 1 and 2) all requirements will be taken to cause less stress and minimal harm to the animal. e.g. In case of i.n (intra-nasal) infection we will use light anaesthesia to reduce animal stress and maximise the volume being delivered. We will use small gauge and fine needles to minimise trauma in the case of intra-venous and intra-peritoneal drug administration. Mice will be monitored for any unexpected signs and symptoms of disease progression to avoid exceeding the allowed severity limit. Mice will be euthanised at early end points to avoid exceeding the allowed severity limit (moderate).
In the lupus nephritis (kidney injury) model (Protocol 3), we will use a specific strain of mice that spontaneously develop kidney disorders and validate our complement inhibitor therapeutics to prevent the onset of disease progression. Lupus prone mice will survive normally without any complications until they reach the age of 14 weeks when they start to develop signs and symptoms of lupus nephritis and kidney injury. These symptoms include; elevated levels of creatinine and blood urea nitrogen, increased albumin and protein levels in urine. We will not inject any compounds that could accelerate kidney injury but ameliorate or prevent inflammation and tissue injury. We will use therapeutic compounds that are expected to minimise the kidney injury and improve the renal function.

Why can’t you use animals that are less sentient?

We need to study the immune response towards bacterial infection and how the immune response might cause tissue injury as a result of uncontrolled activation of the complement system. This will require animals to be exposed to the insults for a relatively long time (days or weeks) and this cannot be done in anaesthetised mice. In addition, using immature life stage of animals is not a good choice to study the immune response, especially since immature developmental stages of animals are likely to have an immature immune system and therefore will provide results that cannot be extrapolated to reflect the responses expected in mature animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Mice will be closely monitored for any sign of disease progression. Mash (soaked mouse pellets which are easier to access and eat) will be used during our studies if needed to minimise weight loss. Any pain or stress will be diagnosed as early as possible and animals will be culled by humane methods (schedule 1 methods) if necessary. A proper environment including shelter and a comfortable resting area will be provided to the animals. All clinical signs and manifestations will be scored in scoring sheets. These scoring sheets will be kept and discussed after each experiment to refine our procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our group has an excellent reputation in the field of complement immunology and we keep ourselves updated with all new and novel experimental designs and models in our field. This includes non-animal models. All newly published data in our field are discussed internally within our group to enrich our knowledge and that could help to find novel experimental designs or other non-animal models that could help in our study. In addition, all our experiments will be conducted in a way that allows us to publish our results according to the ARRIVE guidelines. we will follow all guidelines provided by LASA,
PREPARE and NC3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By following the updates on NC3Rs and NORECOPA (websites as well as additional guidance literature from Laboratory Animal Science Association (LASA). Related events such as conference and symposium will be attended.

Home Office

NON-TECHNICAL SUMMARY

87. Improved targeting of cancer for imaging and therapy

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Cancer, Imaging, Therapy, Theranostics

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to develop approximately 4 novel imaging agents, 1-2 drugs for cancer therapy and 2-3 theranostic agents.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The proposed research will accelerate the development and clinical translation of new imaging agents and cancer therapies. The research will:

i. Enhance the understanding of cancer biology in living subjects.

ii. Develop new imaging agents for cancer.

iii. Develop new methods to indicate very early on whether patients are not responding to treatment, avoiding unnecessary toxic side effects for patients, saving time and treatment-associated costs, and providing an opportunity for patients to be switched to other drugs.

iv. Develop new targeted therapies that exploit tumour biology, including 'imaging-directed targetedagents' for selective killing of cancer cells or reversing of drug resistance with minimal toxicity.

Our research group is multidisciplinary and includes a clinical team of medical doctors that are able to translate compounds that are successfully developed preclinically into the clinical setting by performing clinical trials in humans. Thus, there is potential for direct impact to cancer patients.

What outputs do you think you will see at the end of this project?

The main outputs of this project are:
- Development of new imaging agents (~3 compounds in 5 years) - i.e., contrast agents that accumulate specifically in the tumour providing better imaging contrast - that are successful enough to progress for use in humans.

- Development of new therapeutic agents (~1-2 compounds in 5 years) - i.e., compounds that can be used for treatment of tumours - that are successful enough to progress to clinical trials.

- Development of new theranostic agents (~2 compound in 5 years) - i.e., compounds that allow simultaneous diagnosis (imaging) and treatment (therapy) of tumours - that are successful enough to progress to clinical trials.

- Understanding the biology of cancer in living subjects;

- Publications to increase the existing knowledge about cancer.

Who or what will benefit from these outputs, and how?

The outputs of this project will primarily benefit cancer patients. We will develop imaging agents that allow earlier diagnosis and staging of cancer non-invasively, instead of being restricted to biopsy, an invasive procedure that is often not accurate at representing the whole tumour, and more difficult to use in the metastatic setting. Our imaging agents will also help predict which patients/tumours are likely to respond well to certain treatments. Furthermore, these agents can be used to evaluate the success of the treatment very early on, thus saving patients from the suffering caused by side effects of treatments and offering the possibility of switching to more beneficial treatments before the tumour becomes too aggressive. We will also develop cancer treatments that have maximal anti-tumour activity while minimising side effects to the rest of the body, and that prevent or reverse resistance to drugs. Lastly, we will develop theranostic agents - i.e. compounds that act as both imaging and therapy agents - which will allow treatment and its monitoring simultaneously, contributing to the likelihood of treatment success.

How will you look to maximise the outputs of this work?

We will aim to maximise the outputs of this project by seeking collaborations with appropriate expertise whenever suitable; by bringing the whole group (and possible collaborations) together to think about experimental designs or troubleshooting possible arising issues; by sharing the knowledge with the community and by publishing all results, whether positive or negative.

Species and numbers of animals expected to be used

- Mice: 7400
- Rats: 590

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our aims are to develop new imaging agents, new targeted drugs and new theranostics (where imaging and therapy are combined in the same molecule) for personalising cancer care. The need for this is that 1 in 2 people will be affected by the disease in their lifetime making efforts to develop these diagnostics and therapeutics important; particularly because current drugs are ineffective in most cancers. A significant part of our work will be done using isolated cancer cells grown in the laboratory in cell culture dishes, as well as computer-based approaches. These initial experiments will ascertain relevance of the processes being studied, and permit optimisation.
Ultimately, however, animals have to be used to determine whether in the whole organism, the specific biological target is being modulated, and if the sensitivity and specificity or contrast are achieved over healthy organs. Our approach is staged: starting from animal models that are easy to monitor visually to more complex models for which we will add imaging to clinical signs for monitoring. Mice and rats will be used in the studies because they are the simpler animal for which suitable models of cancer are available. Adult mice – usually 6-12 weeks - will be used. This is because mature rodents have more stable physiological state (respiratory/pulse rate, rectal temperature, weight) and are more tolerant to infection. In some cases, will use immune-deficient animals for tumour induction as this will give us the opportunity to study the biology of human tumours without

rejection; the studies will be done in a manner to avoid infection.
Most animals will undergo procedures involving mild discomfort like a pin-prick and non-invasive imaging. Animals will be anaesthetised for the imaging procedure. Animals may receive therapeutics, undergo surgery or develop tumours, procedures that could potentially cause moderate discomfort. Where appropriate, animals will be given analgesia/anaesthesia to avoid pain. Animals will be monitored closely including use of image-guided monitoring of tumour size. Serial sampling by imaging is both better science and reduces animal use; it also provide earlier disease detection than clinical signs, thus less severe. Animals will be housed with appropriate bedding, nestling material and with cage toys for a stimulating cage environment. We will monitor animals in accordance with National Cancer Research Institute (NCRI) guidelines for the welfare of animals in experimental neoplasia, as well as UK Laboratory Animal Science Association good practice guidelines (LASA guidance). At the end of the study, animals will be humanely killed or euthanised. In summary, we aim to develop future imaging diagnostics and novel therapeutics that will benefit science, animals and people, without compromising animal welfare. We consider the overall severity as moderate.

Typically, what will be done to an animal used in your project?

Typically, an animal used in our project will be given a tumour though injection of cancer cells under the skin, although in some occasions we may inject them in the organ where the tumour normally grows (i.e., a mammary tumour will be injected in the mammary fat pad of an animal). The animal and its tumour will be monitored until the tumour is big enough to undergo experimental evaluation - this usually happens 3-4 weeks after injection of cancer cells. Experimental evaluation involves giving the animal a new compound that has been developed in our lab, which may fall into three classes: therapeutic agents, i.e., compounds with anti-tumour activity for cancer therapy, imaging agents, i.e., contrast agents that allow visualisation of the tumour through imaging, or theranostic agents, i.e., compounds that allow diagnosis and therapy of cancer simultaneously. For example, for evaluation of an imaging agent, the animal will be anaesthetised, have the contrast agent injected in its tail and put inside a temperature-controlled imaging scanner for 1 hour. Once the scan is finished, the animals will be humanely killed while still under anaethesia so that the tumour tissues can be collected to validate the experiment and confirm the accumulation of the compound tested.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the animals used in our project will be implanted with tumours under the skin which won't cause significant discomfort because the tumours will be of relatively small size. However, in some cases, where the tumours are grown in their organ of origin - say, a prostate cancer is grown in the prostate - the animals may experience adverse effects associated with tumour growth. These are vary depending on the tumour type, (for example, prostate cancer may lead to changes in urinary flow, whereas brain cancer may affect the animal's behaviour) and, depending on the level of pain and distress that causes to the animal, we may either treat these symptoms or kill the animal to prevent further suffering. Furthermore, while we aim to design safe compounds, they may, sometimes, lead to side effects such as loss of appetite or alterations in behaviour. Once again, these symptoms may be treated or the animal may be killed, depending on the extent of the symptoms. Clear limits have been outlined in this project licence that will guide the decision to either treat or humanely kill an animal.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In this project, 50% of mice are likely to experience moderate levels of severity, and 50% are likely to experience mild levels of severity. For rats 36% are likely to experience moderate levels of severity and 64% are likely to experience mild levels of severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We develop compounds that can be used for cancer therapy, cancer diagnosis, or both simultaneously.
It is essential to prove that these compounds are both safe and effective before we test them in humans, and only living beings can reproduce the complexity of human biology. In this project, we propose the use of rodents since they are a low order animal species with a significant resemblance to our biology.

Which non-animal alternatives did you consider for use in this project?

We systematically start any experiment by non-animal alternatives such as computer modelling for predictions or lab culture of human tissues and cells that have been obtained from tumour samples extracted from patients.

Why were they not suitable?

These non-animal alternatives can only replicate a very small fraction of the complexity of tumours inserted in a living being. For example, a substance that is effective at killing tumour cells in petri dishes may cause organ failure when injected in a living being and is thus not suitable for therapy.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals based statistical consideration and on the previous outputs of this group in the past. This is a 5-year project in which we propose to develop around 5 compounds for cancer

diagnosis and therapy, but the success rate of new compounds is small and thus we will need to develop and test a great number of compounds in order to obtain 5 that are successful. Testing new compounds is a complex process and their success or failure may not be evident until significant research has been done; thus any one molecule, whether successful or not, may entail the use of a large number of animals.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are an imaging-based group which means we can acquire information through imaging rather than having to kill the animals every time we require it; this allows us to maximise the data generated by one animal, thus reducing the overall number of animals needed. Furthermore, we reduce animal use by reducing the number of controls needed and we do not use excess number of animals than required for relevant statistics.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Apart from the non-animal alternatives described, we will minimise the number of animals by having consistent experimental techniques thus reducing variability, by obtaining as much information as possible from one animal (for example, acquiring as many organ samples as possible at every cull).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice and rats are the most suitable models for this type of research because they share close resemblance to human biology and models of human cancer can be replicated in these animals. Mice will be used whenever possible, with rat models only used whenever unavoidable. In the majority of our work, we will use immune-deficient mice (mice that have been genetically engineered to have a weakened immune system) because they allow the growth of tumours without rejection, minimising the overall number of animals needed. Most tumours will be implanted subcutaneously (i.e. under the animal's skin) because these are valuable models of human cancer but cause little discomfort to the animal. More complex tumour models (such as tumours grown in their organ of origin or metastasis models) will be used only if the type of information needed cannot be obtained with subcutaneous models. We use imaging as a means to acquire data, which does not require the animal to be killed whenever information is required, thus reducing the number of animals needed. Furthermore, any procedures that cause moderate discomfort to the animal will be carried out under anaesthesia. Recovery from anesthesia will take place in a warm quiet environment.

Why can’t you use animals that are less sentient?

Less sentient animals are further apart from human biology. Furthermore, we consider that is ethically superior to use adult animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement measures carried out in this project will include: use of anaesthesia and pain-relief medication whenever possible as well as enrichment of the animal's environment. We will frequently monitor animals, especially during treatment, and will increase monitoring if any adverse effect manifests; depending on the severity of harm, the animal will be treated or culled. Tumour monitoring will also be performed through imaging techniques. Extensive characterisation of any substance prior to injection in animals and having clear limits on animal injections will minimise the likelihood of adverse effects and suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NCRI guidelines for the welfare and use of animals in cancer research, as well as LASA, PREPARE and ARRIVE guidelines together with body condition scoring guidelines as detailed in the protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Frequent meetings are held at our institution on the advances in the 3Rs and their implementation. All staff working under this licence will attend these meetings and frequent advice regarding the well-being of animals will be sought from the vets and animal care staff.
We will follow external sources including National Centre for Replacement Refinement and Reduction of Animals in Research resources (website https://www.nc3rs.org.uk/) and NCRI guidelines.

NON-TECHNICAL SUMMARY

88. Improving gene expression from viral vectors for gene therapy applications

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The overall aim of all work to be performed under this project is to develop improved gene therapies. In doing so we will develop, screen and evaluate novel tissue-specific and regulatable systems for testing in small rodent models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We plan to use new tools in animal models, mostly mice, as a means to demonstrate improved preclinical efficacy of gene therapy expression systems. These tools will be administered to wild type rodents to establish the bio-distribution and efficacy of gene expression. The project will further initiate a systematic pathway towards translation of the vectors tested in this project into clinic, whereby expression cassettes tested and validated here will be integrated into clinical programs ongoing at parental company. Our newly synthesized genetic tools are specifically designed to tackle particular diseases by targeting gene expression to those organs or tissues most affected in the disease. This will result in improvement/ enhancement of current available therapies, and the development of new treatments. As we are addressing many inherited/acquired diseases, where no treatment is currently available, our approach is of crucial importance to the field of gene therapy, enabling effective targeting of the diseased organ (or organs) and contributing potentially curative therapies to a wide variety of central nervous system, neuromuscular, cardiovascular, haematopoietic and metabolic genetic disorders.

What outputs do you think you will see at the end of this project?

The benefits will include:
Creation of novel tissue-specific or regulatable systems to control gene expression especially tailored for inherited/ acquired diseases. This is will greatly help with combating of many human difficult incurable diseases by creating safer and efficient therapies
Information from first round screening in small rodents to further improve on the development of gene expression systems that are translatable to the clinic.
Optimised gene expression systems to develop new clinical candidate gene therapy drugs targeting many neurological, neuromuscular, cardiovascular, metabolic, and haematopoietic disease that will be used to support new IND applications and go into patients
Development of new intellectual property and the dissemination of knowledge by means of publication and presentation in scientific conferences.

Who or what will benefit from these outputs, and how?

Our parent company is well positioned to exploit the results of these initial pre-clinical research studies. It is well-funded and has developed substantial resources in translational research, regulatory affairs and large-scale commercial manufacturing of viral vectors for gene therapy purposes. It has already produced vectors for a number of clinical trials, which have been managed both internally, or in collaboration with large biotech or pharma partners.

How will you look to maximise the outputs of this work?

We have a wide and excellent network of collaborators both in academic and industrial sectors and we are making a good use of this networking by sharing ideas, knowledge, and information. Our parent company has built numerous partnerships with other global pharmaceutical companies who will be interested in employing our technology in their clinical programmes to benefit patients eventually. The expected output of this project will be of crucial importance for the successful development of novel gene therapies targeting many incurable inherited/ acquired diseases.

Species and numbers of animals expected to be used

- Mice: 3500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will focus on the use of mice. As all mammals have almost the same regulation processes of gene expression, mice represent the most suitable animals to assess gene expression. They represent the lowest sentient mammalian species. Hence, we have chosen them because they have long been used to produce the well-characterised preclinical screening models of many diseases.

Typically, what will be done to an animal used in your project?

