We will use mice which allow us to target silencing agents to specific groups of nerves, in order to study the roles of these nerves. None of these animals will experience any adverse harmful effects as a consequence of the genetic alteration that they carry. In the majority of cases, animal sensory perception will be measured by testing of reflex withdrawal thresholds i.e. at what level of a stimulus does the animal withdraw their hind paw? By halting the stimulus as soon as a withdrawal is made, we will ensure that the minimal level of stimulus is used to characterise sensory perception. Some mice will be used to experimentally model neuropathic pain. Such manipulation may occur in a variety of ways. Genetically altered animals with a predisposition to develop diabetes (and consequently, painful diabetic neuropathy) are a great refinement on classical toxin-based models of diabetes and result in less severe hyperglycemia, do not include the direct neurotoxic actions of drugs and therefore much better model human diabetes. Some animals will be treated with chemotherapeutic agents to mimic chemotherapy-induced neuropathy. In all cases, agents will be used at doses which induce the neuropathy, but are limited for their impact on the general wellbeing of the animal. Finally, some animals will undergo surgical lesion of nerves, to model traumatic nerve injury induced neuropathic pain. Such surgical interventions are well established models which have been refined for decades and across many laboratories, to best replicate the human condition and refined to minimise animal suffering. In all cases, we will monitor for any evidence of undue animal suffering and act swiftly to minimise this, in most cases by humanely killing the animal.

Why can’t you use animals that are less sentient?

Mice are the most commonly used animals for study of the somatosensory nervous system, because there is vast prior knowledge on their physiology. This foundation of knowledge has accelerated new advancements in the field. In most tested instances, the peripheral nervous system of mouse and man have been found to be highly similar and this is particularly true in the context of nerve injury and pain. Less sentient organisms e.g. fruit fly, can detect sensory stimuli and are amenable to genetic manipulation. However, their nervous system architecture and physiology is very different to that of mammals and is not suitable to address the questions of complex neural processing posed in this project. We will perform some studies under terminal anaethesia to investigate the cellular changes that occur upon certain stimulation. However, this only provides an indirect

measure of the sensory experience and so behavioural studies on awake animals are also required.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will follow robust standard operating procedures for handling, monitoring and general care of animals. For example, prior to behavioural studies animals will be habituated to researchers to reduce stress and anxiety levels during handling and testing. All staff members involved in animal studies will have substantial experience in husbandry or will be trained to such an extent prior to undertaking any work in this project. Strict monitoring of animals will occur, especially in cases of experimental manipulation which have the potential to alter animal behaviour. Where appropriate (e.g. before, during or after surgery) preventative measures (e.g. anaesthesia, fluid replacement, pain relief and heated cages) will be used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will perform all studies in line with published (NC3Rs) and local guidelines. In particular we will adhere to the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines) on the reporting of scientific studies involving animals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will perform all studies in line with guidance found on the NC3Rs website and in the published literature. We will also monitor our local 3Rs webpage and attend 3Rs days run by our institution.

NON-TECHNICAL SUMMARY

97. Investigating the role of cellular stress in neurodegenerative diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will examine the impact of stress at a cellular level on the development of neurodegenerative diseases such as Alzheimer's disease and motor neurone disease. It will help us to understand how environmental factors that lead to cell stress might be involved in the development of these disorders.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Neurodegenerative disorders are a large and growing financial and emotional burden on society, with as yet only limited palliative treatments. Understanding more about how these diseases progress, and how different factors such as cellular stress may be involved will provide us with crucial insight into the disease mechanisms, and hopefully yield new novel targets for the development of treatments.

What outputs do you think you will see at the end of this project?

Outputs will include new information regarding how cells in the brain respond to acute stress such as fever, how this response is affected by aging, and whether this response might be involved in the progression of diseases such as Alzheimers and motor neurone disease. It will also aim to validate the use of specialised slice cultures as an alternative to live animal models for this kind of research. It will lead to several publications that will advance our understanding of how cell stress may be linked to disease, and help us understand more about the mechanisms that underly this interaction.

Who or what will benefit from these outputs, and how?

Initial benefits (obtained throughout the course of the project), will be seen by other researchers in the field of neurodegenerative diseases, as we will provide information to improve our understanding of what may go wrong as we age to lead to these diseases. We will also validate a model as an alternative to live animal research, which will be of benefit to researchers, and hopefully lead to a reduction in total animals used in this area of research. Longer term (over the course of the project and beyond), data obtained from this project may provide us with new targets to try to develop therapeutics to treat neurodegenerative diseases such as Alzheimers and motor neurone disease.

How will you look to maximise the outputs of this work?

All data obtained in this work will be widely shared throughout the academic community, with the goal of publishing all findings, positive or negative, in relevant scientific journals. As new findings are obtained, collaborations with both local colleagues and those further afield will be sought out to further develop our research. In addition, efforts will be made to engage with the local lay community to share any findings of interest, and in cases of specific interest to patient groups, we will liaise with the appropriate support group to try to disseminate the relevant information widely and accurately. **Species and numbers of animals expected to be used**

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will work with adult mice as we are interested in how changes in our environment that result in stress to our cells, can impact on the function of proteins that are known to be important in diseases such as Alzheimer's and motor neurone disease. Since these diseases are known to be related to aging, we are also interested in whether the effects of this cell stress are changed as we age, hence some mice will be aged. The mouse has been selected as they possess a brain region called the cerebral cortex, which is only found in mammals, and this region is preferentially affected in many neurodegenerative diseases. Some mice in this project will have genetic alterations to allow us to understand more about the human version of a disease linked protein, or to more easily be able to identify and track the protein of interest in our studies. Understanding the cell mechanisms that may underlie an altered risk of developing a disease such as Alzheimer's may help us to develop new drugs to treat the disease.

Typically, what will be done to an animal used in your project?

The work planned in this project falls into three categories:

1. Normal and genetically modified mice will be exposed to a single short (2h max) period of increased temperature (42^{o}C max) designed to raise their core body temperature. They will be left to recover for a maximum of 48 hours before they are culled for tissue collection.

2. Normal and genetically modified mice will be exposed to a maximum of 6 short (2h max) periods of increased temperature (42^{o}C max) throughout their life-time. They will be aged out to a maximum of 2 years old, and during their life around half of these animals will undergo behavioural tests to look at how well their brain works. These tests will include tests of memory, and tests for mobility. In most cases, mice will be tested 4 times in their lifetime.

3. Neonatal normal and genetically modified mice will be culled prior to weaning to provide tissue for further study.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals undergoing a heat exposure may experience increased lassitude and discomfort during the procedure, however, this is expected to dissipate rapidly once they are returned to normal room temperature, and all animals are expected to return to normal within 30 minutes, with no long term consequences of either a single or repeated exposure.
Animals on this project that are maintained out to old age may develop various age-related issues that are common to mice, such as benign tumours or hair loss, and in some cases sore patches on the skin. If these effects are only mild, and cause minimal distress, the animal may be maintained for several months, however, if any of these issues are thought to cause significant pain, discomfort or distress, the animal will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The genetic modifications used in this project are not expected to have more than a very mild impact on the

general health and welfare of the animals. The acute effects of heat exposure are expected to result in moderate but transient discomfort to the mouse, hence all animals undergoing this heat exposure (approximately 50% of the experimental animals to be used on this project) would be classified as falling into the moderate severity category. All other animals are not anticipated to exceed a mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project is interested in the impact of cellular stress on brain function, and whether it might interact with the aging process to alter our risk of developing diseases such as Alzheimer's and motor neurone disease. One part of this project is designed specifically to understand how the cell stress response might function in the brain of a live animal, to improve our knowledge of this process, and also to explore whether we can successfully model this response using non-animal models. Another part of this project is interested in the long term consequences of a cell stress response on the function and dysfunction of proteins known to be important in neurodegenerative diseases, and how it might be altered as we age. This requires us to be able to study the brain throughout aging. Both the complex circuitry of the brain and the process of aging are challenging to model outside of a living animal, hence using animals is the only way to address these questions. Finally, we are also interested in understanding how any brain changes we see may relate to changes in behaviours such as learning, and these characteristics can only be measured in a living animal.

Which non-animal alternatives did you consider for use in this project?

Various cells, including stem cells (grown in a dish).
Brain slice cultures (thin slices of brain that are grown in a dish).

Why were they not suitable?

A part of this project is designed to try to validate cell or slice culture alternatives as a suitable model system to address some questions posed in this project, and where possible, these cultures will be used in place of live animals. Basic cell and stem cell cultures can provide information regarding what happens within a single cell, while brain slice cultures can provide information about local cell networks. However, neither of these options can fully mimic the impact of interactions between the millions of cells within the brain, and also how communication with, and the function of other parts of the body can impact on the brain. In addition, neither cells nor brain slices can give us any information on the practical behavioural consequences of any changes we see.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

Numbers to be used on this project have been estimated based on total numbers planned for the various different experiments to be conducted under the remit of this licence, as well as the number of animals likely to be required to maintain different lines of genetically modified mice. Initial studies have been designed to use the minimum number of animals assessed as being required to reveal any significant changes in response to the experimental protocol. For the longer term studies, numbers have been selected based on assessment of similar types of measurements in previous studies, and aim to be the minimum number of animals needed to identify whether a statistically relevant difference exists between the different experimental groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the design phase of each experiment, appropriate searches were done on each mouse line of interest to ensure we had access to all relevant information regarding expected outcomes in these animals. This was combined with more general knowledge on how much variation there is between control animals for each of the factors being measured. Extra consideration was made for a number of variables we control, including sex, age and background strain. The statistical approaches to be used at the end of the study formed a major part of the experimental design process, ensuring that all experimental approaches are robust.
The experimental design was also discussed with other researchers familiar with these kinds of studies, to further validate the design, and to ensure that we had included adequate control groups to each experiment, such that all data obtained will be valid.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As far as possible, all experiments will be conducted longitudinally, to allow us to maximise the data obtained from each animal. For tissue harvest, all organs of interest will be harvested from each animal, and experiments will be designed to allow multiple follow ups in the tissue from each animal, thus minimising the total number of animals required.
Where relevant, small scale pilot studies will be conducted prior to each full scale study, with follow up analyses to ensure both that the objective is a valid one, and also that experimental design can be optimised to use the minimal number of required animals. This will ensure that unnecessary large scale experiments do not take place.
As far as possible, breeding strategies will be designed so that all animals from a mating are used for an experiment, and for general maintenance of a line, animal breeding will be monitored and controlled to ensure that we obtain sufficient mice to maintain the line, while minimizing the birth of mice that are not required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain

management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the work planned in this project will use mice. These include healthy control animals and genetically modified mice that contain human and or tagged versions of proteins linked to neurodegenerative diseases. These genetic modifications are not anticipated to result in any significant distress to the mice, as the proteins will be the normal, healthy proteins. Rarely, the expression of the human version of the protein, or increased levels of total amounts of the protein, might result in very mild clinical symptoms as the mouse reaches old age, but this is anticipated to be very mild, and will not impact on the ability of the mouse to feed, drink and move freely about their cage.
To induce the cell stress that is central to this project proposal, the majority of live mice used in this protocol will be exposed to a chamber heated to 42^{O}C for a maximum of 2h, and in some cases, this may be repeated up to 6 times in their lifetime. This is expected to result in transient discomfort to the animal during the procedure, but will not cause any pain or significant suffering, and is not expected result in any lasting harm to the mice.
Where possible, tissue will be harvested from neonatal animals for follow up study, rather than conducting the work in live animals. The use of this model will ensure that animals do not experience any distress or suffering as a result of the experimental aims.

Why can’t you use animals that are less sentient?

This study is interested in how cellular stress impacts on the functioning of the brain throughout aging, and specifically how it interacts with proteins linked to neurodegenerative diseases, and how this interaction might affect disease relevant processes. Where possible, embryonic or newly born animals will be used to generate specific cell or brain cultures for investigation. However, the specific impact of cell stress to brain cells in vivo, either acutely or through aging over the longer term, can only be measured by exposing live animals to a cell stress induction. Since the brain region of specific interest to most neurodegenerative diseases is the cerebral cortex, only mammalian species which contain this can be used for this work.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The core body temperature of animals experiencing hyperthermia will be frequently monitored throughout the heat exposure and during the recovery period, and compared to baseline readings obtained prior to the procedure. Animals will only be left unattended once they have returned to their standard temperature. If the temperature or duration is found to cause unexpected distress, it will be immediately terminated, and future experiments modified to minimise such welfare costs.
Any animals undergoing frequent handling as a part of the experiment will be handled regularly prior to the start of the experiment, to ensure that this process does not induce unnecessary anxiety or stress to the mouse. In addition, all mice will receive appropriate training for all behavioural tasks prior to the onset of experiments, both to minimise anxiety and stress, and also to improve outcomes, which should ensure consistent data from all mice, and hence allow the use of the smallest number of tests and animals.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All work will be conducted following the general principals of the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

I will regularly check the NC3Rs website for updates, as well as liaising with both our NTCOs and our local NC3Rs regional programme manager. Any relevant changes will be implemented immediately for all new experiments, and consideration will also be given to implementing changes to ongoing experiments, provided any such change is not expected to have an impact on the animals such that it may alter research outcomes.

Home Office

NON-TECHNICAL SUMMARY

98. Investigating the role of physical cues in nervous system function in wild type and transgenic animals

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants.