Animals will be used in this project for screening and validation of our novel gene expression systems, which are designed to especially target diseased organs of interest. We are not planning to use any severe surgical procedures, or invasive protocols. Instead we will be administering our tools via common and minimally invasive routes like IV, IM, IP and SC following local guidelines and then to be followed by non-invasive monitoring. Our focus will be on using adult mice at about 6-8 weeks for short term durations. At the end of each experiment, the mice will be sacrificed humanely by schedule-1 procedure or by perfusion under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

We are not expecting our administered reagents to cause any severe harmful effects on animals like weight loss, tumours, or abnormal behaviour. Perhaps animals will suffer from transient stress or mild pain after injections. We are expecting these effects to disappear very quickly and settle within hours without any need for intervention. However, effective pain relief and anaesthetics will be used carefully when there will be any need. Any animal will be immediately killed if it shows signs of suffering that is greater than minor and transient or in any way compromises normal behaviour, under guidance of the NVS. We will be looking for any general debilitation and persistent signs of distress or pain include reduced mobility, hunched posture, piloerection, rough ungroomed coat. If signs continue for 24 hours, we will seek NVS advice as to whether end point has been reached or whether symptomatic treatment can be carried out. If animals do not respond to treatment or show further deterioration, they will be killed by a schedule 1 procedure or by cardiac perfusion under terminal anaesthesia.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

No animals are expected to exceed mild discomfort.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this project is to screen and pre-clinically validate our novel gene expression systems, with the ultimate goal to apply our systems in gene therapy. To serve this purpose, we need to study gene expression that is controlled by our tools in mammalian systems, and very often, in different organs, tissues, and cell types simultaneously. As all mammals have almost the same regulation processes of gene expression, mice represent the most suitable animals to assess activity and functionality. We are not aware of any alternative method that allows evaluation of such responses other than using animals.
In this context, the FRAME website (www.frame¬uk.demon.co.uk) and NC3Rs website (www.nc3rs.org.uk) that lists alternatives to animal research have been examined without success. Furthermore, *In vitro* and *in silico* techniques are also not sufficiently advanced (and are not likely to be so for some considerable time) that they can model the integrated actions of the nervous system, for example. For these reason, *in vitro* studies using immortalised cells are of limited use and i*n vivo* models are the only way to fully evaluate the effects that a novel therapeutic agent will have. Importantly, the main purpose of this project is to conduct preclinical evaluation of novel therapies in relevant rodent models of disease. As part of this process towards clinical translation, medical regulatory bodies require *in vivo* studies in a relevant mammalian model as part of the traditional approval path to the clinical. However, wherever possible we always attempt to use *in vitro* models in this process to minimise any *in vivo* testing. An example of this is that, where possible, we test all therapeutic agents routinely and thoroughly on cell lines first in order to validate their quality, purity, efficiency, and lack of cytotoxicity before any further steps into *in vivo* models. These *in vitro* studies will be done before any *in vivo* studies. We continue to keep abreast of the latest developments and potential application of new technologies as potential replacements to certain aspects of *in vivo* work.
Therefore, we need to use animals in our studies because many systematic questions of gene regulation require better understanding that are not possible or feasible at present alternatively. We have always considered the use of animals ethically, but as we are not aware of an alternative way to evaluate gene expression *in vitro* that would enable this proposed study to be carried out successfully and in a practical manner, we believe their use to be justified in this instance .

Which non-animal alternatives did you consider for use in this project?

In silico computer modelling.
In vitro Cell line cultures.
*In vitr*o Organoid systems.

Why were they not suitable?

The diseases we aim to study are multisystem diseases, which cannot be modelled in vitro, neither in single cell cultures nor in mixed culture or organoid systems. Available non-animal based alternatives are of limited use and they cannot be fully representative of human disease models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used will be chosen based on prior experience in experiments of this kind and with an aim to reducing this number but retaining effective statistical power in all cases. When performing mouse work, we calculate the minimum number of mice required to be sure that we will get an answer. We will also seek to reduce the number of animals studied by careful experimental design, the adoption of sensitive outcome measures with small variation and the study of only the most relevant time points. For all the experiments proposed we will use a group size which is the smallest compatible with achieving statistically meaningful and robust results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We widely employ *in silico* designs and analysis in all our projects by using algorithmic, computer modelling and simulation. All our expression systems are initially tested, validated, and selected *in silico* efficiently before moving to apply them in our *in vitro* assessment ,where relevant, and eventually in *in vivo* studies. Likewise, we will also use bioluminescence-based biosensors to detect protein expression in live animals, rather than sacrificing groups of animals at repeated time points or, for example, performing repeated blood collections.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will make a good use of small-scale studies using minimum numbers of animals to get preliminary data before scaling up to bigger studies. Moreover, we will also endeavour to control experimental variables by making experimental material more homogeneous to reduce variability in the response. To achieve that we use viral material that has been subjected to rigorous QC and QA (these capabilities are located on-site), observe participant animals under similar biological/environmental conditions, employ standardised measurement methods, use calibrated equipment, perform all end-point analyses at the same time point where possible and blinding experiments to observers and testers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The principles of refinement will be adhered to throughout experiments. Effective pain relief and anaesthetics will be used rigorously. Also, we will be widely utilising biosensors which is a non-invasive approach for animal whole body *in vivo* imaging, providing a good refinement practice. Animals will only be used in our experiments if

they are in excellent health. Animals will be housed communally in IVC and in many cases in enriched environments to maximise social / welfare / rehabilitation considerations.

Why can't you use animals that are less sentient?

In vitro cell culture studies will be conducted, where possible, before animal experiments to select effective tools for gene manipulation. This reduces the numbers of animals required. We require a mammalian model as the studies need to correlate to the human organs' physiology and immune system, and mice represent the lowest sentient mammalian species. Furthermore, mice are the lowest species commonly used in experiments of this kind over the last 50 years meaning a great deal is known about their anatomy, neurophysiology, genetics and behaviour.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Generally, we will adopt good planning and scientific methodology throughout to avoid unnecessary suffering for animals by implementing:

1) Careful assessment of the initial and continued experimental design.

2) Expanding our background knowledge for relevant research, procedures, and findings.

3) Staged and gradual approach through small size studies.

4) Teamwork and resources, skills, staff performance the availability of suitable equipment and facilities.

5) Mice are monitored, by both staff and by our own team members. All our procedures will be done early in the day so that the animals have time to recover and have them under observations. Where possible, we will avoid conducting procedures on the last day of week.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines at National Center for the Replacement Refining & Reduction of Animal Research (NC3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

During the project we will continually review relevant published literature, comparing our objectives with those previously undertaken by others, and assess whether the results and conclusions of newly published studies have any impact on our experimental design. Importantly we will keep abreast of publications released by the National Centre for the Replacement Refining & Reduction of Animal Research (NC3Rs) for updates, guidelines and regulations.

NON-TECHNICAL SUMMARY

89. In vivo studies of ADP-ribosylation signalling

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, embryo, aged
Zebra fish	embryo, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to gain a deeper understanding of the biological processes regulated by the modification ADP-ribosylation. ADP-ribosylation is a kind of chemical signal found in biology, responsible for various cellular processes - most of which are still largely unknown. We plan to do this by analysing novel GAA (genetically altered animals) (mice and zebra fish).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Ultimately there are numerous **fundamental gaps** in our knowledge with regards to the normal biological role of ADP-ribosylation. Whilst we make advances other areas of ADP-ribosylation still almost nothing is known about the impact in a living being. ADP-ribosylation is a wide-reaching process with potentially significant impacts on behaviour/brain disorders, metabolism/diabetes/obesity and cancer/ageing which we will investigate here.

What outputs do you think you will see at the end of this project?

Major outputs:

1) Novel GAA (genetically altered animals) models (zebra fish and mice) to study ADP-ribosylation in a normal biological context.

2) Investigation of clinically relevant outcomes from such GAAs including novel aspects of ADPribosylation in neurobiology, metabolism and cancer.

3) Validation of treatment strategy for cancer

4) High-quality high impact publications.

5) Outreach to general public.

Who or what will benefit from these outputs, and how?

Research community (many fields but particularly the ADP-ribosylation field where such *in living being* knowledge is fundamentally missing) will benefit from the availability of novel GAA models and the new data generated by them. Both immediately as proof of concept – i.e. if they can target a protein for inhibition because the KO (knock out - deletion of gene in a living being) is survivable – and over time as further insights may inform their own research directions. Other researchers may start their own line of investigation with our GAA models as we would freely distribute them as requested.

Long term, the **general population** and **health care providers** will benefit from novel insights into three major areas of human disease;

Neurobiology – 10 million people are living with a neurological condition in the UK (globally the WHO puts this number in the billions). There are over 600 types of neurological conditions including stroke, migraines, autism, Parkinson's, Alzheimer's, dementia, motor neurone disease which has a significant cost to the NHS; £3.3 billion was spent in 2012-13 on neurological services. In addition, the burden of living with a neurological condition for sufferers and their carers is huge (14% of social care budget). Defects in ADP-ribosylation pathways have been directly linked to several neurodegenerative disorders as well as autism.

Metabolism – There are 3.8 million people living with diabetes in the UK. The cost of treating diabetes and its complications to the NHS is estimated at £14 billion a year (2018 data – 10% of the budget). Further, the

prevalence of diabetes is estimated to rise, especially considering that over 60% of the adult population are overweight or obese (increases the risk of diabetes up to 13-fold). Diabetes is a chronic, lifelong condition in which a person cannot regulate their blood sugar level. ADP-ribosylation genes have been implicated in metabolism including mutant mice where the blood sugar level is altered. Additionally, some ADP-ribosylation genes are expressed in the mitochondria a major site of energy and metabolic functions in cells.
Cancer – There are about 0.4 million new cases of cancer a year and around 130,000 cancer related deaths. The annual NHS costs for cancer services is huge, £5 billion, but the cost to society as whole is greater still at £18.3 billion (2015 data, including loss of productivity etc.). Some ADP-ribosylation genes have already been successfully targeted as cancer treatment (for example the drug olaparib a PARP1 inhibitor is now used to treat breast and cervical cancers) however given the wide involvement of other ADP-ribosylation genes in a variety of human cancers it is likely targeting these other genes could also be a valid strategy.
Total persons directly affected by one of these major disease areas in the UK is **14.2 million** at a total cost to the NHS of **22.3 billion** annually. This does not include those people at risk of disease (for example the 62% of obese adults in the UK) whom might benefit from preventative measures. Thus long term the **drug discovery/pharmaceutical industry** could benefit as well since our research will unlock new functions of the ADP-ribosylation pathways, including ways in which the ADP-ribosylation pathways might be targetable for disease prevention and treatment.

How will you look to maximise the outputs of this work?

Availability of new GAA models to the rest of the research community (through distribution to international mouse consortiums) thus widening the impact and number of fields our GAA models can be utilised in.
We readily collaborate with many scientists who are experts in their own field thus increasing the fidelity and impact of our science and its reach across several fields.
Research will be published in scientific journals and presented at conferences locally and worldwide. We keep an up to date website and will engage locally with Ley public through out-reach programmes, and other avenues.

Species and numbers of animals expected to be used

- Mice: 26,500
- Zebra fish: 6,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice and zebra fish all life stages.
Mice and zebra fish are physiologically and metabolically and genetically very similar to humans and they have relatively short generation times (baby-to-baby length 10 weeks for mice and 3 months for zebra fish) making them an ideal model of choice for generating genetically altered mutants. We can use the new mutants to study novel aspects of ADP-ribosylation in biomedical research such as behaviour, metabolism and cancer development.

Typically, what will be done to an animal used in your project?

Typical procedures performed during this project

~85% Breeding and maintenance. The vast majority of animals on this project will only be used on breeding

and maintenance protocols. Animals (mice and zebra fish) whenever possible will live in social groups with cage/tank enrichment in state of the art facilities until being killed by an appropriate humane method. Most mice are unlikely to suffer any project harms, not even mildly (called subthreshold to indicate no adverse effects whatsoever). Most zebra fish will be mild as they will need fin clipping as a means to genotype them (determine if they are mutant or not). Fin clipping involves taking a small section of fin, which does not hinder the fish and is performed under anaesthetic.
~5% Ageing and harmful mutants. Other animals will be aged and monitored for the development of mild-moderate conditions due to the presence of harmful mutations, such as neurodegeneration, metabolic defect and cancer.
~5% Behavioural testing where mice are subject to mild tests of naturally, appetite (mild food restriction) or aversely (bright light, loud noises, withdrawal reflex) motivated behaviour. A battery of tests lasts about 7 weeks (one test per week) and animals are usually tested again in old age.

~1% Metabolic testing where mice may have mild food restriction, administration of non-toxic substance (by injection or gavage) and limited blood sampling (4 times in 2 hours). A series of tests may be conducted over 4 weeks and animals can be retested again in old age.
~1% DNA damage testing where mice receive toxic agents (either irradiation or injected drugs) at short time points (<72 h) (before clinical symptoms present, mild). Or mid-term (50 days) follow up to a non-lethal dose (mild to moderate).
~1% Xenografts where mice receive an injection in their flank of human cancer cells to allow a tumour to develop. Mice may also receive treatment (typically new therapeutic agents).
~1% Models of carcinogenesis where mice receive toxic agents (either irradiation or injected drugs) over a short period to initiate cancer development. Depending on the method some mice also receive pro-inflammatory agents.

What are the expected impacts and/or adverse effects for the animals during your project?

Harmful mutants - such as neurodegeneration, metabolic defect and cancer. It is likely animals with such conditions feel generally unwell and experience pain, they may also have abnormal behaviour, difficulty moving, lose or gain weight. Animals will be closely monitored for harmful effects so that they are humanely killed at onset of pathological symptoms.
Aging - age-related welfare concerns include skin, eye and dental problems as well as increased risk of tumours and organ failure. These are mostly mild but long term conditions. Mice which appear generally unwell and/or have detectable tumours will be humanely killed.
Behavioural - acute stress from removal from home-cage (social animal, misses cage-mates) plus stressful stimuli such as bright lights/loud noises. May induce mild transient anxiety in mice.
Food restriction - mice should get hungry but not starving (mild and transient), just sufficient to motivate behavioural tests or get baseline blood chemistry.
Toxic/inflammatory agents - loss of appetite, weight-loss, diarrhoea, anaemia, likely pain and generally feeling unwell. These effects usually occur 7-14 days after receiving a dose and usually mice get better on their own but we do provide more palatable and easy to access food to ease suffering.

Xenografts - tumour development over a period of weeks (3-6). Mice with these subcutaneous tumours usually only have mild inconvenience since there is no internal tumour burden, but it is probably still uncomfortable to have a tumour on your flank.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice

80% Subthreshold

10% Mild
10% Moderate
Zebra fish

95% Mild
5% Moderate
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently no suitable alternatives exist for a number of important basic biological questions which we wish to study in this project, as follows;
Are our gene of interest (GOI) essential for and/or critically involved in;

- life, normal growth, longevity and fertility?
- behaviour, neurodegeneration and other neurological conditions?
- appropriate metabolic responses?
- DNA repair and cancer development?

Additionally, it is important to validate any therapeutic strategies in a living system to best assess their success.

Which non-animal alternatives did you consider for use in this project?

The vast majority of the work in our laboratory utilises alternative methods to study the processes regulated by ADP-ribosylation including: use of alternative species, cellular culture, biochemistry analysis, protein-shape analysis, evolution biology (how similar genes are between different species like from bacteria compared to human) and literature review (what is already known, what has already been done). With particular focus on replacement we implement two main methods;

1) Use of alternative species such as; bacteria and yeast and fruit flies (instead of zebra fish & mice) and;

2) Cellular culture (growing human or animal cells in dishes for experiments; such as cell growth and death).

Why were they not suitable?

These questions can only be answered using animals since no cell culture nor computer technology is currently sophisticated enough to replace the complexity of a whole living organism. Additionally, not all genes are conversed between flies and humans hence the use of mice or zebra fish is still required to study the effect of KO on these genes.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mouse: Breeding and maintenance is calculated based on minimum requirements for safeguarding the line, replacement of breeders at 6 months, 2-3 breeding pairs and a few stock as back up in the case of infertility. To test fertility, expand breeding for cohort generation (for us and our collaborators) we would set up further crosses which is also included in this estimate. These numbers are multiplied by the number of strains we are expected to have. Experimental cohorts often require age/sex matched controls (within a week for metabolic testing within 3 weeks for behavioural testing) thus these are large breeding setups. We don't often use the heterozygous mice (half mutants) so these are killed as surplus. Experimental numbers are calculated based on average group size, expected number of groups, how many strains we expect to test and extra numbers in case we have to repeat.
Zebra fish: Breeding and maintenance is calculated based on minimum requirements to safeguard the line and for experimental numbers. We currently have only 1 zebrafish line and are not currently planning to expand but zebra fish produce a lot of offspring (up to 200 eggs at a time) hence the high number allowed under the licence. As with mice, we tend not to keep the half mutants (except for breeding) so they are killed as surplus. NOTE: this is a reduction from our previous licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During planning phases of an experiment we communicate with other researchers in relevant fields and techniques to confirm our strategy and receive up to date guidance. Typically, this includes reexamination of the current literature, noting experimental setup and expected outputs and group size, then putting a draft plan together and contacting our collaborators for advice/input. In the event that we don't have access to a set of expertise we will contact the Home Office Liaison officers who can direct us to local support. When effect is unknown we will test a small amount of animals first (pilot study) to inform our design.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding strategies are a key component of managing our animal numbers. We require age matched (sometimes within a week) controls of adequate numbers for large experimental groups.
Breeding strategy for minimal colony management is also essential for keeping overall numbers low.
Another strategy is freezing mouse sperm (or fish eggs) to stop breeding animals and preserve the special genetic alteration indefinitely. We often routinely harvest animal tissues for archival purposes and to be able to go back to the precious biological material if a later need arises.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal models: Mice and zebra fish, all life stages
Methods:

Breeding and maintenance. The vast majority of animals on this project will only be used on breeding and maintenance protocols. Animals (mice and zebra fish) whenever possible will live in social groups with cage/tank enrichment in state-of-the-art facilities until being killed by an appropriate humane method. Most mice are unlikely to suffer any project harms, not even mildly (called subthresh-old to indicate no adverse effects whatsoever). Most zebra fish will be mild as they will need fin clipping as a means to genotype them (determine if they are mutant or not). Fin clipping in-volves taking a small section of fin, which does not hinder the fish and is performed under an-aesthetic.
Ageing and harmful mutants. Other animals will be aged and monitored for the development of mild moderate conditions due to the presence of harmful mutations, such as neurodegeneration, metabolic defect and cancer. Animals will be closely monitored for harmful effects so that they are humanely killed at onset of pathological symptoms.

Behavioural testing. Mice are subject to mild tests of naturally, appetite or aversely motivated behaviour. Not expected to cause more than transient unease/mild anxiety, in addition we perform testing in escalating order of severity, thus we may avoid the need for harsher tests altogether. We do not perform the highly aversive water immersion tests or inescapable foot shock tests.
Metabolic testing. For each test mice may have mild food restriction (minimum required time for scientific purposes), administration of a non-toxic substance (once) and limited blood sampling (over 2 hours only). This is the minimum sampling and administration of substance that still produce valid scientific data. Animals are allowed to recover a week between tests.
DNA damage testing. Mice receive toxic agents (either irradiation or injected drugs) at short time points (<72h) (before clinical symptoms present, mild). Or mid-term (50 days) follow up to a non-lethal dose (mild to moderate). We have a stringent welfare monitoring system in place to detect animals suffering from gastrointestinal syndrome that would not get better on their own. Mice suffering significant symptoms of gastrointestinal syndrome are humanely killed before end stage disease.
Xenograft studies. Immunocompromised mice receive an injection in their flank of human cancer cells to allow a tumour to develop. Mice may also receive treatment (typically new therapeutic agents). Immunocompromised mice are most refined since they will not have the severe welfare concerns associated with tissue rejection. Risk of infection is low since we house animals in state of the art, clean facilities. We will not allow the subcutaneous tumours to ulcerate or get too big to impinge on the animal welfare more than mildly. We are not using internal tumours in this protocol as they are harder to monitor and may have a higher welfare burden on the mice.
Models of carcinogenesis. Mice receive toxic agents (either irradiation or injected drugs) over a short period to initiate cancer development. Depending on the method some mice also receive proinflammatory agents. During the acute initiation phase of tumours, a proportion of mice will suffer symptoms of gastrointestinal syndrome (an unavoidable consequence of the toxic agents). These effects usually occur 7-14 days after receiving a dose and usually mice get better on their own but we do provide more palatable and easy to access food to ease suffering.

Why can't you use animals that are less sentient?

The methods described in this project require juvenile, adult and aged mice and zebra fish. They must me sentient for behavioural testing and they cannot be terminally anaesthetised for any of the tests. Ageing, behaviour, metabolism and carcinogenesis require whole organism participation over a period of time (days to years).
Use of a zebra fish model instead of mouse represents a refinement - where available and where we do not plan

to test more involved aspects of neurodegeneration, metabolism or carcinogenesis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals are kept in social groups whenever possible, with cage enrichments and are regularly monitored for development of adverse phenotype. Animals are aged only for as long as clinical signs present to get maximal data with minimal distress.
We always perform testing in an escalating order of severity, thus we would only utilise harsher tests if there were clear biological evidence to justify it. Whilst this may mean we ultimately end up using more mice overall, in some cases it will also alleviate the need for the moderate tests in the protocols altogether. For example; currently we have only performed spontaneous behavioural testing
(considered the mildest) and will only look to escalate to more aversive tests if there are good biological reasons to do so.
The same is true with our DNA damage protocols; that is before performing an *in vivo* radiation sensitivity assay (where mice are kept up to 50 days following whole body irradiation without reconstituting them) we would first check if there was a disruption in the acute DNA damage response (where mice are killed prior to the onset of radiation sickness) > since the two are likely correlated.
When determining the cancer susceptibility of a new strain the chosen method will weigh up the harms to the scientific merit, thus if it is possible to perform the test without the use of toxic agents (perhaps by crossing to a cancer prone strain instead) we will always aim for that.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow the ARRIVE guidelines for publishing.

Table: Recommended maximum volumes and sites for dosing

ROUTE (Mouse)	Oral	Intra-peritoneal (I.P.)	Sub-cutaneous (S.C.)	Intra-venous (I.V.)	Intra-muscular (I.M.)
Common sites	Gavage, or in food or water	Body cavity	Scruff or flank	Tail vein	Anterior thigh
Maximum volume (ml)	0.4 (gavage)	1-2	0.5	0.2	0.05

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Attend 3Rs research day. Read the 3Rs newsletter and would contact them if we discovered any way to replace, reduce or refine animal welfare. Attend departmental welfare meetings. Member of international transgenic society to keep up to date there and readily collaborate with experts in other fields to ensure best practice and most refined method.

Home Office

NON-TECHNICAL SUMMARY

90. Infectivity and strain behaviour of prions

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

BSE, Scrapie, Zoonoses, Infectivity, Strain Typing

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine potential prion infectivity in various tissues that they may be risk assessed for consumption by animals or man or to validate prion disinfection methods.

The strain typing of prions to determine the strain properties of prion that are responsible for known and emerging animal Transmissible Spongiform Encephalopathies (TSEs) with the intention to identify animal TSEs that can behave like BSE with particular emphasis on the zoonotic potential and the ability of Bovine Spongiform Encephalopathy (BSE) to overcome species barriers.

A retrospective assessment of these aims will be due by 14 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence?
- Did the project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

TSEs are chronic, incurable and fatal diseases of the brain caused by pathogens which mainly consist of a single protein termed prion. TSEs cause diseases in both humans and animals, including diseases that are zoonotic (passing from infected animal to man such) as BSE. All these diseases are currently untreatable and ultimately fatal.

This research is linked to statutory TSE surveillance schemes and it aims to minimise the impact of TSEs in animal and public health. The main focus of the research activities is to refine and enhance the existing bioassay methodology in order to improve the delivery of reliable data from sensitive surveillance cases as soon as possible.

What outputs do you think you will see at the end of this project?

The outputs and data that will be generated from this project will inform on the pathogenesis of TSEs, strain diversity of prions, qualitative and quantitative data regarding tissue infectivity, evaluation of decontamination methods and new in vitro diagnostic tests.

Who or what will benefit from these outputs, and how?

A large amount of this information is required by and has direct impact on government policy so it will be firstly communicated to the relevant authorities/laboratories as soon as data become available.

Data will be submitted to and peer-reviewed by funding bodies, peer review via preparation of manuscripts for publication and presentation at national and international meetings.

How will you look to maximise the outputs of this work?

As well as scientific publication, the research group is a member of various European and International collaborations, and advises policy makers in the UK and global organisations.

Species and numbers of animals expected to be used

- Mice: 9,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Transgenic mice are the biological system of choice for these studies. With the different prion transgenes inserted from cattle, sheep or bank voles the various transgenic lines reflect the susceptibility of theses host species. Compared to the host species they offer considerable advantages on speed (months rather than years) and physical size, social structure and husbandry requirements are conducive to humane care in containment laboratory settings.

The established model uses mice at a few weeks of age as they are fully immunologically developed and dependent on the type of experiment being undertaken may have to last up to 1000 days.

Typically, what will be done to an animal used in your project?

The mice used in the project are transgenic. The transgenes are not harmful and all breeding is done under this project, Protocol 1.

The mice used for experimentation will be given a general anaesthetic under which an identification microchip is inserted and a small amount of material that is likely to contain a TSE is injected intracerebrally. The mice will be recovered from the anaesthetic and then if the material contain TSE's some months later they will start to develop clinical signs of TSE. They are clinically assessed regularly by trained staff, once the clinical signs are confirmed the mouse is euthanised and the clinical and pathology information is combined for analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

There will be impacts around the intracerebral injection of TSE for which anaesthesia and pain relief will be given.

The other impact will be as they develop clinical signs of TSE. They are regularly clinically assessed by trained staff, once the clinical signs are confirmed the mouse is euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

35% mild (breeding only), 55% moderate 15% severe .

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 14 March 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Non-animal alternatives such as immunohistochemistry, Western blot, PMCA and RT-QuIC are used for statutory diagnosis and in research projects. However, none of these methods can assess infectivity or define fully strain characteristics. Only when information about infectivity or the finer detail of prion strain is required will the mouse bioassay be used.

Which non-animal alternatives did you consider for use in this project?

TSEs agents lack nucleic acids and do not induce immune responses. Therefore none of the immunological and genomic approaches available can be applied to detect them.

In pursuing our efforts to minimise animal use we are committed in trying new approaches in diagnosing TSE agents and characterizing their strains. Therefore we have undertaken research into emerging technologies in the TSE field including cell culture , organ culture and PMCA were tested to identify prions.

For the last 30 years there have been several attempts to use cell cultures for detection of infectivity or for strain typing. However, there has been incremental progress in this field confined mainly to mouse adapted experimentally produced prion strains. The organ culture methodology is more recent but it

has proved unreliable and similarly with the cell cultures it is not used any more in TSE diagnosis or research.

From these techniques only Protein Misfolding Cyclic Amplication (PMCA) promising in amplifying prions in vitro. However, this amplification may not necessarily be associated with infectivity. The organisation has contributed to this work under the previous licence and will further support the validation of this method as it represents the only realistic possibility in replacing partially mouse bioassays. Real Time Quaking Induced Conversion (RT-QuIC) is a more straightforward and reliable method for amplifying prions in vitro based on the same principle as PMCA. This technique is currently being established at the organisation included in the same project as bioassay and experiments have already been designed to compare it with mouse bioassays for TSE diagnosis.

Also in collaboration with other organisations we assess the ability of transgenic fruit fly (Drosophila Melanogaster) bioassays as an alternative to mammalian bioassays for detection of infectivity.

Under this Project Licence any emerging in vitro or non-mammalian bioassay method will always be validated against animal bioassays to identify if they can be adopted as suitable alternatives.

Why were they not suitable?

Currently only mouse bioassay can give the information about infectivity or the finer detail of prion strain as a clinical and pathological output is required to determine disease phenotype.

It is possible that in future PMCA, RT-QuIC or transgenic fruit flies may partially replace mammalian bioassays in TSE detection testing. However, currently no alternatives exist for the role of mammalian bioassay in strain typing.

A retrospective assessment of replacement will be due by 14 March 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The mice requested for this research represent a maximum estimate of the numbers required given current policy demands on established and emerging TSEs.

Based on data from the previous licences the number of animals under genetically altered mouse breeding protocol has been calculated as a realistic estimate to support production of mice for the experimental protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical input for studies has been and will continue to be sought to ensure validity of data from the organisations biostatisticians.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Research work during previous projects demonstrated that transgenic mice have superior sensitivity and specificity compared to wild type mice. As a result only transgenic mice are included in this licence. In infectivity experiments this results in a reduction from 20 down to 8 mice per group. When wild type mice were used for strain typing experiments serial passages were mandatory requiring at least 52 mice to characterise a strain. In contrast use of transgenic mice for similar experiments requires only 8 mice as strain typing can be achieved during first passage and serial passages are seldom required.

All transgenic lines are homozygous and their breeding in linked to experimental requirements thus avoiding any excess breeding.

A retrospective assessment of reduction will be due by 14 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project uses small panels of transgenic (genetically modified) mice for TSE strain typing. These mice have no animal welfare issues associated with the transgene. Anaesthesia and analgesia are used for the initial and only injection of potentially infectious material intracranially. Then there is an incubation period of generally several months during which time the mice are clinically normal but regularly neurologically monitored by trained staff. When consistent signs of TSE infection are seen the animal is humanely euthanised.

Why can't you use animals that are less sentient?

The evaluation of the pathology to define strains requires a fully developed central nervous system and clinical signs can only be observed in conscious fully developed animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We currently use post-operative analgesia, and monitoring regimes. The majority of inocula used are sterile for conventional pathogens, however in a small number of unavoidable cases there may be a concern over the inocula containing endotoxins. These inocula are heat treated and will initially only be given to a single mouse. If this mouse does not show any adverse reactions for 7 days the rest of the group will inoculated. If the mouse shows adverse effects it will euthanised. The inoculum then is diluted in 9 volumes of saline (1:10 final dilution) and the diluted inoculum is used to challenge a single mouse initially and if the mouse does not show any adverse reactions for 7 days the rest of the inoculations resume. If the mouse shows adverse effects it will euthanised and a further dilution (1:100) is tested as described above. If the single inoculated mouse shows any adverse effects in the 7 day post inoculation period then no further attempts to challenge mice with this inoculum are made.

When there is a concern over the presence of endotoxins increased post-operative monitoring regime is used to identify animals suffering from the effects and euthanase them if they are not going to recover from the effects.

For the diagnosis and identification of different types of TSEs at end of the experiment the mice have to have consistent clinical signs before humane euthanasia. Experience has shown taken to early, there are not sufficient pathological changes in the brain for analysis.

Regular monthly meetings involving the NVS, NACWO, animal care and laboratory staff , personal and project licence holders to ensure current knowledge is brought to bear. All aspects of the performance of the bioassay are discussed, what is going well and if there was anything that could be done better. If there are any suggestions for refining the procedure they will be considered and if appropriate, incorporated into the protocol.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Home Office The Harm–Benefit Analysis Process

Home Office Guidance to ASPA

Home Office Code of practice

RSPCA Guidance on Welfare of mice

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have regular contact with the NIO, NACWO and NVS through various forums and use of the library function which can scan for relevant publications. In developing this work I have been in contact with other researchers outside of the organisation who also specialise in the TSE field and any viable alternatives to mouse bioassay will be continually pursued.

A retrospective assessment of refinement will be due by 14 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

91. Injury and repair of the Spinal Cord

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

spinal cord injury, axon repair, gene therapy, central nervous system, regeneration

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to promote regeneration of the neurons of the Central Nervous System after Spinal Cord Injury.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important because spinal cord injury (SCI) is a devastating event, often resulting in permanent dysfunction of the Central Nervous System (CNS - consisting of the brain and the spinal cord). Treatments to restore function must enable the regeneration of the neurons that were damaged during the injury. The injury of mature neurons of the CNS results in a loss of function and sensation. This happens because the injured neurons cannot transmit information anymore. SCI severely limits an individual's ability to complete basic tasks, such as standing, walking, feeling pain or sensations.

These effects drastically impair one's freedom, safety and quality of life. Every year in the UK, over 1,000 people sustain a SCI in addition to the existing 50,000 cases of people living with paralysis. It is estimated that SCI costs the healthcare system £1 billion annually.

Unfortunately, to this day, SCI still remains a debilitating condition for which there is no cure. As of yet, no treatments that would promote the repair of neurons has completed the clinical trials and with damage being permanent (i.e., paralysis), patients are still waiting for an effective treatment to recover some mobility and sensation. A treatment promoting spinal cord regeneration would have a great impact on improving the quality of life of these patients.

Through our work in the laboratory using cellular models of regeneration (e.g., nerve cells in a culture in an artificial medium), we have identified several new ways to stimulate neuronal regeneration after an injury. We now wish to translate these findings to animal models of SCI whereby the complexity of the mammalian spinal cord can be better understood, and behavioural studies conducted. This licence will enable the testing of these new regenerative methods in the rat spinal cord with the hope that our novel technologies and discoveries will successfully progress to clinical trials.