Key words

CNS development, neural disorders, mechanotransduction, mechanobiology, atomic force microscopy

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our brain is the most complex organ in our body. How nerve cells know where to send their long extensions called 'axons' to connect to distant cells is currently still poorly understood. To investigate how the growth of nerve cells is controlled during embryonic development and after injury, we combine approaches from biophysics and engineering with state-of-the-art cell and molecular biology. We are mainly interested in how the local stiffness of the surrounding tissue regulates neuronal behaviour, and how nerve cells sense the stiffness of their environment. The long-term goal of this research is to discover new mechanisms controlling the growth of nerve cells. This is important for fundamental research and might help us to understand how the brain develops. It might also help to develop novel strategies to promote neuronal regeneration after, for example, spinal cord injuries.
The questions that we want to answer within the lifetime of this project licence are:

- What are the mechanical properties of tissue and cells in health and disease?
- What is the role of physical cues in shaping the development of the nervous system?
- Do physical forces affect the behaviour of single cells?
- Does the stiffness of the surrounding environment affect intracellular mechanisms that direct cellular functions?
- Do different pathological processes affect neural functions through changes in the physical properties of their surrounding tissue?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

During the development of the nervous system, the nerve cells build long extensions (axons) which connect different areas in the brain. Only if the correct areas are connected with one another will the brain work properly. Previous work has shown that axon growth is strongly influenced by the mechanical properties of the surrounding tissue. We now aim to understand how tissue stiffness regulates neuronal function. By answering the questions above, we will contribute to a better understanding of brain development and neuronal growth. Our fundamental research may also lead to break-throughs in our understanding of different pathological processes in the nervous system such as, for example, neurodegenerative diseases or spinal cord injuries, which currently bind patients to wheelchairs for the rest of their lives.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

4760 mice
1150 rats
2650 Xenopus (frog)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

We will need to breed and maintain genetically modified (mice, Xenopus) and non-modified animals (rats and mice, Xenopus). These protocols are expected to have minimal or no impact on the health and welfare of the animals.
In exceptional cases, a moderate impact on their health and welfare might be reached due to the nature of the genetic alteration. Specifically, in the wobbler mice used to investigate the impact of tissue stiffness on the onset and progression of a neurodegenerative disease, the degeneration of nerve cells may result in symptoms which strongly resemble amyotrophic lateral sclerosis (ALS). Clinical signs include reduced bodyweight, unsteady, wobbly gait, and reduced muscle strength of the head, neck and forelimbs. These animals will be closely monitored and humanely killed when weight loss reaches or is likely to exceed 15% of their initial weight. Furthermore, wobbler mice will be regularly assessed for both paw condition and gait impairment and be humanely killed as soon as either reaches a predefined severity level or if the mobility of more than two limbs is affected. Occasionally, wobbler mice may show eye infections due to grooming problems (< 5%). If the infection persists for more than three days despite treatment, the animal will be killed. Very rarely, wobbler mice may have seizures or show signs of laboured breathing (< 1%). These animals will be killed immediately.
We will induce superovulation in female frogs and mice. This means that we will administer a specific drug to females, which induces a stronger production of egg-cells and therefore a larger number of offspring. Minimal or no impact on the health and welfare of the animals is expected.
In order to breed some of the genetically altered mouse strains, we will need to order embryos which will be implanted into pseudo-pregnant mothers which will eventually give birth to the offspring, which is later used for breeding and maintaining the rest of the mouse colony. Since one method used requires a surgery this can affect the health and welfare of the animal. However we minimise this by using good technique and pain relief after surgery.
In order to induce a pseudo-pregnancy in a female mouse, we need to sterilize male mice that will be held with the females. This is essential because the female hormonal system changes in the presence of the male, resulting in the acceptance of the embryos in the female. Since the sterilisation method used requires a surgery this can affect the health and welfare of the animal. However we minimise this by using good technique and pain relief after surgery.
We will use genetically altered mice as well as genetically normal (wild type) rats and mice on this licence. Where it is necessary to use immature cells, pregnant dams will be killed after they have been anaesthetised before the pups are removed from the uterus and killed for use in our experiments.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Our work is set up to minimise the number of experiments with living animals whenever possible. We will make extensive use of cell culture when observations in the living animals will not be crucial. Unfortunately, we cannot replace our animal work completely with cell cultures (i.e. cells that are grown in dishes in the laboratory), due to the lack of available cell lines that are relevant to neuroscience studies. Our studies in living animals and in cell cultures will be accompanied by in silico models (i.e.
computer-based studies and simulations that do not require animal use), which will replace some experiments, and help us make informative predictions to only pursue promising experimental conditions.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Experiments will first be run as a pilot study with a minimum number of animals, taking into consideration good experimental design principles, including randomisation (random allocation of animals or tissues for experiments) and blinding (keeping researchers unaware of the experimental treatments until the study is over) to prevent potential bias of researchers and increase confidence in the conclusions of our studies. Successful pilot studies are the basis for standardising the protocol which reduces variability and mistakes, by using biostatistics approaches and principles of good experimental design. Importantly, in all our experiments we try to retain tissues for later use, and to share tissues among researchers whenever possible. Finally, in the context of frog experiments, our researchers arrange their experiments on the same days to minimise the numbers of frogs undergoing procedures as frogs lay thousands of eggs at a time.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We will always use the animal species of the lowest possible complexity. Wherever possible, we will work with frogs, an excellent animal model for studying the development of the nervous system, especially in the context of the optic pathway. The Xenopus optic pathway, where neurons from the retina grow along the brain to connect with the optic tectum (the analogous of the visual cortex in humans), is one of the best understood systems in the field of axon growth and guidance. Hence, much knowledge exists already, minimizing the number of required experiments. Then, we will test whether the findings which result from the frog embryo experiments can be reproduced in higher animals, we use rodents because their neurobiology is similar to humans'.
Mice and Rats will be housed in groups whenever possible. Environmental enrichment material will be provided (chew sticks and play tunnels). In order to reduce stress, non-tail capturing methods are used (cupping/picking-up the animals using a tunnel). Wobbler mice will always be housed with at least one non-wobbler littermate who can help them groom. They will be housed on soft bedding. To facilitate feeding, extra-long nipples will be provided on the water bottles and they will be served pellets from the floor.
The frogs are kept in a temperature-controlled aquatic environment. They are handled as little as possible as this induces stress in the animals. Instead of invasive methods for identification of the frogs, pictures are taken of each frog and used for identification to reduce handling-induced stress as well as inflammation and injuries. The frogs are provided with enrichment tunnels for refuge so they can display natural behaviours. The dedicated Named Animal Care & Welfare Officer (NACWO) attends and contributes to National Centre for the Replacement, Refinement and Reduction of Animals in Research (NC3Rs) events, and has provided a significant welfare improvement using visual welfare methods of diseases and clinical signs in photographs. Breeding and maintenance are accomplished with standard husbandry practices. Pilot studies are run on a few animals at a time and discussed on a case by case basis.
Surgical procedures will be carried according to the LASA "Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017)".
Furthermore, we will plan our experiments, maintain our animals, and monitor the components of our study according to the PREPARE guidelines.
We consider and apply ARRIVE guidelines for improving the reporting of our experiments. This allows us to maximise the published information and can therefore help to reduce unnecessary studies.
Everyone working with animals will be supervised will be supervised and trained by experienced members of the lab, and when people with the required expertise are not available internally, we will ask our animal facilities or our collaborators for training and support, either directly by their staff, or by providing the appropriate contacts

(e.g. using Training and competency databases).