What outputs do you think you will see at the end of this project?

Definitive spinal injury and recovery experiments should identify one or more new treatments that have the potential to improve recovery after spinal cord injury in human patients (i.e., start of clinical trials). Among these outputs, we have three main axes for this research project (in animals):

-At the end of this project, we will better understand how some molecules involved in neuronal growth are involved in the axon regeneration process. The axon is the part of a neuron which is damaged during injury and through which the information is "transported" to other neurons.

-We will also know if a molecule that we have identified as a new target can regenerate the spinal cord in the same way as it has been shown to regenerate the optic nerve after an injury.

-Additionally, new data will be collected and interpreted about neurons, glial cells and astrocytes (two different types of cells, present in the CNS, which are essential to the functioning of the neuronal networks).

This work will improve our understanding of the global picture following an injury.

It will help us to assess which are the right doses of our viral vectors to be used and the duration of the treatment (i.e., how long these vectors need to be expressed in the body). A viral vector is a harmless modified viral structure used as a precise and specific delivery system. Whilst being totally safe for the host, it allows drugs to reach a specific target/organ.

We will obtain this information by studying how long our therapeutic treatments will be present in the body and assessing the level of recovery.

Results arising from our use of viral vectors and other drug treatments will be shared with the research

community. The viral vectors that will be deemed the most effective should ultimately reach human patients via clinical trials.

Who or what will benefit from these outputs, and how?

The outputs of this work will be disseminated to academic scientists during the licence, whenever we have opportunities to share it at conferences or workshops, in order to avoid duplication of the work. It will also give us the opportunity to build new collaborations to improve the quality of our research for the duration of the licence. Moreover, we will publish our findings in peer-reviewed journals, allowing both academic and pharmaceutical scientists to benefit from our research and help us develop tools to treat spinal cord injury. Tools, particularly viral vectors (therapeutic tools using a harmless viral structure), will be made available to other researchers.
In the long term, we hope that our work will benefit patients and we hope to complete the preclinical work to begin a clinical trial.

How will you look to maximise the outputs of this work?

We will share the information found in our studies as much as we can. In addition to weekly lab meetings, we communicate regularly during meetings organised for the strong research network of groups in the field of spinal cord injury. These collaborations allow us to share workloads and ideas (depending on the expertise of each group), avoiding duplication of the experiments and accelerating the progress in this field.
We will regularly take part in national and international conferences and present work annually to establish new collaborations in order to share our knowledge. These collaborations also help us to optimize our protocols (i.e., techniques used during experiments and the design of the experiments).
We will publish regularly, both positive and negative results, to increase awareness and inform the community as to which treatments are worth progressing and which we feel would not be worth further experimental exploration. Our university is a leader in research and our work is taken seriously and considered respectable in other institutes. We will ensure that the published results are open access to maximise their impact and increase awareness of scientists from around the world and the public. **Species and numbers of animals expected to be used**

- Rats: 1260

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Spinal cord injury in humans leads to lifelong paralysis and loss of sensation. The aim of the work is to develop new treatments for spinal cord injury. Rats and humans demonstrate a similar pattern of recovery after a spinal cord injury. Rats are therefore a suitable species to model regenerative therapies. Non-mammalian animals do not show the same biology: invertebrates (e.g., insects) don't have a spinal cord, fish and most amphibia present a much greater recovery and regeneration after spinal cord injury compared to humans and utilise different mechanisms of repair. A mammalian model is therefore necessary.

Recovery from Central Nervous System (CNS) damage is typically greater in younger mammals. However, as most of the patients are injured during adulthood, the challenge in spinal cord repair lies mainly on modelling the repair of mature neurons of the CNS. Therefore, reproducing this type of injury requires adult animals.
Rodent spinal cord injury models are also highly developed with a large cohort of supporting literature and methodology. Rats also appear to be the best choice for the following reasons:
-Considering the anatomy and the size of the animal, it is much easier to produce a reproducible partial spinal crush in a rat than a mouse.
-The behavioural tests we use have been highly developed and refined. They provide robust and reproducibly valid scientific data which enables us to gauge the efficacy of our treatments.
-We have access to a large choice of different strains of rats, among which some are more suitable for behavioural studies. These strains acclimatise well to our behavioural tests which are often enjoyable for them.

Typically, what will be done to an animal used in your project?

Rats are required for all the protocols defined below and will undergo only one of them. Each protocol is a combination of different procedures. The procedures used in this project are either surgical (i.e., the rats will undergo a general anaesthesia followed by recovery) or behavioural (i.e., different abilities or sensitivities will be tested). In total, the rats will undergo 2 general anaesthesia (insensitivity to pain, especially as artificially induced) with surgical procedure(s) and followed by recovery, at the maximum.
Here are the different **procedures** our rats can undergo:
Injections *(protocols 1, 2 and 3)*: Rats will receive an injection of a new potential treatment, into the nervous system (in the brain, spinal cord, dorsal root ganglia (DRG) or sciatic nerve), which should promote neuronal repair after a spinal cord injury (SCI), or a fluorescent tracer (control viral vector or chemical tracer).

The viral vectors (active or control) and the fluorescent tracer are injected with a needle, under general anaesthesia, in one or several sites (to extend their diffusion and expression). A viral vector is a harmless modified viral structure used as a precise and specific delivery system. Whilst being totally safe for the host, it allows drugs to reach a specific target/organ. The rats recover well after the injections.
The injection of a fluorescent tracer allows us to visualise some structures from the central nervous system. This is essential to be able to analyse the effect of our treatments, once we have collected the organs after the rats have been killed.
Spinal cord injury (*protocols 2 and 3)*: Some rats will undergo partial SCI that results in partial disability for approximately one week. A partial disability means the rats can show a small motor impairment, but will still be able to move around their cage and to eat and drink normally. Additionally, we expect the rats to have issues completing meticulous tasks such as grabbing a pellet of food, that require fine skills for the use of their paws. The partial injury of the spinal cord used in our research represents the most common type of SCI encountered by patients.
Behavioural testing *(protocols 2 and 3)*: Some rats will undergo various behavioural tests to assess their functional recovery after an injury. Here are some examples of tests:
-We can record their gait on a glass runaway to assess any impairments.
-We can record their ability to grab a pellet of food through a grid to assess fine motor skills.
-We can test their sensitivity to cold by applying ice on a paw and timing the withdrawal.
These behavioural tests are harmless for the rats and they actually often seem to 'enjoy' them.
Therefore, by combining some of the procedures above, we have been able to define 3 different protocols our rats could undergo.
Protocols

Protocol 1) The main objective of this protocol is to test how well our new therapeutic tools (i.e., viral vectors) are expressed in the CNS structures after an injection.

There will be an injection of a viral vector and/or a tracer into the CNS or into a nerve such as the sciatic nerve, which runs from the back into the leg. In our case, we used viral vectors as treatments because they will allow

us to modify the level of expression of some molecules into the nerve cells, which are involved into the repair process of damaged nerve cells.
Injection of a viral vector in this protocol will allow us to validate its use in a rat model: we need to validate that this treatment is expressed in the brain and the spinal cord before assessing its efficiency in association with an injury. These viral vectors express, most of the time, a fluorescent molecule which allows us to visualise the structures of the brain and spinal cord which the treatment has reached. If the viral vector is not fluorescent, we will inject a separate tracer to visualise the structures. Then, we will be able to visualise the expression of the treatment with an extra protocol, after the death of the rat.
This protocol will also allow us to determine the best route and dose of administration for our viral vectors.
This protocol lasts between 2 weeks and 3 months in general.
Protocol 2) The main objective of this protocol is to study the recovery of a rat, after a spinal cord injury without repair.

This protocol will allow us to study the morphology of a spinal cord injury (how the injury modifies the anatomy and the expression of some molecules into the CNS) and to assess the recovery of the rats, after the injury, without a treatment.

An injection of a tracer may be used to help to visualise the modifications of the structures of the CNS may happen before, during or after the spinal cord injury, depending on the tracer used.
To study and assess the level of spontaneous functional recovery after injury, some rats will undergo under behavioural testing to assess their movement, their agility or their sensitivity to various stimulations (e.g., heat, grabbing an object).
The behavioural testing may happen every day, with 3 different tasks maximum, and up to 12 weeks, after the injury.
This protocol lasts between 1 and 4 months.
Protocol 3) The main objective of this protocol is to study the recovery of a rat after a spinal cord injury with repair (i.e., administration of a viral vector).

The rats will have a spinal cord injury and will have an injection of a viral vector (or its control) to help to promote repair of the injured nerve cells. Depending on the viral vector, the injection will happen before, at the same time or after the spinal cord injury.
If needed, an injection of a tracer to help to visualise the structures of the CNS may happen before, during or after the spinal cord injury, depending on the tracer used.
To study and assess the efficacy of the treatments to improve the level of functional recovery after a spinal cord injury, some rats will undergo under behavioural testing to assess their movement, their agility or their sensitivity to various stimulations (e.g., heat, grabbing an object).
The behavioural testing may happen everyday, with 3 different tasks maximum, and up to 20 weeks, after the injury.
This protocol lasts from 2 to 6 months.
After the death of the rats, we will study the anatomy of the tissues from the central nervous system (brain and spinal cord) following the injury and the repair (if there was some) to observe the structure and see if we have managed to promote the repair of damaged neurons.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects which may appear during this project are related to surgical procedures and not from any behavioural test. They are as described below:
-Injections of tracers and/or therapeutic treatments (in areas other than the spinal cord or dorsal root ganglia (DRG) - DRG are nervous centres located just next to the spinal cord) may cause occasional pain, distress or discomfort. These adverse effects should resolve quickly after surgery (<72h) and painkillers will be provided

daily, if necessary and in consultation with the animal unit staff, as rats are monitored daily after a surgery.
-Injection of tracers and/or viral vector into the spinal cord and DRG may also cause occasional pain, distress or discomfort. These adverse effects usually resolve within 72 hours but may last up to 5 days post-surgery. The longer recovery is necessary due to cutting deeper into the tissue to access and expose the spinal cord and DRGs. Pain-killers will be provided daily if necessary (depending on the daily pain assessment), and in consultation with the animal unit staff.
Partial spinal injury leads to reduced mobility and a temporary disability (i.e., the general quality of life of the rats is not impacted) for around a week. Impaired movement can include dragging of legs and reduced agility. During this time the rats will be provided with access to ground level food and drink. We will also increase daily observations. Mobility usually improves within one week and monitoring will remain until rats are sufficiently recovered. Their recovery is assessed with a specific score sheet and indication sheet adapted to this surgery (e.g., clinical signs, assessment of gait) to help the animal unit staff. To aid recovery, a heated pad shall be attached to the underside of the cage (up to 48 hours post-surgery). Pain-killers will be provided daily and up to 7 days if necessary, and in consultation with the animal unit staff.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All rats will be in the moderate severity, which means they will undergo a general anaesthesia with a surgical intervention. Their recovery will be monitored and pain-free as pain-killers will be given to them regularly. And their quality of life is not impacted by any of the protocols we will use.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our group has been working on spinal cord injury for a long time now. Through these years of work, we have developed a strong understanding of models of regeneration, of nerve cells from rat, in culture: these nerve cells are put in small plastic dishes at 37˚C, with a special liquid, which allows us to keep them for several weeks. We chose this kind of cells, as they are the ones involved into the control of movement in animals and human and are actually damaged on the occasion of a spinal cord injury. Indeed, it is the part of the nerve cells through which the information for movement circulates through the spinal cord. Hence, when the spinal cord is injured, these nerve cells are injured and cannot transmit information anymore. This leads to partial -at least- paralysis. This model helped us to validate the different therapeutic treatments to promote the regeneration of these nerve cells, in the central nervous system, after an injury. However, in order to validate these new therapeutic treatments, we need to develop and use an animal model. This will allow us to test whether these potential treatments are working in a physiological environment and injury context. The context of the injury is very different in an animal compared to a plastic dish. In an animal, there are many physiological responses (inflammation, formation of scars etc.) which can happen and so impact the efficiency of the treatment. The injury also affects many nerve cells at the same time, not just a single one in a dish. To progress our treatments to clinical trials, we need to validate these studies through the relevant animal models.

Which non-animal alternatives did you consider for use in this project?

The laboratory has developed a new model of culture of nerve cells in plastic dishes to test the tolerance and the efficiency of our treatments before testing them *in vivo* (i.e., in an animal). This model of nerve cells predicts more accurately than other models of cell culture in plastic dishes which treatments will be effective at enabling the regeneration *in vivo*.

Why were they not suitable?

Nerve cells grown in culture dishes are useful for studying some aspects of injury, but they cannot replicate changes relating to a spinal cord injury, such as inflammation and scarring. Nerve cells grown in culture also behave differently to those found in a living organisation, including limited electrical circuitry and communication with other cell types.
It is therefore necessary to use animal models to assess the biological and behavioural responses, both following an injury and after therapeutic treatment. There is also a requirement to demonstrate that a treatment is safe and effective in animal models before progressing to clinical trials.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers were estimated based on statistical calculations of the number of animals needed in experimental groups to produce valid results and based on previous experimental experience. As the experimental methods are improved and refined, the difference between the results in the same experimental group decreases, and this will make it possible to use fewer animals with fewer complications during the experiments requiring a surgical step.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments are constantly assessed at the pilot stage (i.e., the first experiment conducted with a reduced number of animals to adjust some parameters before running the full experiment) and full experiment stages. This ensures that the correct number of animals necessary to achieve robust statistical results is used. The *National Centre for the Replacement Refinement & Reduction of Animals in Research* (NC3Rs) experimental design assistant is a tool which we use to help to design each type of experiment. It is a tool which we use regularly, particularly when there is new information available which would enable us to further refine our experiments.
The animals are placed in the experimental groups randomly: we do not decide beforehand which animals will be allocated to each group and the groups are homogenous.

We are performing ‘blind studies’ for the injections of our vectors: it means that the surgeon performing the injection does not know what is injected and is only told after the results have been analysed. Thereby, there is no bias in the analysis of the results.
During the behavioural assessments and histological studies (i.e., the nature and composition of animal tissues) that allows us to assess how effective our treatments are, researchers do not know which treatments have been used in each animal. This ensures that our researchers interpret all results without risking bias introduction.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Experiments will be clearly and properly planned, defining the objective and outcomes of each of them, before being performed. Methods will be discussed with the animal unit staff to be sure that all the necessary equipment is in place in order to be able to do the work in optimal conditions.
We will always perform pilot studies before undertaking a full experiment, to ensure that larger studies are as accurate as possible, and to avoid replication. These pilot studies allow us to assess if the experiment is well designed and to identify problems as well as formulate improvements early on in the licence. These pilot studies will also help us to check if we have the necessary staff and expertise to run the full study and that the equipment to process samples is working optimally.
When we perform tests on rats like behavioural ones, we multiply their frequency throughout the life of the rats, to have more robust results.
We will collect as many tissues as we can from any rat from our experiments to maximise their use: we systematically collect tissues to perform further studies (e.g. looking at the morphology of the tissues).
We are also coordinating with other groups to share animal tissues in order to reduce overall animal numbers.
We will plan our experiments in accordance with the guidance provided in the *Planning Research and Experimental Procedures on Animals: Recommendations for Excellence* (PREPARE) guidelines. This will not only mean we use the right number of animals but will also ensure our results are robust and reproducible.

We will follow the *Animal Research: Reporting of In Vivo Experiments* (ARRIVE) guidelines when preparing our data for publication. In doing so, we will ensure our findings are complete and clearly presented when published, and are easily accessible to other groups. This should reduce unnecessary duplication of animal experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this kind of experiment, the most appropriate animal model appears to be a quadruped as we need to assess the motor and sensitive functions, following injury and repair.
The rat is a better species to use than the mouse because it is easier to perform a reproducible injury on them due to their larger size; moreover, they are more responsive to behavioural tests. The performance during the behavioural tests can be further improved by selecting the most appropriate rat strain.

The animals will receive a partial spinal cord injury. The lesion (i.e. the injury of the spinal cord) model and assessment has been refined over the years so that only a partial injury is made, which produces a partial disability for a few days: animals will show a reduced mobility and agility. This impairment of mobility and agility does not affect their ability to eat and drink as usual. After a few days, animals behave normally in their cages. The behavioural tests are very sensitive and are used to detect minor disabilities (detectable with cautious study) and assess the recovery in animals after injury.

Why can't you use animals that are less sentient?

We cannot use invertebrates (e.g., worms), fish or amphibia, as they are not suitable to develop a treatment for human spinal cord injury. Some preliminary work on regeneration biology is done in nonmammalian species, but for experiments on recovery from spinal cord injury in humans and veterinary animals only mammalian species provide an adequate model: as we explained it, this animal model is necessary due to the anatomy of the spinal cord and the need for similarity with the human one.
We also cannot use animals that have been terminally anaesthetised as we need to assess the efficiency to promote nerve cell regeneration. Thereby, we need the animals to remain alive for several months after surgery. We need animals with nerve cells which have reached a mature stage to be representative of human injury: therefore, we need to use adult animals and cannot use embryos or immature life stages for our experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have put in place a post-operative assessment sheet, specific to our model of injury or injection into the spinal cord area, to help the technicians to monitor better the recovery of the animals after surgery.
This post-operative assessment sheet will be refined during our work, depending on our observations and in collaboration with the animal unit staff. Likelihood of pain during the post-surgical recovery period will be controlled by the administration of pain killers, as directed by a veterinarian.
The behavioural tests used are not painful or stressful and are usually enjoyable for rats. In order to reduce stress, the assessor spends time with the animals to achieve familiarity.
Full training will be provided to new technicians who are unfamiliar with these procedures: we have filmed previous study procedures to show how we expect our animals to recover. These movies are available to help them to familiarise with the way our rats recover from a spinal cord surgery. It helps new technicians to learn how to assess our animals correctly and in turn, means that animals recovering in our experiments receive the same high quality and consistent level of monitoring and care they need.
We have also developed, if needed, the use of jackets to protect the surgical wounds on the back of the rats following a spinal cord surgery. Animals are acclimatised to the jackets a few days before the surgery and can wear them for a few days after the surgery until the wounds are healed. This prevents damage to surgical wounds, for example from back scratching.
It happens that some animals have to be single-housed following a surgery to prevent further damage to their surgical wounds (e.g. if wounds have been re-opened after playing with cage mates). In this case, whenever possible, we will divide the cage in 2 with clear plexiglass during the scarring of the surgical site. With this system, rats can see each other, which reduces the stress caused by the single housing.
Pain is not necessary for any of the studies and we will administer pain-killers to our animals when needed, as directed by a veterinarian. Regular discussion with a veterinarian will allow us to improve the management of pain, if any new and more suitable recommendation appears during the work.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Any new practices on animal work utilised by the establishment laboratory will be incorporated into our research. Excellent information is available on our establishment website, which is constantly updated with new 3Rs information.
The *National Centre for the 3Rs* (NC3Rs) website will also be regularly consulted to be sure that we are applying the latest recommendations in terms of refinement.
We are already following recommendations about the use of *vitro* models to reduce the number of animals as explained here: https://www.nc3rs.org.uk/vitro-model-spinal-cord-injury-replace-use-rodents
The *Laboratory Animal Science Association* (LASA) website provides updated information, especially regarding good research practice to perform aseptic (i.e., germ free environment) surgeries. (https://www.lasa.co.uk/wp-content/uploads/2017/04/Aseptic-surgery-final.pdf)
We will also consider any new publications in a peer-reviewed journal which is relevant to our field and which will offer new refinements for our protocols. (e.g. https://www.researchgate.net/publication/339667378_Refining_rodent_models_of_spinal_cord_injury)
To finish, we will also review regularly the best practice guidelines on substance administration volumes and frequencies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our establishment offers continuous training and advice through the training facility and the animal facilities. We will keep informed by regularly consulting the website they provide to be sure that we are not missing any new updates.
The *National Centre for the 3Rs* (NC3Rs) will also be the main reference to assess whether our experiments are matching the highest standards of 3Rs, and we will adapt our protocols if the recommendations evolve throughout the duration of this project. If any alternative to animal use materialises during this project, we will assess its suitability for our research.
Regular consultations on the latest practical guidance from *Laboratory Animal Science Association* (LASA) and the *Royal Society for the Prevention of Cruelty to Animals* (RSPCA) will provide other sources of new recommendations and advances.
We will keep our training up to date and will provide extensive training to any new lab member who joins the group to work on the project.
As a licence holder, I will stay updated by consulting information for licence-holders provided by our establishment and by speaking to other project licence holders.

Home Office

NON-TECHNICAL SUMMARY

92. Intestinal failure in neonates and adults: mechanisms, protection and repair

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Ischemia, Reperfusion, Nectrotizing, Colitis, Stem Cell

Animal types	Life stages
Mice	adult, neonate
Rats	adult, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The overall aim of project is to further our understanding of the pathophysiology of intestinal failure and test the efficacy of novel stem cell derived therapeutic strategies that may have implications for the treatment of these conditions in humans.
A retrospective assessment of these aims will be due by 16 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Lack of blood flow induces damage to the gut during neonatal as well as adult period of life, which results in severe consequences to human health. Presently, there are no treatments to cure patients who experiences such episodes. Previously, studies have shown that molecules produced by stem cells promote tissue regeneration when these molecules are given to an individual from whom the stem cells were initially isolated. Here we will test for the first time whether stem cells or molecules that they produce derived from one animal or human can alter the disease progression of a gut of another animal that has experienced periods of ischemia.

What outputs do you think you will see at the end of this project?

Knowledge gaps need be filled regarding the mechanisms of intestinal failure in two settings: Ischemia reperfusion injury (IRI) and Necrotizing enterocolitis (NEC) .

- Improved scientific understanding of the mechanisms of injury by NEC and its sequelae (short bowel syndrome and neurodevelopmental complications) is essential for the development of effective therapies against the disease. This will be achieved through analysing the tissue at the histological level, profiling the expression of key proteins that control the major mechanisms underpinning tissue homeostasis, as well as key gene markers reporting on tissue health.

- A short-term benefit of this proposal will be to define the mechanisms of pathology and how they can be modulated by stem cell factors in rodent models

- The key outputs will be the generation of new information, which will be communicated via publications in peer reviewed international journals.

Provision of this information will allow usage by third parties.
The outcomes of these studies will be made available to interested parties through a number of routes. Firstly, we will publish our work in international peer reviewed journals. Our work will also be communicated at national and internal conferences and workshops.
All raw data will be made available upon request following clearance for the provision of this information from the University Data protection unit.
The long-term benefits of this project will be the translation of knowledge gained in establishing the stem cell secretome based therapy to these pathologies. This long-term goal will require a tiered process that involves safety testing, testing in a non-rodent model for efficacy before entering a phase one clinical trial (first in human).

Our collaborators already have an established pig model for both conditions which will accelerate the translation of positive results from this licence should they arise. Furthermore, the translational route will be accelerated by partnering with clinical teams who are closely involved in the training aspects of this project.

Who or what will benefit from these outputs, and how?

The short-term benefits of this proposal will be gaining mechanistic insight into the two indications at multiple levels, ranging from whole organ function down to the identification of molecules that are perturbed as a conscience of the diseases. The identification of aberrant molecules is likely to be of particular benefit to third parties as they themselves could become therapeutic targets. Therefore, the short-term benefits are like to be important to not only the general scientific community but also to groups around the world working on these diseases.
Long-term benefits include the development of novel efficacious therapeutic strategies for patients with NEC and IRI for their improvement of their quality of life. This is an important target as NEC and IRI is associated with significant morbidity (short- and long-term) and mortality. Caring for such patients is difficult for relatives and healthcare professionals and has significant impact on limited resources. In order to achieve this, it is essential to appreciate that NEC and IRI are multi-factorial diseases. In the present project, we account for this by using two distinct models of “NEC-like” injury. The therapies we will investigate include stem cells or factors derived from stem cells in both a rat and mouse model of IRI and in rat for NEC by various routes of infusion relevant to clinical translation in animals at appropriate stages of development relative to the indication.
The clinical use of differentiated or undifferentiated stem cell conditioned media provides an attractive, less invasive, safer alternative (minimising cancer, reducing immunological risks) to stem cell transplantation. The benefits could be in future be reaped by those who suffer with ischemic-induced damage of the gut.
However, this is only the first step towards use in the community. Future studies will require safety testing a process that is likely to take two to three years after the successful completion of this project.
How will you look to maximise the outputs of this work?

We will communicate the results arising from this study by presenting our progress at both national and international conferences and meetings as well as communicating completed studies in the form of publications.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 2300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents are being used in this project as they can be used to develop the symptoms of the diseases that are the focus of this project: Ischemic Reperfusion injury (IRI) and Necrotising Enterocolitis (NEC).
The IRI work and work on NEC will be conducted on adult rodents and new-born rodents respectively, as these developmental ages mimic the times of respective disease onset in humans. Both animal models were first developed in rat due to the size of organs that need to be manipulated. We will establish the protocols in the rat and then move to the mouse for IRI. The mouse is a more attractive model due to logistical reasons in the first

instance as they are more readily maintained (smaller cages, and cheaper to maintain) Secondly after demonstrating that we can perform IRI in mice we hope (through amendments to the license) to work on transgenics.. If unsuccessful, then we will conduct all our studies in the rat.
All work on NEC will be carried out in rat due to the size of newborn pups and the type of intervention that is required to induce NEC. This work in the first instance would be technically challenging, although not impossible in mice.

Typically, what will be done to an animal used in your project?

Typically, rodents will be maintained until the desired age and then be induced to develop a disease state, which will be achieved either through surgical intervention (Ischemic Reperfusion injury (IRI)) or treatment comprising of exposure to reagents and stressful conditions (Necrotising Enterocolitis (NEC)).
Thereafter they will be treated with a stem cell secretome, which has potential therapeutic properties.
The treatment will be allowed to have time to work, during which time the rodents will be monitored to assess the impact of the treatment.
The experiment will be terminated at a set period. The animals will then undergo physiological examination which will allow us to gauge how well the tissues are working. Thereafter the animals will be killed, and tissues collected for further investigation aimed at revealing how the treatment has altered the course of the disease.

What are the expected impacts and/or adverse effects for the animals during your project?

The interventions described in this license will compromise the working of the gut, which will have impact on both body weight and potentially other physiological processes. Examples of adverse effects could include hunched posture, piloerection, anorexia, septicaemia, abdominal pain, inactivity, foam coming out of the mouth.

Additionally, rodents may show signs of general malaise and decreased activity.
We will implement rigorous monitoring regimes which will allow us to identify any signs of adverse effects and depending on the nature of the adverse effect we will either stop the intervention followed by a recovery protocol or humane kill the animal to prevent further pain, suffering and distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The most severe category is severe which will be experience by no more than 15% of the animals in this proposal. A small proportion of animals will be used in studies to evaluate whether the treatments improve survival.
However through the use of a rigorous monitoring regime informing of when an animal shows signs of no longer being recoverable, we will perform humane killing to minimise pain, suffering and distress.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 16 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of the project is to explore the clinical benefit of stem cell secretory factors on ischemic gut disease in adult and neonates. Mice and rats are the lowest sentient species that can be used to reach our objectives. Alternative experimental models for research into gut diseases have been developed including those carried out in test tubes or with whole animals including amphibians and fish. However, none of the latter faithfully replicate the condition in humans.

Which non-animal alternatives did you consider for use in this project?

With some aspects of the project, experimental animals can be replaced by in-vitro testing, and as outlined in the programme of work such in-vitro testing will replace intact animal experimentation wherever possible in the project. Such in-vitro testing will include appropriate dissociated cell culture, cell line testing and testing on organoid culture preparations appropriate for each disease model. Organoids technology is relatively new and allows scientists to grow a 3D collection of cells that have all the major cell types found in the human gut. Furthermore these have been used to develop models of necrotizing enterocolitis. We have extensive expertise in the development of gut organoids starting with tissues harvested from rodents.

Why were they not suitable?

While in-vitro studies are very informative on the impact of a disease or condition on a particular tissue, they have very little value when the nature of the disease or condition acts in the whole body. While organoids are incredibly informative when addressing key developmental issues related to the gut, they are presently still not a good model for studying the types of diseases investigated in this study. Organoid 3D architecture is not as regular as seen in vivo. More importantly organoids lack several essential components of the living digestive tract, such as the enteric nervous system, the vascular system, lymphatic systems and functional adaptive and innate immune systems. However co-culture protocols are being developed that allow numerous cells types to be grown at the same time. But, as more components are introduced, these compromise the development of the primary gut tissue.
Nevertheless, we will assess progress for outcomes that overcome these limitations. Thereafter, we can use these as testing ground prior to work in animals.

A retrospective assessment of replacement will be due by 16 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything

others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals estimated will allow us to carry out comprehensive studies to evaluate the efficacy of stem cell-based treatment for ischemic gut injuries. The investigations will involve examining the animals as well as tissues using a battery of tools which necessitate the provision of starting material for each study. The experiments have been designed to generate statistically significant data, which allows us to reach quantitative conclusions regarding the efficacy of the intervention.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Generally, advice will be sought from our Consultant Statistician, where appropriate, to ensure a statistical design that is used is efficient and minimises the number of animals required yet maintains sufficient precision and power. For example, advice will be sought when a specific pre-clinical model introduces large subject-to-subject variation.

Furthermore, a number of studies including our own have shown that the impact of IRI and NEC effect more than just the primary tissue under investigation, that being the gut. Therefore, in order for an intervention to be examined further for possible use in humans, it is now apparent that an intervention should be examine at the tissue functional level as well as in non-gut tissue, in particular the nervous system. We have developed a pipeline that extracts the maximal amount of data from each animal by not only determining gut function whilst the animal is alive, but then to isolate as many tissues as possible after the animal has been killed. This approach means that a single animal will generate data related to a wide variety of bodily functions.
We hope that the advent of robust and complex organoid based in-vitro culture systems will allow us to generate guiding and pilot data that allows us to conduct more precise experiments in live animals. For example when robust gut complex gut organoid protocols become available, we will carry out experiments to establish optimal doses of condition media before transitioning into animal based studies.
We will also use experimental protocols for both conditions that have been optimised over a number of decades for our studies. These protocols are the most robust yet and will have an impact on the number of animals being used. Again we will survey literature for developments that further refine them in-order to reduce animal numbers for a particular outcome.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The proposal aims to minimize animal usage by drawing on our extensive experience in this area of research. These insights will be deployed not only to keep the number of mice and rats to their lowest possible number but also to conduct the experiments in the shortest time span thus minimizing animal suffering.
A retrospective assessment of reduction will be due by 16 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For both ischemic-reperfusion injury (IR) and necrotising enterocolitis (NEC) it is necessary to induce damage to the gut. Pain and suffering will be minimised through use of appropriate anaesthetic and analgesic regimes. The models selected provide the most data on paracrine mediated stem cell induced repair of tissue damage and will generate data for our company and others to develop definitive therapies while answering basic questions on stem cell biology.

Why can’t you use animals that are less sentient?

Small rodents (mouse: rat) are the simplest appropriate pre-clinical models to study these diseases and their potential amelioration. While there are species differences in physiology between humans and rodents, these are minimal and the use of species phylogenetically closer to humans is not required by the appropriate regulatory bodies and thus is not proposed as part of this project. Rodents are the animals of choice since they are amenable to surgical interventions whose outcome leads to tissue destruction very similar to IR and NEC.
Non-vertebrate models including nematode worms and fruit-flies do not share the same physiological parameters as humans and are thus not informative for this type of study.
Fish and amphibians have gastro-intestinal systems more similar to mammals than non-vertebrates. However, they are quite distinct to mammalian guts including major changes to the 4 distinctive layers found in rodents and humans. These changes could reflect their great reliance on an aquatic environment for their survival and differences in the diets. They are not good models for the diseases being investigated in this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The procedures to induce IR and NEC have been developed over decades and refined to delivery intended scientific outcomes with the least suffering to the animals. We will use the most optimised versions of these protocols available.
Importantly these protocols have been developed and refined, in order to best mimic the human condition and at the same time deliver this desirable outcome with the use of the smallest number of animals, by our partners who will be intimately involved in this project. These include some of the most eminent neonatal surgeons in the world. They will provide the expertise and oversight to this project. They will not only roll out the project but also ensure that all experimenters are fully competent in performing all aspects of the project.
As outline in our lifespan study, the use of paired animals (1 untreated: 1 treated) allows us to reach our endpoint (evaluating the impact of the intervention on survival) with the fewest possible animals.
For all surgical interventions, monitoring of the animals during recovery may be extended or increase in frequency if required. Furthermore, appropriate anaesthetic and analgesic regimes may be deployed to help

manage pain.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will seek to carry out the experiments using best practice advised by differing parties including:
Laboratory Animal Science Association (LASA) for best practice guidelines for administration of substances and genetically modified mouse welfare guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will seek advice from the Home Office inspector as well the named veterinary surgeon for alternative approaches using either less sentient animals or non-animal systems that allow us to achieve our goals.
A retrospective assessment of refinement will be due by 16 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

93. Investigate the role of physiological hypoxia and inflammation on cardiovascular disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Hypoxia, Cardiovascular disease, Endothelium, Pulmonary, Physiology

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall purpose of this project is to understand how the oxygen sensing pathway influences tissue and organ adaptations under physiological and pathological disease conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The physiological responses to hypoxia (reduced oxygen availability), or to variations in the way tissues receive oxygen are complex and multi-dimensional. It forms a key component of many pathologies in humans and animals, and is particularly relevant to cardiovascular disease such as pulmonary hypertension, chronic obstructive pulmonary disease and myocardial infarction, where the restriction of blood flow leads initially to local tissue hypoxia (lack of oxygen) that if not quickly resolved initiates tissue dysfunction and potentially death.
A greater understanding of this response has the potential to aid drug discovery and target diseases including hypertension and COPD and heart attack.