Home Office

NON-TECHNICAL SUMMARY

99. Investigating the role of the extracellular matrix in disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, adult, pregnant, juvenile, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our previous work has identified that a genetic defect (a mutation) in a protein called collagen affects many tissues in the body and causes stroke, blindness and kidney disease for which there is no treatment. This project will investigate how these mutations in collagen cause disease, and we will determine if we can interfere with the mechanisms of these mutations to inform on possible new treatments.
A retrospective assessment of these aims will be due by 27 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Disease such as stroke, heart, eye and kidney disease are a major burden on Society and for many of there is an urgent need for better treatments. We have previously identified that mutations in collagen can lead to genetic forms of stroke, eye and kidney disease. By determining the mechanisms by which collagen causes these diseases, we will significantly increase our understanding of how these diseases develop. As these mechanisms may represent therapeutic targets, this will also guide the development of new and more effective treatments.

What outputs do you think you will see at the end of this project?

Outputs from this project will include the generation and publication of scientific manuscripts. In addition, oral and poster presentations will be generated and presented at local, national and international meetings.

A major output will be the increase in knowledge of how collagen plays a role in disease. Collagen has been implicated a large variety of diseases, many for which there are no treatments. Increasing knowledge gained in this project will help other researchers and industry in their research investigating these disease and/or other types of collagen.
Finally, this project will also help the workforce in the UK by providing high quality training to PostDoctoral Researchers and PhD students in multiple disciplines.

Who or what will benefit from these outputs, and how?

Impacts from this research will benefit directly other researchers, as well more indirectly and in the longer term will inform the general public and clinicians.
Researchers will benefit through publication of manuscripts and presentation during the course of this project. This also applies to clinical researchers. In the longer term the information on potential treatment targets for vascular disease may impact on patient management and ultimately treatment. In so doing this would be a benefit for the general public and the NHS.

How will you look to maximise the outputs of this work?

Outputs will be maximised through publications, oral presentations and public engagement activities including

press releases. In addition attending and presenting at scientific conferences will be used to disseminate information gained.
I am part of several multi-centre programmes of work with international collaborators. This will maximise the global reach of this work.

Species and numbers of animals expected to be used

- Mice: 3400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project focuses on the mechanisms of disease due to Col4a1 mutations with the aim of identifying therapeutic approaches. In addition identified mechanisms and treatment will also be investigated other vascular disease models for example Ehlers Danlos Syndrome due to Col3a1 mutations.
The animal models used are well established models for these diseases. For example, the identification of the human disease caused by collagen IV mutation was based on the analysis of mouse models with mutations in the same gene. This illustrates that mice are a very accurate model of the human disease and a powerful model to investigate how the disease develops and to analyse potential treatment strategies. In addition there is a wealth of genetic tools available to researchers and protocols are well established and standardised.
The mice models have been previously generated and recreation of other animal models such as zebrafish can be more difficult due to species differences: the cardiovascular system of mice has a much higher homology than the zebrafish cardiovascular system to the human cardiovascular system.
The use of well-developed protocols and pilot studies minimises the welfare costs to the animals. All possible measures will be undertaken to minimise animal stress as it is well established that stress has a strong influence on cardiovascular parameters such as blood pressure.

Typically, what will be done to an animal used in your project?

The vast majority of animals will be used for breeding and maintenance and analysis will be performed on tissues collected post-mortem. A minority of animals will undergo in vivo phenotyping protocols such as measurement of blood pressure and magnetic resonance imaging (MRI) to analyse brain haemorrhaging. The phenotypes of animals may be altered through administration of substances or altered diets with the aim of ameliorating the disease and identifying its underlying pathways.

What are the expected impacts and/or adverse effects for the animals during your project?

The adverse effects to the animals include the development of eye, kidney and vascular disease due to the mutation. Other very rare adverse effects are associated with the use of anaesthesia and protocols have been optimised to minimise adverse effects such as correct dosing and close monitoring of animals. As we will investigate older animals of more than 12 months old, we expect these to develop signs associated with normal ageing. In addition some of the adverse effects of the mutant animals can also increase with age. Close health monitoring of these animals will be performed to control the adverse effects.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect that the animal models (>95%) will have a mild severity limit, and <5% will have a moderate severity.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 27 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Currently no tissue culture and/or in vitro systems are available that accurately model the development of diseases that affect multiple tissues phenotypes, or their progression with increasing age.
Consequently, animal-based approaches are required to investigate the effect of mutations in genes and proteins on whole body biology or increase our knowledge of how diseases develop. In a similar manner to determine how a disease develops and whether a novel therapeutic strategy is able to modulate the disease, animal work is required.

Which non-animal alternatives did you consider for use in this project?

Whenever possible, we will employ in vitro approaches including cell culture to perform the molecular analysis of the mutations and how they affect how cells function. These cell culture experiments will also be used to investigate the efficacy of a treatment strategy. Data obtained from these cell culture experiments will then guide the animal-based work.

Why were they not suitable?

No tissue culture and/or in vitro systems are available that accurately model the development of diseases that affect multiple tissues phenotypes, or their progression with increasing age, necessitating research using animal models.

A retrospective assessment of replacement will be due by 27 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our extensive experience of working with animals combined with published research has generated a large amount of data that was used to estimate the number of animals required. Much of this has been based on our previous published research using these model and the techniques employed within this project. This has enabled us to establish the size of appropriate animal cohorts. In addition our experience with, and detailed knowledge of the used animal models has enabled us to develop appropriate breeding schemes and identify the number if animals that need to be generated. This experience has resulted in a significant decrease in the numbers of animals used.

Statistical analysis combined with pilot experiments has also been used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The molecular analysis of mutations will be performed where possible in cell culture experiments. In addition, we have performed large mutagenesis screen on invertebrates, rather than in mice, which has signficantly reduced the animals used in this project. Data from these approaches will then guide our animal based work.

Where possible experiments on animal cohorts will be coordinated so that experiments will begin simultaneously for the entire cohort to allow optimal use of animals and reduce the number of animals. Statistical advice is sought to optimise approaches to ensure that maximum information is gained from the lowest number of animals. In addition, pilot studies are performed to determine how many animals are needed for an experiment, reducing overall the number of animals. Animals will be randomised, both sexes will be used and researchers will be blinded to the genotype and treatment status. This ensures effective blinding to prevent unconscious bias.
All procedures will be undertaken in accordance with current guidelines as listed on NC3Rs (http://www.nc3rs.org.uk/our-resources) comply with current good practice including ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To reduce the number of animals required we will collect multiple tissues of each animal and coordination of animal studies within the laboratory will ensure optimal use of animals. Performing multiple phenotyping assays will reduce animal numbers and provide an accurate characterisation of co-occurring phenotypes within one animal.
A retrospective assessment of reduction will be due by 27 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project uses mice as animal models due to the available genetic tools and standardised phenotyping protocols. The mice models have been previously generated, model the human disease, and recreation of other animal models is difficult due to species differences.

Why can't you use animals that are less sentient?

Although zebrafish is extensively used in analysing the development of the cardiovascular system, rodents are still the standard species for adult phenotypes. Due to size difference it is much easier to analyse adult mice compared to zebrafish and the rodent cardiovascular system has a much higher homology than the zebrafish cardiovascular system to the human cardiovascular system.
Human disease due to mutations in collagen progress with age and age is a major risk factor for stroke in the general population with the risk of stroke most increasing significantly above the age of 55 . It is therefore necessary to recapitulate these age points in our experiments through the analysis of mature adult mice (3-12 month of age) and in some cases older mice to investigate the impact of increasing age on disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Several approaches are adopted to implement refinement.
This includes pilot studies to develop expertise, optimise protocols and determine endpoints before the actual analysis. Measures will be undertaken to minimise animal stress. This includes training; for example animals will be trained before measurement of blood pressure. In addition whenever possible grouped housing will be utilised and animals are monitored daily. Further intensive monitoring will be performed where appropriate including on older animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All procedures will be undertaken in accordance with current guidelines as listed on NC3Rs (http://www.nc3rs.org.uk/our-resources), this includes the ARRIVA guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our animal work is performed with guidance from the NVS and Home Office Inspectorate, and we will keep abreast about advances in the 3R via the NC3R's website.
A retrospective assessment of refinement will be due by 27 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

100. Investigation of influenza virus infections in animals as models for human disease.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Influenza, Virus, Infections, Pathogenesis, Vaccines

Animal types	Life stages
Ferrets	juvenile, adult
Pigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to improve animal and public health and welfare in relation to influenza virus infection. This will be achieved by improving our understanding of viral pathogenesis and dissemination and to develop intervention strategies applicable to viral transmission between animals and humans. Animal models of human disease will be employed to investigate these factors.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Animal Influenza viruses have the capacity to infect humans and so can have a Public Heath impact. Indeed, pandemic influenza is included in the UK National Risk register of Civil emergencies. This licence therefore provides the essential capability to safeguard the UK by enabling research into influenza viruses that have the potential to cause pandemics in humans. Scientific results are communicated to stakeholders who include academia, biopharmaceutical companies and government organisations in the UK, USA as well as internationally .

What outputs do you think you will see at the end of this project?

The Objectives for this licence will support scientific capability to investigate influenza viruses that are constantly evolving, necessitating continued monitoring and research.

Objective 1 will specifically provide key reagents and tools to characterize influenza virus antigens, assess the antigenic relatedness of different influenza virus strains and data will be supplied to inform the selection of candidate vaccine viruses (CVVs) by international organisations.

Objective 2 will underpin characterization of influenza infection and outcome (pathogenesis) parameters and transmission of virus infections in a susceptible animal species (pigs) as an animal model for humans. Disease intervention strategies will be assessed to inform epidemiological assessments and disease mitigation strategies. The studies will also include preclinical investigation of intervention strategies such as candidate vaccines and antiviral drugs.

Who or what will benefit from these outputs, and how?

Beneficiaries will include funders commissioning the research carried out e.g. funding agencies in the UK and EU, governments and biopharmaceutical companies conducting fundamental research. International organisations will also benefit from knowledge-sharing. Ultimately the general public and global influenza community will benefit from the enhanced capability to inform influenza risk and disease mitigation strategies worldwide.

How will you look to maximise the outputs of this work?

The outputs of this work can be maximised through participation in collaborative studies with external organisations. As detailed, the establishment already has representation on several organisations and also has joint-funded projects that are active or in negotiation. This allows co-ordination of research efforts and good use of animals. Research findings are presented at external meetings and published.

The establishment ensures dissemination of knowledge to stakeholders, in accordance with the UK Government data sharing policy and also within the remit for engagement with international organisations . In the case of notifiable disease or increased risk information is disseminated through expert reports and disease risk assessments.
The establishment ensures active engagement with stakeholders, for example through the organisation's evidence and policy teams.

Species and numbers of animals expected to be used

- Pigs: 250
- Ferrets: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The pig and ferret species can be naturally infected with influenza viruses of relevance for human infection and are therefore biologically relevant hosts. In addition, influenza virus infection results in similar responses in the respiratory and immune systems in humans, pigs and ferrets. For these reasons, both pigs and ferrets are both considered valid animal model species for human influenza virus infection. Where possible, an alternative to live animals is sought, for example cell or organ culture. However, for certain scientific questions where complex virus-host interactions need to be studied, it is not possible to replace a live animal. For example vaccine efficacy investigations require study of the complex interactions between virus and host immune system.

Typically, what will be done to an animal used in your project?

Procedures will involve inoculation of influenza virus with or without prior immune stimulation (e.g. administration of immunological reagents such as vaccines or antigens). Substances will be delivered by injection or into the nasal cavity. The study outcomes will generally be followed by analysing longitudinal blood and nasal samples. Some studies to assess virus transmission (either directly or indirectly) will require co-housing of contact healthy animals with infected animals or introducing animals into a virus-contaminated environment. Study duration will depend on the study design and scientific question to be addressed. Generation of an immune response normally requires 4-10 weeks. Influenza virus infection is normally monitored for a duration of 5-14 days.

What are the expected impacts and/or adverse effects for the animals during your project?

The main potential adverse effects are the clinical signs resulting from influenza virus infection which are predicted to be similar or milder to infection in humans. Clinical score sheets are used to ensure humane endpoints are applied and thereby minimise suffering. Transient mild adverse effects may also be experienced as a result of restraint during sampling or inoculation. Anaesthesia will be applied if anaesthesia is not more severe than the procedure itself.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Ferrets

Mild 100%

Pigs
Mild 99%
Moderate 1%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Only viruses of scientific importance will be selected for full assessment in animals. A complete biological system is frequently required to fully study the course of clinical disease and virus-host interactions during infection and particularly the immune response of the host. For example, the mechanisms of virus transmission from one animal to the next and disease interventions such as protective immunity from vaccination, cannot be studied in non-animal alternatives.

Which non-animal alternatives did you consider for use in this project?

In vitro and ex vivo methods will be developed and used where appropriate, for example: continuous cell lines and organ or tissue explant cultures.

Why were they not suitable?

These alternatives are suitable to address some, but not all influenza research questions. Alternatives to animals cannot be used, for example, to address questions such as virus-host interactions, transmission, mechanisms of disease induction by a virus (pathogenesis) or vaccine efficacy.
Modelling of risk pathways in agricultural settings e.g. in a pig herd and assessment of risk or mitigating approaches at the animal-human interface also requires live animals of the relevant livestock species and animals representing human models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken

to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers have been estimated based on previous research programmes and project licences.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of a statistically valid minimum number of animals per study will be determined based on expert advice from a professional Biostatistician. Animal studies will be designed in a consistent manner so that inter-study comparisons and data analysis can be performed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animal studies will be designed to maximise collection of biological materials and, where feasible, run in parallel. This will potentially reduce the number of control groups required and therefore increase the data output and research questions that can be addressed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Ferrets represent a valid human model for influenza infection and pigs can serve either as a human model or as a natural livestock host species.

Why can’t you use animals that are less sentient?