What outputs do you think you will see at the end of this project?

One aspect of our work will look at the role of substances within cells which are involved in the regulation of oxygen which will
increase our understanding of the mechanisms involved which themselves are important with regard to the new generation of drug treatments for anaemia and cancer, currently in clinical trials. In particular, we hope to determine the role of a key substance and identify the mechanism of action for publication.

Pulmonary hypertension is a progressive and destructive disease of the blood vessels of the lung in which a substance known as HIF plays a key role. We will also determine the role of this substance which we hope to publish and also progress towards phase 1 or 2 clinical trail.
Our work will also focus on pulmonary hypertension cardiac arrhythmias which can shorten the life expectancy of patients. We have shown in pre-clinical models of PH that intervention with substances known as HIF2a inhibitors reduces many of the pathologies associated with this disease. This work will determine the role of HIF2a on cardiac arrhythmias in our pre-clinical models of PH. This will lead to a publication of new knowledge and contribute towards the progression of this drug to clinical trials.

Who or what will benefit from these outputs, and how?

This work will provide important mechanistic insight into the role of hypoxia and HIF2a in the mechanisms involved and the disease pathology of pulmonary hypertension. The data produced from this project will be presented at national and international conferences and published in academic journals. The knowledge gained from these investigations will also have wider implications in our understanding of acute pulmonary vascular disease pathology (bacterial sepsis, ARDS, acute mountain sickness).
The data gained will be shared with the pharmaceutical industry to advance the development of specific HIF2a inhibitors.

How will you look to maximise the outputs of this work?

The findings from this project will be made available to other scientists through publications in open access journals and presentations at scientific conferences and meetings

Species and numbers of animals expected to be used

- Mice: 3580
- Rats: 550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use both rats and mice.
We plan to use genetically altered mice that specifically targets the ability of the gene to produce a functioning product (known as gene expression) in the blood vessels of the lungs and allow us to investigate the role of our target genes in the development and progression of pulmonary hypertension. Modulation of these target genes in the lungs will prevent or accelerate the development of pulmonary hypertension. These mice have been specifically developed to target genes expressed in the blood vessels of the lung. The efficiency and specificity of gene modulation does not exist in other animal models.
We also plan to use rat models of pulmonary hypertension. These models offer a closer fit to human disease, closely matching immune cell function, lung remodelling and heart response observed in pulmonary hypertension. These models described offer the best pre-clinical to test new drug treatments for this lung disease.
We will use adult animals in both mice and rats, as they are immunological mature animals.
Typically, what will be done to an animal used in your project?

We all experience a degree of hypoxia (reduced/low oxygen) in our lifetime, whether this is self-induced (high altitude or extreme exercise) or disease originating (lung disease or cancer). Our overall objective is to obtain a better understanding of how and why our bodies specifically respond to low oxygen conditions with the view to using this knowledge to treat lung disease
We will use mice that have been genetically altered or novel drug treatments to improve our understanding of the normal physiological responses to acute and chronic low oxygen exposure. The body will normally rapidly respond to hypoxia by increasing respiratory rate, heart function and modify the method we use to generate energy (metabolism)
Acute hypoxia: The blood vessels in the lung respond to hypoxia by constricting (hypoxic pulmonary vasoconstriction-HPV). We will determine the role of our genes of interest in this highly conserved physiological response. Typically, mice and rats will receive our investigative drug or control vehicle by oral gavage (through a feeding tube in the throat) 30-90 minutes before the experimental procedure and hypoxia exposure. Mice and rats will be anaesthetised and a blood-pressure recording catheter inserted into the heart to measure HPV (blood pressure increases in the heart during HPV). The oxygen content of the air the mouse is breathing will be reduced to stimulate HPV. The pressure recording will take 30 minutes from start to finish. This is a terminal procedure, so the animal will not feel any pain. We will collect tissues and fluids for later analysis.
We will determine the effect on ventilation and metabolism by using non-invasive techniques. Mice or rats will be single housed inside these apparatus and will be exposed to the low oxygen environment for between 60-120 minutes.

We will also investigate how mice with diseased lungs respond to acute hypoxia and determine if the response is different to healthy lungs. We will use genetically modified animals that spontaneously develop pulmonary hypertension (3-4 months). The severity of the lung disease will be initially checked using a non-invasive imaging technique. These animals will progress through the sample procedure to measure HPV, respiration and metabolism as outlined above.

Chronic hypoxia: Typically mice or rats will receive our investigative drug or control vehicle by oral gavage twice a day for the duration of the protocol, or genetically altered mice for our genes of interest. These animals (mice or rats) will then be exposed to chronic hypoxia for a maximum of 35 days. During this time blood and urine samples may be collected, or respiratory rate will be recorded over a maximal 180 min period (non-invasive). We will assess heart function at the end of the hypoxia exposure via a terminal procedure. Tissues and fluids will be collected at this point for later analysis.

Models of Pulmonary hypertension: We will used both mice and rat models of pulmonary hypertension to determine the role of low oxygen, and hypoxia responsive genes in the initiation and development of pulmonary hypertension. We will use a combination of genetically altered mice and wild-type rats exposed to chronic hypoxia to initiate pulmonary hypertension. We will treat these animals (mice or rats) with our investigative drugs, administered twice a day for the duration of the protocol (21 days). We will use non-invasive methods to determine the progression of the disease and determine the change in metabolism. We also have the option to surgically implant a blood pressure measuring device (radio-telemetry) into a major blood vessel of the mice or rats. The animal (mouse or rat) is anaesthetised and receives an injection of pain relieving drugs before the catheter is carefully inserted into the blood vessel and secured. The transmitter is then inserted just under the skin on the flank of the animal. The wound is then sutured closed. The animal will quickly recover from the anaesthetic (5-10min) and surgical procedure over the next 7-10 days. This technique allows for blood pressure analysis over a continuous 28-days in conscious animals which is ideal for chronic hypoxia and drug intervention studies.

What are the expected impacts and/or adverse effects for the animals during your project?

For many of these experiments, the adverse effects are mild, in that animals (mice or rats) do not suffer undue stress by being subjected to the levels of oxygen employed by us experimentally. They will experience some increase in breathing rates and slightly lower levels of activity, much as is experienced by mountain climbers and other people at high altitudes. Some animals (mice or rats) will have surgically implanted units used to monitor parameters such as blood pressure and heart rate. When this is done, all procedures will be carried out with aseptic (sterile) surgical techniques and appropriate levels of anaesthesia, and pain relieving drugs will be administered during recovery from surgery.

Exposure to hypoxia: Manipulation of oxygen at the levels proposed are not expected to trigger adverse side effects, and the majority (>95%) of mice and rats tolerate these variations well up to 35 days. It's expected that mice and rats exposed to reduced oxygen levels undergo a mild weight loss due to decreased activity and metabolism, especially during the first week in the chamber. Both mice and rats will be weighted every week and those that show 15% of weight loss will be removed from the chamber and killed by a humane method.

Transgene inducing or deleting agents: In the majority of mice (>95%) no adverse effects are anticipated. Any animals that lose 15% of their body weight when compared to age matched controls will be promptly killed using a humane method.

Surgery: Surgical procedures will be carried out aseptically. In the uncommon event of post- operative complications, animals (mice and rats) will be humanely killed unless, in the opinion of a veterinary surgeon, such complications can be remedied promptly. Peri- and post-operative pain relief will be provided. All animals (mice and rats) are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. Animals will be closely monitored. Uncommonly animals that fail to recover by the end of the working day, exhibit pain, distress or significant ill health or otherwise deteriorate despite intervention will be killed by a humane method. Any animal not fully recovered from the surgical procedure within 48 hrs (eating, drinking and return to normal behaviour) will be humanely killed.

Diet alteration: Mice and rats generally tolerate a high fat or high salt diet favourably, Weight gain progress will be monitored weekly. However, animals will be humanely killed if they show signs of ill health, such as open fur-

coat and hunched posture, inactivity or inappetence for a period of 24h. Animals may gain up to twice as much weight as normal chow-fed animal over the same period of time (up to 3 months of high fat feeding). We do not expect significant weight gain or loss in the high salt diet, although daily monitoring of water use will be done to ensure that animals always have sufficient water. Previous studies have shown that high fat-fed animals feed, drink and move normally, may develop a greasy coat that the animals are not bothered by. However, if the weight gain appears to be inhibiting regular movement, or if the animals are observed to have lost appetite or are not drinking, the animal will be humanely killed immediately.
Substance administration and withdrawal of blood and/or urine: Most animals will undergo the administration of substances and withdrawal of body fluids will be undertaken using a combination of volumes, routes and frequencies as result some animals may experience no more than moderate levels of discomfort.

Plethysmography (measuring ventilation): Animals under this procedure are not expected to have any adverse effect other than initial distress when facing constraint within a chamber, observed by a failure to settle and that should disappear after 30-40 minutes, otherwise will be returned to its cage and tested other day. This will be reduced by conditioning in the chamber if necessary.
Housing in metabolic chambers: Animals housed in metabolic chambers supplied with 21% oxygen and free access to food and water are not expected to show any deviation from normal behaviour or well-being, as seen in their regular cages. If any, a transient exploratory behaviour will be observed when exposed to the new environment for first time. A small amount of bedding will be provided to help adaptation. In the unlikely event of clinical signs, such as open-fir coat and hunched posture for a period of 24h, the animal will be humanely killed. Upon exposure to low oxygen, animal will show a mild and transient increase in ventilation (no more than 20-30 minutes) followed by a drop in blood pressure and heart rate that will result in a reduced activity and loss of appetite for a period of 12 to 24h. Otherwise, both mice and rats adapt well to the oxygen levels proposed in this procedure and no further deviation from normal behaviour or wellbeing is anticipated. Animals will be humanely killed if showing signs of ill health, such as open fir coat and hunched posture, inactivity or inappetence lasting for a period of 24h hours. If mice and rats are maintained individually for more than 24 hours, they will be monitored extensively upon reintroduction to cages to ensure that no fighting or aggressive behaviour arises.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We estimate that 70% of mice will experience mild and 30% of mice will experience moderate severity and 60% of rats will experience mild and 40% will experience moderate severity.

What will happen to animals at the end of this project?

- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The response of cells to hypoxia differs from tissue to tissue, as well as within tissues themselves, and the fully evolved process cannot be modelled in any other system than a complete organism. Cultures grown in the

laboratory and even complex organoids (artificially grown mass of cells resembling organs) cannot replicate the complex interactions in the body that occur in hypoxia in tissues, or even the specific nutrient and mechanical environment in which they take place.

Which non-animal alternatives did you consider for use in this project?

We do use cell culture in the laboratory to test simple hypothesis and learn more about molecular pathways in the cell when feasible. Where possible, we do use all feasible methods to monitor and explore physiological changes outside of animal models. For example, we use cell co-culture systems wherever possible to model simple cell-cell interactions, and to validate functional and metabolic discrepancies. These co-culture systems are an important mechanism for replacement of in vivo (live animal) systems.

Why were they not suitable?

As discussed above, the response of cells, tissues and organs to hypoxia is incredibly diverse; we and others have identified hypoxic gradients across tissues and organs which influence physiological and pathological processes. These complex interactions between tissues and organs cannot be captured in laboratory culture systems.
We will continue to explore such systems for co-culture of multiple cell types to allow us to replace use of animal models wherever possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have a great deal of experience working with the animal models described in this project. We consulted with a trained statistician to ensure that our statistical monitoring is sufficient to minimize animal use

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The laboratory possesses and has access to highly refined equipment such as radiotelemetry receivers for monitoring of blood pressure, metabolic chambers coupled to oxygen mixers and detectors and whole-body plethysmographs, to accurately determine physiological outputs that ultimately will translate into reduced number of animals per group.
These models have been refined to enable us to maximise our data output from each animal. For instance, in the rat pulmonary hypertension model, each animal that has undergone a procedure will also have data on heart and liver metabolic profiles and tissues and fluids stored at -80C for future analysis.
All work carried out would be done in context of the NC3RS* ARRIVE** guidelines and framework to maximise research output whilst limiting unnecessary studies and use of research animals.
* National

* National Centre for the Replacement, Refinement and Reduction of Animals in Research

**Animal Research: Reporting of In Vivo Experiments

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use certain types of animals ('backcrossed lines') to avoid background variability that could potentially confound or mask phenotypes (the observed properties of the animal) deriving from genetic alterations, which will contribute to narrower and more specific range of observations, increasing the reliability of our results and therefore leading to reduced numbers of animals.
All of our genetically engineered mouse strains have been cryopreserved by sperm or embryo freezing. We will only produce mice in response to experimental demand.
Cell biology questions can and will be addressed using primary cell lines, purified from specific organs of interest, and these are used to guide our work in animals.
Collaboration with other groups at our institution, especially those undertaking different facets of cardiovascular research work, will allow for reduction of the total number of animals purchased and used at the institution.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are ideal models for the studies we proposed within this licence, for several reasons, including the physiological resemblance and ease of modelling the disease at hand, as well as the ability to genetically manipulate and expand new mouse colonies.
We have a great deal of experience running the methods described within this licence; these methods have been refined to cause the least pain and distress to the animal whilst maximising data collection and reducing group variability. We have developed non-invasive methods were possible, including whole-body plethysmography and metabolic analysis. Measurement of these physiological parameters occurs rea-time, so we use the earliest endpoint that allows scientific value. Mice will be otherwise closely monitored throughout the duration of any procedure.
We also use rat models of pulmonary hypertension. These models have been developed and refined as the gold-standard method to develop and test new potential therapeutic treatments. We will use non-invasive imaging to gauge the initial disease severity and track the development of pulmonary hypertension in these models. This close monitoring will enable us to complete the protocol at the earliest endpoint that allows scientific value.

Why can’t you use animals that are less sentient?

We aim to study how hypoxia/HIF signalling impacts on physiological and pathological disease processes. These studies required adult life stage for both mice and rats to ensure a mature and functional immune, cardio-pulmonary-vasculature to give the closest comparison with human physiology. Immature or embryo life stage mice or rats do not have a fully function immune system and/or cardio-pulmonary vasculature that is required to study cardiovascular disease processes.

The use of other vertebrate or invertebrate class is less than ideal to study the impact of hypoxia on physiological and pathological disease processes. The physiological structure/function of their major cardiovascular organs (lungs, heart, liver) are significantly different to that of humans, this would hinder direct comparison to pathological disease processes being investigated and negate any possibility of testing the stated hypothesis.

Many of the methods used in this protocol have been refined to be mild and non-invasive were possible.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All surgical procedures will be performed aseptically by trained surgeons, at least to the HO minimum standards for aseptic surgery, and according with the advice of the NVS. Pain relief will be provided during surgery and maintained after surgery for as long as necessary to alleviate pain. A close monitoring of post-operative animals will be undertaken.

We have a great deal of experience with blood pressure radio-telemetry, which allows us to monitor cardiovascular function for longer periods of time without mouse handling and/or restraint, reducing mouse stress and experimental variability. Improvements have been also been made in relation to the site and placement of the radio-telemetry device
Likewise, if new methods are developed, that are able to decrease animal distress or harm whilst maintaining accuracy and reliability, they will be evaluated.
All procedures that involve an alteration of normal mouse housing will be conducted after proper acclimatisation and training of the animals, as this increases consistency, diminishes variability and more importantly reduces the number of mice required to obtain statistically reliable results.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will keep up to date with the guidelines issued by LASA (https://www.lasa.co.uk) and NC3Rs (https://www.nc3rs.org.uk). These websites highlight a number non-invasive alternative protocols and promotes the advances made with new in vitro (laboratory based) techniques. (example https://www.nc3rs.org.uk/our-science/search-our-science?cells-systems%5B%5D=248)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Many of the methods described in the project are the gold-standard for animal welfare and quality of data collection. The companies that developed this equipment are constantly refining and fine tuning their capability. We will keep on top of technical advances in this area of research, for instance Data Sci have now developed a radio-telemetry probe to constantly measure blood glucose concentrations. We will assess the benefits of this methodology and new developments in the field before progressing with the described protocols in this project. The LASA website highlights a number non-invasive alternative protocols and promotes the advances made with new in vitro techniques.