In studies involving study of virus-host interactions, it is not possible to use less sentient animals as study requires use of the biologically and epidemiologically relevant host species with a complete immune repertoire.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The species chosen are valid animal models or are a biologically relevant host e.g. pigs are the agriculturally relevant host for swine influenza and also represent a valid model for humans. Pilot experiments are used to refine protocols for the study of viruses with unknown properties e.g. to establish dose, route and timeline of infection required for infection and transmission. The research team strive to continually improve clinical score systems and the refinement of the humane endpoint(s).
The Clinical Score sheets used in this licence reflect refinements made over the course of the preceding licence. Animal species have their own specific and disease-relevant clinical observation criteria and score sheets. No animal will be allowed to progress beyond the described humane end point using a 2-3 times daily monitoring

system. On site veterinary teams and animal welfare officers (NVS and NACWO) are integral to each study. Clinical signs serve as study endpoints when the scientific objective does not require progression of disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice guidance and information is obtained from NC3Rs, IAT and the RSPCA. Publications and articles are also reviewed during the approval process prior to each individual study. Where specialist training is required, inter-institutional exchanges and training visits are organised. Our team follows the ARRIVE2 in reporting data from animal studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Establishment applies the Culture of Care in animal studies. The Establishment frequently attends or organizes external meetings on laboratory animal welfare e.g. NC3R, RSPCA and IAT meetings. Staff attending these meetings provide meeting feedback reports locally. In addition, the Establishment has a Species Group Care and Use Committee and all PILs and NACWOs are invited to attend meetings. Specialist topics are presented and refinements, such as environmental enrichment, are communicated and opportunities are used for implementation. In addition, specialist knowledge exchange is organised by field and lab exchanges with other organisations conducting influenza research.

Home Office

NON-TECHNICAL SUMMARY

101. Investigation of Normal and Aberrant Haematopoiesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

blood cells, cancer, stem cells, treatment

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to

1. Understand the mechanisms within the body that control normal and abnormal blood formation. Abnormal blood formation can lead to such things as blood cancers like leukaemia.

2. Test ways that would lead to improved blood formation systems where these are not functioning correctly.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Many blood-related disorders, cancerous and non-cancerous, remain incurable or inadequately treated. Improving the outcome of patients with such disorders will require better understanding of how disease develops at the microscopic level and within the whole animal. For the latter, use of carefully chosen mouse 'models' (mice that have had their genes altered to mimic the human disease) have proven very useful and often essential for research into how diseases develop in humans.
Our aim is to maximise the knowledge we can obtain from animal models of diseases of the blood and blood-forming organs and use it for the purpose of testing and developing potential new treatment approaches as we have done in several occasions in the past.

What outputs do you think you will see at the end of this project?

1. Provide proof that the processes and mechanisms identified in the laboratory as responsible for abnormal blood production are also true in the context of a living organism

2. Provide proof that treatments identified as promising for abnormal blood production in the laboratory are also active in the context of a living organism and do not cause unacceptable harm.

For example, this will provide the required proof-of-principle for proceeding with early clinical trials in healthy volunteers and then patients with bone marrow failure syndrome such as Diamond-Blackfan anaemia.

3. Provide proof-of-principle that transferring certain types of immune cells from donors to recipients of stem cell transplants will ameliorate complications of the stem cell transplant and thus improve the survival of recipients. We will also provide proof-of-principle that certain types of immune cells are more effective and

less toxic than others for the treatment of blood cancers. All these experiments are required for regulatory authority approval before these potentially novel therapies reach patients in clinic.

4. Information from 1-3 might be used by academic or industry stakeholders to develop improved treatments for patients

5. All the above will be freely available in the public domain in scientific publications

Who or what will benefit from these outputs, and how?

1. Patients with blood disorders

a) Patients with bone marrow failure syndrome may benefit from discovery of new therapeutic targets tested and validated in in vivo models. Validation of therapeutic targets will be followed by pre-clinical testing of candidate small molecules that may be identified by in vitro screening methods and validated in vivo, in relevant models. It is realistic that we will be able to identify therapeutic targets during the life of this PPL and possibly have an initial candidate small molecules to test and validate beyond that period.

b) Patients with blood cancers may benefit from novel, effective immune cell subset -based immunotherapy that is less toxic than current options.

It is realistic to expect that by the end of the life of this PPL and given availability of funding, the output from the proposed animal work will guide early and inform early clinical trials for patients with different blood cancers.

2. Academic or industry stakeholders

Validation of therapeutic targets in 1a may prompt industry or academic chemical biology laboratories to develop or re-deploy existing small molecules for therapeutic purposes.

Output from 1b will certainly benefit other laboratories around the world that develop immunotherapies and currently is the case attract early investment for further pre-clinical and clinical development from the pharmaceutical industry.

How will you look to maximise the outputs of this work?

Outcomes from our work on animals, once published, will be freely available in the public domain in scientific publications.

The applicant has a strong track record in patient public involvement and engagement activities in which the importance of using regulated animal experimentation is discussed.

We will continue engaging patients and their families with different types of heritable bone marrow diseases through research day events organised by our Institution.

The applicant is a Consultant Haematologist and an active clinician treating patients with blood cancers and with experience in clinical research. Therefore, he is well placed to lead clinical development of the cancer immunotherapy programme.

Our laboratory is also working closely with leading clinicians who lead one the largest single centre clinical services for the diagnosis and treatment of patients with heritable bone marrow diseases. Therefore, any advances with translational potential will be swiftly explored in clinic.

Species and numbers of animals expected to be used

- Mice: 7,780

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For decades, mice have been used to investigate how blood cells are made and how the immune system develops and functions. They have also been used to test treatments such as chemotherapy drugs and immune therapies against cancer before they were tested in humans.
Mice are less sentient than higher mammals but are still relevant to human biology, and in particular normal and aberrant haematopoiesis, i.e. the process in the bone marrow that is responsible for the formation of all blood cells types. Moreover, there is a considerable amount of information in the literature that can be used as baseline and mutated and transgenic strains are available.
Extensive literature also shows that murine haematopoiesis at the molecular and cellular level greatly overlaps with human haematopoiesis and many human blood diseases, e.g. thalassaemia have been modelled successfully in mice.
Currently, immunosuppressed mice are considered the most appropriate animals for testing efficacy of different types of cellular immunotherapies including against cancer and for prevention and treatment of complications of blood stem cell transplants used to treat patients with blood cancers.

We will be using mouse strains that are optimal for studying growth of human cancer and testing of different treatments including immune therapies.
We will use mostly adult animals although is some cases, when we want to generate mice with high levels of human blood cells, we will use neonates.

Typically, what will be done to an animal used in your project?