Home Office

NON-TECHNICAL SUMMARY

94. Investigating blood development

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Stem cells, Haematopoiesis, Zebrafish, Single-cell Transcriptomics, Blood

Animal types	Life stages
Zebra fish	adult, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand which genes are important to maintain the correct number of different blood cell types in a normal environment and under immune challenge.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the

duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

With the extraction of information from single cells, we will identify key genes and pathways that play a role in making blood cells. The results from this work will inform the ways to grow blood cells in vitro for use in regenerative medicine and will increase our understanding of mechanisms underlying blood pathologies.
What outputs do you think you will see at the end of this project?

This study will generate a number of valuable experimental and computational tools that will be made freely available to the scientific community. For example, we generated new computational tool to identify different cell types and genes that are necessary for development of these cell types.
Furthermore, we generated a user-friendly data storage for interactive exploration and visualisation of single-cell data from blood and immune cells in zebrafish.

The results from this work will inform the ways to grow blood cells in vitro for use in regenerative medicine and will increase our understanding of mechanisms underlying blood pathologies. We will develop a user-friendly website which will allow researchers to access and understand our data. Our project will open up a new field of research in lower vertebrates (e.g. killifish and other fish breeds) and is designed to allow other researchers to build on our achievements. Our website will allow researchers bringing expertise from related fields but without our background knowledge to immediately begin productive work.

We will present our research at a range of leading academic conferences to engage researchers from multiple fields in our research and ensure follow on use of the data made available through our website. We will also present at major conferences for commercial fisheries, e.g. Aqua-Fisheries.

We will present our research in high impact peer reviewed journals. This will ensure wide exposure for our research and encourage other researchers to further exploit our findings.
Who or what will benefit from these outputs, and how?

As this project tackles important basic questions, it has relevance to many people or groups who support and fund our research. Researchers will gain important insights into blood development and better understanding of the processes involved in blood diseases. Furthermore, our work would be of interest to those concerned professionally with breeding fish and fisheries, government departments concerned with food security, and the wider public interested in animal welfare, ecology, the food chain and broader scientific questions. These benefits would not be direct, but instead a long-term indirect benefit that will arise from the fundamental data our research will generate These researchers and industries will benefit because of the discoveries our research will lead to as we are studying the immune system of fish and its response to germs.
How will you look to maximise the outputs of this work?

We will maximise our output by presenting our work and ideas at national and international leading conferences. We will present both, positive and negative results to inform the research community of the drawbacks of different techniques and approaches.

Additionally, we will continue to work with researchers in the field which will enable the exchange of knowledge, ideas and techniques. This would maximise the quality of research in the field.

Species and numbers of animals expected to be used

- Zebra fish: ~11,200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Each day human body generates more than 200 billion blood cells. All these different blood cells perform various functions such as clotting of blood, fighting germs and carrying oxygen. Importantly, all these different blood cells also exist in zebrafish and perform similar functions. In this project we would like to understand how are these different blood cell types generated and how are their numbers regulated. To do this it is essential that we study these cells in their natural environment i.e. in the body of the fish. The system that uses cells made in a dish does not resemble the environment in which different blood cells are developing and functioning. To understand their exact function and origin, it is necessary they are studied in the context of the whole body as opposed to being studied in a dish.

Typically, what will be done to an animal used in your project?

For our first objective, fish will be killed using an excess of the anaesthetic and their blood cells will be isolated from different organs. We will then study the genetic material of these blood cells. The fish used could be at the embryonic, juvenile or adult stage. For our second objective, we will use the information we gained from studying the genetic material of blood cells and create animals where we alter their genes. These animals will be used to isolate distinct blood cells from zebrafish and to learn how different genes affect blood development. For this process, we will take blood from these fish and inject them into another fish i.e., recipient fish. Recipient zebrafish will be exposed to radiation and an injection of donor blood cells under anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of fish (94%) will experience no side effects, 5% of fish are expected to experience mild effects such as being unable to maintain skilful and effective coordination of movements. A small proportion of animals (under 1%) are expected suffer moderate effects such as reduced food intake and being unable to maintain skilful and effective coordination of movements.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of fish (94%) will experience no side effects, 5% of fish are expected to experience mild transient effects. A small proportion of animals (under 1%) are expected to suffer moderate effects.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

For developmental purposes, it is the interaction of different cell types in the blood of intact animal that controls most developmental choices. As we are intending to understand the function of genes that currently have no known function, it is essential to have every cell type of the whole animal present to detect the function of genes.
Which non-animal alternatives did you consider for use in this project?

After attempting to work with cells in a dish, we determined that dish does not resemble the exact environment in which different blood cells are developing in a body. Therefore, we need to use animals to fully understand how different blood cell are made. We will, however, use artificially grown blood cells from human to extend some of our findings and observations from zebrafish to human system.
Why were they not suitable?

They failed to produce the blood cells of interest which made it impossible to understand their origin and function.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

As my laboratory has been using the zebrafish model system for the last 8 years, based on previous data generated we estimated the number of animals that we will use.

We estimated ~11,200 would be sufficient to perform all the experiments and achieve the objectives outlined in this project license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals kept in the fish facility we aim to maintain the fewest number necessary to carry out a particular experiment by using computational methods. Furthermore, we use online tools such as NC3R's as well as PREPARE guidelines when designing an experiment.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to reduce the number of fish grown for experimental purposes, we standardised our protocols for clipping embryos at 3 days post fertilisation (dpf). The embryos are sorted as per their genetic makeup (before 5 days after they are born) and only the fish relevant for our research are raised to adulthood. This method reduces the number of fish being grown into adulthood.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

After attempting to work with an in vitro system (to grow cells in a dish), we determined that an in vitro system does not resemble the exact environment in which different blood cells are developing and therefore, would not be suitable for identifying cellular states that underlie blood development. We will, however, use in vitro single-cell differentiation assays of human stem cells to extend some of our findings and observations from zebrafish to human system.

We will be using zebrafish as a model system as these animals are less emotional compared to other model systems used in blood research (e.g. mice, rats, sheep, pigs, etc). We will preserve lines that are not currently in use by freezing the sperm of the male adult fish, thus only maintaining actively used animals in the facility. We will also re-use fish for gamete recovery which in turn reduces the total number of animals in the project.

Why can't you use animals that are less sentient?

We cannot use animals that are less emotional than zebrafish (e.g. fruitfly) as they do not possess all blood cells that human have.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will continue monitoring our fish daily by observing for any unexpected movements or behaviour of the fish (e.g. rapid opening of the mouth at the water's surface, unable to maintain skilful and effective interaction of movements, development of lesions). Additionally, after any time something is done to an animal it will be closely monitored for any signs of pain or distress so an early intervention can occur to stop this.

Fish receive brine shrimp and paramecia for enrichment. All fish are housed in male and female groups where possible to reduce egg bound females and ensuring natural behaviours. Breeding tanks are tilted to replicate a more natural environment. For example, actions such as waiting and circling are observed in a natural environment, but not in a lab due to the unnatural characteristics of the mating tank. By tilting the tank we mimic the bank of the Eastern India's Ganges river where zebrafish were originally found. The fish that are being identified for their genes are housed separately and are kept on the system so that they are able to receive food and fresh water.

In order to reduce the number of fish reared for experimental purposes, we standardised our protocols for cutting the tip of the fin of embryos 3 days after they are hatched. The embryos are sorted as per the gene they possess (before 5 days after they hatched) and only the required genotype (genetic makeup of a cell) are raised to adulthood. This method significantly reduces the number of fish being reared as genotyping at 3 days after they hatched eliminates the need to raise 100s of fish in order to genotype at 3 months of age. This is the main route that will be taken to genotype our fish. However, there will be occasions where it will not be possible to genotype our fish at 3 days after they hatched. For this reason, some fish lines will have to be genotyped at 3 months (adult stage), where a biopsy of the caudal fin (tail fin situated at the rear of the fish) will be taken. The caudal fin is used because there is no circulation and no nerves, therefore the procedure is painless for the animal. In conclusion, some fish will be finclipped at 3 days after they hatched, some will be genotyped at 3 months of age. Some fish will be phenotyped via fluorescence and in cases two fin clips will have to be done. Fluorescence is used for phenotyping fish (observable characteristics) that have their blood cells labelled with fluorescent protein. This fluorescent protein is part of genetic makeup of these fish and its fluorescence is used to select fish of interest in a way that is painless for the animal. All efforts will be made to ensure that unnecessary breeding of fish will be kept to the minimum.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continue using the NC3Rs website and keep up to the date with the PREPARE guidelines to ensure experiments are conducted in the most refined way in addition to following animal welfare information through the Laboratory Animal Science Association (LASA) website. Furthermore, we will also follow guidance on the housing and care of zebrafish
https://www.rspca.org.uk/webContent/staticImages/Downloads/HousingAndCareZebrafish.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs through newsletters received from the institute's aquatics facility as well as routinely checking the NC3Rs website. Additionally, advice and up to date information will also be obtained from the institute's named persons (e.g.: NACWO, NIO and NVS).

Home Office

NON-TECHNICAL SUMMARY

95.Investigating the efficacy and potential of a novel delivery system to transfer materials across the blood-brain barrier

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to use a novel delivery system to transfer abnormal proteins across the blood-brain barrier, to generate a more refined animal model for Parkinson's disease. The same delivery system could also be used to transfer compounds of therapeutic potential or imaging capability to the brain, to facilitate the development of drugs and biomarkers for several neurological conditions like Parkinson's disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

One of the main hurdles to brain research is the difficulty of bypassing the blood-brain barrier to facilitate the delivery of substances into the brain to be able to model neurological conditions, drugs to alleviate relevant clinical features, and biomarkers to track disease progression over time. Using Parkinson's disease as an example, this age-related neurological condition is defined by the presence of motor problems that are associated with the loss of a specific group of nerve cells in the brain producing a chemical called dopamine. Conventional animal models can be generated by specifically killing these dopamine-producing cells to reproduce motor abnormalities. Recent advances in Parkinson's research have however highlighted an important role of a protein called alpha-synuclein, which can cause many of the motor and non-motor symptoms when it starts to clump together abnormally. The blood-brain barrier crossing efficiency of the abnormal alpha-synuclein protein, as well as compounds designed to deter their formation, is very poor, meaning that they currently need to be delivered directly into the brain by surgery, thereby limiting their value in neuroscience research. To address this issue, in this programme of work we will harness the versatility of a novel delivery system to validate its capacity to deliver a variety of materials, such as in the first instance abnormal alpha-synuclein, plus drugs and biomarkers that can potentially be used to alleviate or to track alpha-synuclein pathology, into the brain following peripheral administration. In future we feel that this method of delivery into the brain could have much wider applicability.

What outputs do you think you will see at the end of this project?

The main limitation to develop better medications to help Parkinson's disease patients is the lack of good experimental models that fully reflect human pathology. At the end of this project, a more refined animal model of Parkinson's disease will be optimised and made available to the research community through open-access publications in academic journals. In addition to this, several novel therapeutics, repurposed drugs (medications that are approved by medical authorities for human disease conditions, but are not specifically licenced for Parkinson's disease), and novel imaging agents will initially be trialled in our cell models. These drugs and imaging agents that are verified in the lab will then be evaluated in our animal models in the hope to assess their efficacy in minimising the effect in the brain and behavioural functions that are related to Parkinson's disease. Data regarding the efficacy and tolerability of these agents will also be made available to the research community as well as to the general public.

Due to the limited funding currently available for this project, by the end of the current funding period we would have finished characterising this refined animal model of Parkinson's disease to aid further therapeutic development. Therefore, the identification of novel therapeutics, repurposed drugs, and potential imaging agents will be conducted in the lab in parallel to the characterisation of this refined animal model. We are, and will continue to actively seeking for further funding support, in order to be able to evaluate such agents identified

from our cell models in our newly refined animal model.

Who or what will benefit from these outputs, and how?

Research output from this programme of work will directly benefit scientists studying how the disease unfolds in the course of Parkinson's disease, scientists who wish to validate if their experimental therapies can help the disease in a relevant animal model, or clinicians planning to conduct further clinical trials to assess cell therapies in Parkinson's disease. Such data will be made available to the public through open-access academic publications.
For the drug screening and the development of imaging agents: any favourable outcomes indicating the safety and effectiveness in the animal model generated can potentially be translated to help Parkinson's disease patients in the future. My group is based in a research environment that is very experienced in conducting clinical trials in Parkinson's disease. It is therefore possible that research output from this project can be transferred to the clinical domain by the end of the 5 years period of this licence.

How will you look to maximise the outputs of this work?

Research output will be communicated through a number of routes to a range of audiences - including scientists, clinicians, as well as patients and the general public.
Scientifically, the work will be communicated primarily in the form of academic publications in open access journals as well as collaborations at the local, national, and international levels. Research outputs will also be distributed in national/international meetings, including those meetings which are organised by specific charities such as Parkinson’s UK or Cure Parkinson’s trust in UK. The work will also be presented in seminars both locally (within our own department and others within the University/Hospital), as well as in other institutions.
We will also communicate our work openly to the patient community through our social media outlets (e.g. the lab Facebook page), our annual newsletter that is sent out to all patients and their families attending our research centre, as well as our annual open days for patients.

Species and numbers of animals expected to be used

- Rats: 550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In most cases conditions that affect the brain, for instance Parkinson's disease, are not transmittable from parent to offspring, and does not pass down through families. Therefore, to model reliably the symptoms of this condition in animals, we need to use animals that sufficiently reflect the difference of genetic make-up between individuals. Animals known as ‘wild-type’ and ‘out-bred’ have this variability in their genes, and can therefore better represent the diversity that people have with each other and are best suited for modelling Parkinson's disease. Sprague-Dawley rats are a wild-type out-bred strain and are the best animals to use for this purpose.
It is now believed that changes in the brain cells in Parkinson's disease can happen many years before symptoms that affect the movement emerge, therefore in this programme of research animals will be lesioned at 3-4 months of age, and followed over time to track disease progression over the next 6-18 months. In addition, ageing is known to be the main risk factor to developing this condition, and on average symptoms of Parkinson's

disease are rarely observed in people younger than 50 years of age. Therefore, in some experiments lesion will take place at a later stage of life (e.g. 12 months of age), with close follow-ups over the next 6 months to determine if disease progression is accelerated.
On the other hand, for experiments that are designed to test cell therapies, rats that lack a fully functional immune system (such as the RNU rat model) are best to use as their immune system would not attack the newly implanted cells. These rats have been bred specifically for this type of work and lack a functioning immune system; were normal rats to be used they would require daily injections to suppress their immune system. However, in other experiments the use of wild-type rats with daily immunosuppressant injection is still required, as this will better reflect the daily injections given to Parkinson's disease patients after receiving cell therapy.
For the type of work outlined in this research programme, rats are better animals to use. There are several reasons for this. Firstly, rats are mammals and compare with using invertebrates that have a very different nervous structure, the use of mammals to develop a refined model of Parkinson's disease will minimise the risk of future translation into human studies. Secondly, compare with mice, rats are known to be less prone to stress through handling as they are more likely to create a bond with a single handler. This is beneficial as they will be kept and followed for a long time period. To reduce stress further, they will be handled by the same researcher whenever possible, as well as being housed in the same environment as they will have appropriate time to get used to it. Finally, rat brains are much larger than mouse brains, and would therefore provide larger and clear images for data analysis.

Typically, what will be done to an animal used in your project?

In a typical experiment, adult rats will be given an injection of a pathological substance (which is a substance that induces disease or illness) via the tail vein (and occasionally into the brain as well), with the intention that the disease will emerge and progress over the next 6-18 months (depending on which protocol is used, as some protocols allow for animals to be kept until 2 years of age and others only until 15 months of age). Over this entire period, animals will be followed closely for any signs of deterioration of their movement and memory functions using behavioural testing, in order to determine the optimal period for giving medications to alleviate the symptoms. These medications will be identified in the laboratory using cells grown in a dish, and will then be given to the lesioned animals through routes of administration appropriate for individual medications. This includes delivery via food or drinking water, injection at regular intervals, or those that have to be delivered directly into the brain such as cell therapies. In order to track disease progression over time, some of the lesioned rats will be followed by preclinical imaging analysis, including positron-emission tomography (PET) or magnetic resonance imaging (MRI), in order to help develop biomarkers (an indicator of a particular disease state) to monitor the changes in their brain function over time. By the end of the experiments, animals will be killed humanely to correlate behavioural changes with disease features in the brain.