Animals might receive cancer forming cells which will grow under the skin or in different organs including the bone marrow, and may produce tumours.
Tumour bearing animals will be treated with anti-cancer substances or immune cells with ability to eradicate tumours
How the tumour grows and how different anti-cancer treatments affect the tumours will be determined using advanced scanning procedures such as bioluminescence, CT and MRI scans
Animals might be injected with human blood stem cells (special human cells which can develop into many different cell types) to develop blood that has human features. Such humanised animals allow us to better investigate the function of human bone marrow and blood forming processes.
Blood will be taken to assess levels of different molecules and cells of interest.
In some instances, to improve the growth of transferred blood cells or tumour cells, recipient animals might be given doses of radiation.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice which have been exposed to radiation may experience symptoms ranging from transient diarrhoea to radiation sickness for 2-3 days.
They will be more prone to infection afterwards but are held in conditions which minimise the chance of this happening.
Some animals will develop tumours but most are unaffected and are humanely killed when the tumour starts to affect their general health. In general, subcutaneous tumours will be expected to reach the set specific and humane end-points with 4 weeks from tumour cell inoculation. The corresponding duration for systemic tumour would be more variable and will depend on the type and cell dose of the tumour; in general end pints may be

met between 4 and 12 weeks post tumour cell inoculation.
Animals may be subject to minor surgical procedures but these will be carried out under anaesthesia and animals will be carefully monitored during recovery, and kept warm. Painkillers and antibiotics will be administered if necessary following surgery.
Some animals will have blood taken which will result in short lived discomfort.
Imaging is carried out whilst animals are anaesthetised and should not cause discomfort.
All animals are regularly monitored and advice sought from animal care welfare officers or veterinary surgeons where necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around 80% of mice will experience tumour burden, mild irradiation, multiple imaging sessions, administration of test agents and removal of blood samples. Applying humane endpoints to tumours, careful choice of substances, limitations to blood sampling and allowing the animals sufficient time between imaging sessions will result in a likely severity of moderate. The remaining 20% of mice will undergo higher dose of irradiation and risk radiation sickness which will be carefully monitored and humane endpoints applied to comply with the moderate level of severity of the corresponding protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studies in the laboratory only give information on cells in isolation. Since survival and growth of normal and cancerous cells depends on their highly complex interactions with a variety of cells, for example in bone marrow and organs that cannot be reproduced in the laboratory, the systems have to be tested in the whole animal. The same is true for studies on the effects of genes and changes to genes.

Which non-animal alternatives did you consider for use in this project?

Almost always, laboratory experiments will be performed using normal blood-producing cells from healthy volunteers or tumour cell types obtained from patients with blood disorders. For example, we use laboratory experiments to work out the functions of special cells in human bone marrow, blood or (umbilical) cord blood. Other types of cell involved in blood production are also used to study the impact of changes to genes or to look at the effects of substances such as drugs, growth factors, hormones, antibodies, immune cells) on cell survival and growth.

Why were they not suitable?

Laboratory-based studies mentioned above provide limited information and do not accurately reflect what happens in the complex whole body system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Based on our experience from the previous PPL and the projected growth of our research programme especially in the field of cancer immunotherapy.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In all experiments performed, UK Co-ordinating Committee on Cancer Research (UKCCCR) guidelines will be followed at all times. Individual animals will be traced by earmarking at the outset.
In most experiments, post-mortem tissue will be harvested at the end of experiments to perform invaluable laboratory analyses.
We will pay particular attention to the size of the groups, keeping size to a minimum while allowing statistically and biologically relevant results to be obtained. In consultation with the Departmental Medical Statistician and with reference to the NC3Rs' Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) we will undertake a formal calculation approach to estimate the sample size which will ensure delivery of experimental endpoints whilst using the lowest number of animals possible. In addition, we will be guided by similar published experiments if they exist. To minimise animal use when new procedures are being introduced, pilot experiments will be undertaken which will influence the design of further experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mouse colonies will continue to be closely monitored to avoid excess animals. As appropriate, we will plan effective mouse breeding strategies which can provide us with the required experimental mice and controls.
To minimise animal use when new procedures are being introduced, pilot experiments will be undertaken, thereby determining parameters that will influence the design of further experiments.
We will use real time imaging systems such as bioluminescence to track tumour status and immune response. This removes the need to kill mice at certain time-points, resulting in a substantial reduction of animal numbers required to meet experimental end-points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are the only animal species used in the proposed programme of work. Mice may wild-type (as they occur in nature), modified to alter a particular gene, or without a particular immune cell or factor. There are large numbers of mutated and genetically modified strains showing normal and abnormal blood creation. Many publications indicate the relevance of mouse models to human biology and these types of blood diseases in particular.

We will use genetically modified models as required and also models with transplanted tissue or organs of both normal and malignant blood formation.
We will use different strains with depleted immune systems which have been shown to be good receivers of grafted cells (both normal and malignant). Whenever possible, tumour cells will be administered under the skin into the flank as this causes least distress to the mouse. This method produces tumours with poor blood supplies, so this model is of limited value for testing substances which move round the whole body. Additionally, grafted tumours do not generally show the same disease progression found associated with abnormal blood production, so we will also generate and use genetically modified animals showing abnormal blood production.
To mimic features of some diseases such as acute leukaemia, it may be necessary to inject normal or cancer cells into veins.
To establish maximum tolerated, effective dose levels of treatments of interest (e.g. drugs, cells), and to minimise adverse effect on animals, drug dose will be given to mice in increasing amounts.
We will monitor the condition of the animals in all procedures regularly according to the protocol used and as agreed with NACWOs and veterinary surgeons. If unexpected distress occurs, mice will be humanely killed under terminal anaesthesia.
We will periodically seek alternatives to the use of animal models as reported in the literature and in online web sites dedicated to the promotion of the 3Rs such as CAMARADES (https://www.nc3rs.org.uk/camarades-nc3rs-systematic-reviewfacility-syrf) and Norecopa (https://norecopa.no/alternatives)

Why can’t you use animals that are less sentient?

There are no less sentient animals which have haematopoeic systems similar to that of humans. Mice are the only animal species used in this programme of work, with both mutated and genetically modified strains readily available.
Mice are less sentient than higher mammals but are still relevant to human biology, particularly in our field of study. Moreover, there is a considerable amount of information in the literature that can be used as baselines.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have adopted imaging of live animals as a means to reduce the number of animals required in cancer immunotherapy protocols.
In addition our protocols call for frequent monitoring of animal welfare and include measures to prevent and effectively treat procedural complications or pain, and failing these to promptly implement HEP.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will perform our experimental work according to guidelines issued by the Laboratory of the Animal Science Association (https://www.lasa.co.uk/), NC3Rs (https://www.nc3rs.org.uk/) and the United Kingdom Co-ordinating Committee on Cancer Research guidelines for the welfare and use of animals in cancer research (PMID: 20502460).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through scientific literature reporting improved models and methodologies for approaching animal work.
For example, we will adopt a specific genetically modified strain which allows higher frequency and levels of human (blood producing) cell engraftment that the original strain.
We will also stay informed of new developments in the field of 3R by engaging with NC3Rs (for instance, we have adopted the recently published ARRIVE guidelines 2.0); we will interact with
AWERB and the institutional 3Rs manager to be informed of relevant education events, e.g., webinars.