What are the expected impacts and/or adverse effects for the animals during your project?

For the majority of the animals we anticipate no or very little adverse effects to occur. However, after the disease has started and as the animals age during the experimental period, we expect to see clinical signs that are similar to those seen in Parkinson's disease patients. These include: reduced motor activities, reduced gripping capacity, suppressed limb coordination, abnormalities in the pattern of movement, and memory dysfunction. They may also incur adverse effects not associated with the disease itself but those relating to the ageing process, such as tumour formation (most commonly benign mammary tumours in rats) or weight loss. Animals will be closely monitored with veterinary involvement, and animals will be killed if weight loss reaches 15% or the position of a tumour reaches 40mm or affects behaviour such as normal movement.
In addition, some animals will undergo surgery, this may create discomfort in the immediate postoperative period, during which time pain relief will be provided. They may show reduced or altered movements after surgery, where they have received a lesion (cell damage) to mimic an aspect of the human disease. These animals may later receive a treatment to repair the lesion given, such as cell transplantation or drugs that we have tested in the lab. Animals are expected to have mild to no lasting adverse effects after they have recovered

from the surgery itself. Treatments are also likely to result in no adverse effects but if any should arise, they will be monitored for up to 24 hours, in close liaison with the vet. If no improvement is seen during this time then the affected animals will be killed humanely.
In order to study the Parkinson's disease-like clinical signs in our animals, some of them will undergo food restriction to motivate their performance in behavioural tasks which are reward-driven, and they will be carefully monitored to ensure that no sign of dehydration occurs, and any weight loss is kept within a defined limit. We expect no adverse effects associated with the behavioural tests used in this study.
At the end of study all animals will be killed humanely, and tissues will be taken for further investigation in the laboratory.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Only adult rats will be used for all experiments.
For those experiments that are related to disease modelling, most animals (more than 50%) will experience a mild degree of severity. Some animals (less than 50%) will experience a moderate degree of severity that is related to either the ageing process itself (when animals are kept for longer than 15 months of age), or related to the procedures performed on the animals.
For those experiments that are related to treatment most animals (more than 50%) will experience a mild degree of severity. Some animals (less than 50%) will experience a moderate degree of severity that are related to the treatment, such as the injection of cells directly into the brain, or repeated administration of medications at regular intervals. No aged animals will be used for trialling treatment.
For those experiments that are related to testing imaging agents for the first time in animals, animals will experience a mild degree of severity when given the disease lesion but the administration of the imaging agents will be done using a procedure where the animal doesn't wake up. This is to assess the impact of these imaging agents on vital signs of life, without causing unnecessary suffering of the animals. Once considered safe these imaging agents will then be used in the other protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The blood-brain barrier is a highly selective border that separates the circulating blood from the central nervous system. There is currently no cellular model of the blood-brain barrier that provides sufficient level of "tightness" and "selectivity" to study the novel delivery system. Furthermore, the risk of developing Parkinson's disease increases with age. While the use of cell cultures can provide important insights into studying particular aspects of this condition, they can only reflect the early stages of development. It is therefore essential for Parkinson's research to use animals to model the disease condition, to be able to look at the adult/aged nervous systems that are affected by the disease. Another main reason is that Parkinson's disease is defined by the presence of behavioural abnormalities. It is very difficult to study how cells respond to the disease condition in the "behavioural" domain, driving the necessity of the animal model to be able to model accurately and analyse the disease.

Which non-animal alternatives did you consider for use in this project?

My group is currently using cellular models to facilitate the screening of drugs and useful cell therapies, including those that are already licensed for use in the clinic but not for Parkinson's disease. This will help minimising the number of animals we need to use for our research, as only drugs with proven protective activities will be brought forward to animal testing. This same cell culture system will also be used to aid the development of novel markers to track disease progression in animal studies. In addition, we use post-mortem brain samples donated by Parkinson's disease patients and healthy individuals to understand the disease features in the brain. A cross reference between cellular models, post-mortem analysis, and animal research will help ensure the data we generate will be useful to reflect the conditions experienced by Parkinson's disease patients, and will therefore facilitate the development of new drugs.

Why were they not suitable?

As indicated above, we are currently using cells in vitro and expose them to toxic proteins that are known to play a key role in Parkinson's disease to model this condition. However, these cells lack the "ageing" component, which is the main risk factor to the development of Parkinson's disease. We are also using post-mortem brain tissues to verify our findings in cellular models. However, it is impossible to test treatments fully in non-living tissue. Computer modelling is used by some to look into modelling the disease but anything that is found has to be verified using animals prior to use in humans. Therefore, the use of animal models of this disease condition and in which to test new drugs remains unavoidable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in this project is estimated from our previous experience on data analysis, which provides information to predict the minimal number of animals required for each experiment. We also take into consideration the number of experiments we expect to perform, based on the projected funding availability. We have access to statistical advice and will seek it whenever necessary.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have conducted pilot studies under our previous project licenses to obtain preliminary data on the degree of behavioural deficits expected. Such information is then computed using GLIMMPSE <http://glimmpse.samplesizeshop.org> for calculating sample size for repeated measures and longitudinal designs. Further advice on statistical design and analysis can be obtained easily in the establishment, for instance through the establishment's statistics clinics, run by the Faculty of Mathematics which provides a free, walk-in statistical consulting service to university members. Similarly, there are biostatistical assistance provided on-site, to whom I can seek help when necessary. The use of the Experimental Design Assistance from the NC3R website <https://www.nc3rs.org.uk/experimental-design-assistant-eda> will be adopted whenever appropriate. Similarly, animals will be randomised and the experimenter will be blinded when analysing the results, so accurate information can be obtained without bias.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In addition to the use of pilot studies to generate data for statistical analysis, the animals will be followed longitudinally to reduce individual variance. The use of animals will be further optimised by employing preclinical imaging, such as the use of positron-emission tomography (PET) or magnetic resonance imaging (MRI), as well as tissue sharing (such as repeated blood sampling), in order to study disease progression over time.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In this project we will use the novel delivery system to model Parkinson's disease in two ways: (a) by delivering toxic proteins, such as an abnormal form of alpha-synuclein, into the circulation by directly injecting into the tail vein; and (b) by combining the peripheral injection with a direct injection of other toxic chemicals into the brain to more kill the dopamine-producing effectively in the brain. The delivery of these substances through the tail vein will create less suffering and distress to the animals compared with other methods typically used. However, a direct brain injection will occasionally be required to either generate a more substantial level of cell loss, or for treatments that cannot be administrated by other means (such as cell implants). Cell implants are made into areas of the brain where cell damage and death has been caused previously and the intention is for the implanted cells to repair the damage previously made. Where surgery is performed it will be undertaken using strict aseptic surgical technique to minimise the risk of infection, and the animals will be closely monitored before and after the procedure, in order to minimise the level of suffering and to ensure there is no lasting harm to the animals. For all surgical procedures, animals will be given pain killers to minimise the pain they may encounter when they recover.

Why can’t you use animals that are less sentient?

To study a novel delivery system that can facilitate the transfer of materials across the blood-brain barrier, we will need to use a mammalian species that has an intact blood-brain barrier and has been established as a research model for this purpose.
In addition, as the risk of Parkinson's disease increases with age, it is relevant to study the disease and develop novel treatments that affect a mature/aged nervous system. Furthermore, Parkinson's disease is a long-lasting condition that progressively evolves, it is therefore essential to monitor behavioural changes in live animals over time. The rat model we want to generate is therefore the least sentient beings still able to mimic Parkinson's disease. When using non-mammalian species, the issue that will arise is that any novel treatments found cannot be directly translated into a human setting.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Harm to the animals will be minimised by the use of the least invasive (e.g. tail vein injection versus brain surgery) route of administration to deliver the substances that induce the Parkinsonian features wherever possible. With help from the establishment's biofacility staff, our animals will be closely monitored on a daily

basis so that any signs of pain and/or distress will be dealt with in a prompt and effective manner. Animals will be weighed at regular intervals and signs of any adverse effects will be monitored in direct liaison with the vet, to ensure that any welfare costs are kept to the minimum.
For the administration of novel compounds, pilot studies involving only a small number of animals will be tested first. These experiments will also be done using a procedure in which the animal doesn't wake up but their vital signs of life can still be assessed, in order to examine the tolerability of these novel compounds to the animals. This will determine the optimal dosage without creating unnecessary welfare costs to the experimental animals.
Animals will also be housed in groups whenever possible, with environmental enrichment provided after discussion and recommendation from the Named Animal Care Welfare Officer and senior technicians from the establishment's biofacility.
If the Parkinson's disease model created shows definitive clinical signs in animals over time, then an assessment/scoring system will be developed to refine the humane endpoints for future projects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Experimental design will be done in light of the newly published PREPARE guideline, as well as using the NC3Rs Experimental Design Assistant <https://www.nc3rs.org.uk/experimental-design-assistanteda> wherever appropriate. Delivery of substances directly into the brain will be done using aseptic techniques, in line with the LASA Guidance on Aseptic Surgery. All the experiments will be conducted, with the results analysed and reported in accordance with the ARRIVE guideline.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our primary source of 3Rs information will be the NC3Rs website. Researchers involved in this project have access to the establishment’s biomedical services website and receive regular 3Rs updates. More specific advice can be found on the 3Rs search tool on the establishment’s biomedical service website, which provides an abundance of 3Rs information from worldwide websites. Finally, researchers involved in this project will also have constant dialogues with the biofacility staff in order to stay informed about effective implementation of the 3Rs. Such advances will be done in liaison with the Named Animal Care Welfare Officer, vet, and biofacility staff, throughout the duration of this project.

Home Office

NON-TECHNICAL SUMMARY

96. Investigating the mechanistic drivers of neuropathic pain and treatments to reverse them

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Neuropathic pain, Sensory biology, Chemogenetics, Analgesia

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We do not have a clear understanding of the how the nervous system is organised to facilitate the sensation of touch, temperature, itch and pain. We aim to define the contributions of different classes of primary afferents (the nerves responsible for detecting sensory stimuli) and how their signals are integrated in the spinal cord. This work will underpin our concurrent studies seeking to define how changes in this processing results in neuropathic pain and testing treatments to reverse these changes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neuropathic pain results following damage to the nervous system and is a major burden on society, affecting roughly five million adults in the UK. The majority of patients live with chronic and often debilitating pain because current medications are ineffective. Even the most effective analgesic only provides clinically relevant pain relief to 1 in 5 patients. Only when we have a good understanding of how the nervous system is organised to signal normal and neuropathic pain, will we be best placed to design more effective pain-relieving medications.

What outputs do you think you will see at the end of this project?

Work completed under this license will provide information on how we are able to detect sensory signals such as touch, temperature, itch and pain. It will also reveal what goes wrong in this system in the context of nerve injury and the changes which occur that lead to neuropathic pain. Finally, we will test the effectiveness of novel approaches to reverse such changes and their potential as analgesics. Outputs will take the form of publications in peer reviewed journals, abstracts at national and international meetings, and technology development.

Who or what will benefit from these outputs, and how?

In the short term, outputs will have a major benefit for other researchers in the pain field. Our data will allow research and translational efforts to be focussed on the parts of the nervous system that are driving neuropathic pain. During our studies we will test novel approaches for the reversal of pain and so our outputs will benefit drug discovery programmes of biotechnology and pharmaceutical companies. In the long-term, the consequence of both of these benefits will be to improve patient care and meet the clinical need of neuropathic pain.

How will you look to maximise the outputs of this work?

We will maximise outputs of this work by collaborating with other groups in the field of pain research.
Data will be published in international peer reviewed journals and data will be freely provided with an "Open Access" ethos. Unpublished data will be presented at national and international scientific meetings to ensure that it is available to other researchers in the field. We will also participate in open days and other forms of public engagement, to disseminate our work and contribute to public awareness.

Species and numbers of animals expected to be used

- Mice: 7500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse sensory nervous system has been demonstrated to be comparable to human in most tested aspects and there is a large pre-existing knowledge base which will be used to maximise the outputs from this project. Mouse models of neuropathic pain are commonly used and have been designed and refined for clinical relevance. The sensory disturbances that they exhibit mirror many features of human neuropathic pain patients, including exaggerated responses to evoked-pain and spontaneous pain. We will turn off the electrical activity of specific nerve populations to understand the role they play and require genetic strategies to do so accurately. This is only available in a few organisms, of which the mouse is best placed due to the previously mentioned reasons. Neuropathic pain occurs in patients of all ages prevalence increases with age. Therefore we will perform studies with all ages of animals.

Typically, what will be done to an animal used in your project?

The majority of animals will not undergo any procedures which result in adverse effects as they will be born in the process of generating experimental animals. Experimental animals will typically undergo a short surgical procedure to deliver an agent which can silence specific groups of nerves. They will then undergo reflex withdrawal testing of their sensory perception while silencing is activated, in order to ascribe function to the silenced nerves. In some cases, testing will occur when the animal is in a neuropathic state; induced by lesion of a peripheral nerve, diabetes, or administration of a chemotherapeutic drug. In the majority of cases, the time from delivery of the silencing agent to humane killing will be 6 weeks. In cases of delivering agents to neonatal animals, or in studying the long-term consequence of nervous system damage, studies may take up to 14 weeks. However, these cases will be rare and kept to a minimum.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals will not experience adverse effects. Neuropathic experimental animals will experience sensory disturbance consistent with the human experience. These include hyper- or hyposensitity to sensory stimuli and a degree of ongoing pain in some of the models. These do not impact the behaviour or general wellbeing of the animal in terms of feeding or grooming and will be time limited (4 weeks in the vast majority of cases). Models of Type 1 diabetes and animals which receive chemotherapy agents can suffer from weight loss, which we will monitor for very carefully. Surgical procedures may induce transient discomfort (up to 24hrs), but we will provide analgesics to provide pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild- 70% of animals

Moderate- 30% of animals

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal use is necessary to address the functional roles of primary afferents during normal and neuropathic pain. Microneurography studies in humans have defined the response properties of classes of afferents in healthy patients and those suffering from neuropathic pain. They have, for example, been used to demonstrate that following nerve injury, excessive primary afferent activity occurs which correlates with the pain experienced by the patient. Limited interventional studies have also been performed, such as using local anaesthetic nerve block to demonstrate that this excessive activity is critical for pain. However, this approach is not suitable to define the contributions of precise nerve sub-populations and therefore we require use of genetically modified rodent models, in which discreet nerves can be targeted for manipulation and studied.

Which non-animal alternatives did you consider for use in this project?

There exist several replacement alternative experimental models which we will take advantage of, but which cannot be used to fully replace the animal studies.

Primary afferents derived from mouse sensory ganglia and cultured in vitro represent a useful experimental tool and a partial replacement of animal studies. We will use these where possible to define key molecular pathways that contribute to primary afferent signalling and to assess the consequence of treatments to alter intrinsic properties.

Induced pluripotent stem cells (iPSC) differentiated into human primary afferents, represent a powerful cellular model that replicates many of the features of endogenous primary afferents. As a key component of our work is to translate novel analgesic treatments, we will use these cells as a platform to validate findings across species and to provide a replacement of animals where appropriate.

Why were they not suitable?

Normal and pathological sensory perceptions are complex phenomena and involve the whole sensory nervous system axis; spanning the detection of sensory stimuli in the periphery, to the conscious perception in the cortex. As such, certain features can only be adequately assessed in vivo. Many of the relevant processes involve multiple connections of nerves and interaction with other cell types, which cannot yet be modelled in the in vitro systems described above. Primary afferents are highly heterogeneous, and while iPSC-derived human primary afferents model select sub-populations well, protocols do not exist to derive the full diversity present in sensory ganglia.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals optimally required for each aspect of the study have been added together. These calculations underpin our estimate of usage and numbers are in line with our previous experience of similar studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design and data analysis was discussed with a local statistician prior to drafting of this application. The Nc3Rs Experimental Design Assistant was used to design some experimental paradigms.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To optimise the number of animals used, as much work as possible will be undertaken in cellular models before moving to animal models. For example, we will screen the effectiveness of delivery systems and novel therapeutic agents in stem cell derived neurons to ensure that they function as we would expect. This approach will help remove ineffective approaches from testing in animals. We will ensure optimal breeding strategies of transgenic animals in order to reduce the number of animals bred of a genotype not required for experiments. We will openly share tissue and data with other laboratories working in the field of sensory neuroscience to ensure that animal experiments are not replicated across locations.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.