NON-TECHNICAL SUMMARY

102. Investigation of the multiple factors that contribute to opioid overdose

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Heroin, Fentanyl, Respiratory depression, Opioid tolerance, Benzodiazepines

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To determine the mechanisms behind the respiratory depressant effects of opioid drugs such as heroin, prescription opioids and illicit fentanyls (analogues of fentanyl).
To determine how tolerance develops to the respiratory depressant, analgesic and euphoric effects of opioid drugs and investigate how these change in the presence of non-opioid drugs of abuse or during periods of abstinence.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Overdose deaths involving opioids are increasing world-wide. Death in opioid overdose is due primarily to respiratory depression. It is overly simplistic to think that such deaths result simply from the user injecting too much opioid drug. In most cases overdosing is due to other factors such as (i) interactions with other drugs taken at the same time, (ii) loss of tolerance due to periods of abstinence, (iii) the use of highly potent opioids, like fentanyl, that break through the tolerance induced by regular opioid use, (iv) newer illicit fentanyls affecting the respiratory system in novel ways and (v) fentanyl induced overdose being less susceptible to reversal by naloxone.
In order to reduce deaths caused by opioid overdose there is an urgent need to understand more fully the processes involved in opioid respiratory depression in order to be able to explain the dangers, provide public health warnings and develop new more effective ways to reverse an overdose before it becomes fatal.

What outputs do you think you will see at the end of this project?

Our main research outputs are scientific papers in high quality scientific journals. We also give invited talks at scientific and drug treatment conferences as well as to government agencies such as Public Health England.
Who or what will benefit from these outputs, and how?

This research will provide important information on the factors contributing to opioid overdose, especially why the fentanyls are so dangerous and how we could better treat fentanyl overdose and reduce deaths. By quickly publishing our findings while the project is still on going the results from our research will help to inform other scientists working on similar topics and influence the direction of their research. For example, it will stimulate research into which opioid antagonists would be best to use in the treatment of overdoses involving fentanyls. Rapid publication and informing government agencies of our findings will contribute to the development of new guidelines and advice for drug users and treatment agencies on how to prevent and treat opioid overdose. In the

longer term the outputs from this research will inform future drug policy and contribute to Government strategies in relation to the social and health problems associated with opioid drug use.

How will you look to maximise the outputs of this work?

We will publish our research in high quality, international scientific journals.

In addition, all important discoveries will be communicated in non-specialist language to drug treatment workers and the general public via our university web sites, by press releases and by our involvement in public engagement. This includes talking with those involved in harm reduction, those going through drug rehabilitation, giving public lectures and speaking in schools. Being more aware of the dangers of opioid overdose and how it can be prevented is important in the wider community.

Species and numbers of animals expected to be used

- Mice: 1000
- Rats: 270

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice or rats of both sexes will be used. The experiments are not designed to examine age-related differences rather they are designed to examine drug effects on the mature brain.
The neuropharmacological characteristics of the respiratory depressant and pain relieving effects of opioids have been extensively characterised in these rodent species and closely mirror those in humans. The anatomical distribution of opioid receptors in rodent brain is similar to that in human. Consequently, rodents are an ideal model in which to undertake the studies outlined.

Typically, what will be done to an animal used in your project?

60% of mice will undergo acute experiments in which respiration will be monitored before and after injection of a drug. In some experiments their antinociceptive threshold will be measured. To do this mice will be handheld during the tail immersion/tail flick test with minimum restraint to avoid stress, During the respiration monitoring they will be unrestrained, being freely able to walk around the recording chamber for periods up to 2 hours. Water, but not food (munching on food tablets interferes with respiration monitoring) will be available. At the end of the experiment mice will be killed.
40% of mice will undergo a surgical procedure to implant a prolonged drug delivery device under general anaesthesia. Following a period of prolonged drug delivery (up to 7 days) they will then either (i) have their respiration monitored before and after an injection of a drug for periods up to 2 hours or (ii) undergo a period of drug abstinence (from 1 day to 3 months). At the end of the period of abstinence they will again undergo a surgical procedure to implant a prolonged drug delivery device under general anaesthesia and respiratory parameters monitored by plethysmography before and after an injection of a drug for up to 7 days. At the end of the experiment mice will be killed.
45% of rats will undergo general anaesthesia without recovery.
55% of rats will undergo a surgical procedure under general anaesthesia to implant a prolonged drug delivery device, telemetric recording device or have an indwelling IV catheter implanted and then be allowed to recover. Thereafter they will then either (i) have their respiration and respiratory muscle electrical activity recorded by plethysmographic and telemetric recording before and after drug injection, (ii) be allowed to self-administer drugs daily for up to 2 h or (iii) undergo tolerance induction prior to tolerance assessment being performed by administering a dose of opioid and measuring respiration and respiratory muscle electrical activity or by resuming the drug self-administration protocol. At the end of the experiment rats will be killed.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals that have undergone surgery may suffer some post-surgical pain however, to reduce this adverse effect animals will be administering analgesic drugs during the surgical procedure and post-surgery as required (NSAIDS and opioids).
Animals withdrawn from a prolonged period of opioid drug administration may incur withdrawal symptoms including diarrhoea and a jumpy behaviour, 'wet dog shakes' for up to 5 days. We will allow withdrawal to develop slowly by letting the brain concentration fall naturally. We will not administer antagonist drugs to these animals as that would evoke a more severe withdrawal response.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - 60% Mild; 40% Moderate
Rats - 45% Mild; 55% Moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The design of our experiments has taken into account the 3Rs. Where appropriate we will continue to perform in silico Molecular Dynamics simulations of drug-receptor interactions and *in vitro* experiments on cell lines expressing recombinant and mutated receptors as these can be used to generate, test and refine initial hypotheses as well as for proof of principle studies and thus direct our future *in vivo* experiments. They may also highlight similarity in action between different opioid drugs allowing us to group drugs and select only one drug from each group for further study *in vivo*. However, such in silico and in vitro approaches cannot be used to study drug-induced respiratory depression, analgesia and reward. Nor can they mimic the adaptive changes that occur *in vivo* to prolonged drug exposure as they do not replicate changes that occur in neuronal networks controlling complex behaviours, the influences of hormonal changes or long-term changes in neuronal gene expression.

There are two main reasons why animals have to be used in the proposed experiments

1. Opioid-induced respiratory depression, antinociception and reward can only be studied in the intact animal as these are integrated behaviours that require functioning sensory input to the brain as well as reflex neuronal responses to elicit the behaviour.

2. Previous research on cellular tolerance to opioids has used cultured neuronal cell lines and mature brain neurones contained in brain slices (from animals sacrificed by a Schedule 1 approved procedure) that have been exposed to opioid drugs such as morphine *in vitro*. That work has provided a wealth of important information on the potential mechanisms of cellular tolerance to opioids but it does not demonstrate that these mechanisms have a significant role in opioid action and the development of tolerance in complex behaviours resulting from simultaneous drug actions at multiple sites in the brain.

Which non-animal alternatives did you consider for use in this project?

In silico modelling of drug-receptor interaction *in vitro* experiments on cell lines

expressing recombinant and mutated receptors **Why were they not suitable?**

These non-animal alternatives would not provide information on how a drug could modify complex whole animal behaviours such as respiration, analgesia, and reward.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have extensive experience in the type of experiment described in this application and have published our data in peer reviewed publications that ensure high quality of experimental design that complies with the ARRIVE Guidelines and require justification of group sizes. Thus, for any drug treatment the group size (number of animals) will be the minimum number required to observe a robust,
statistically significant effect given the amplitude of the response expected and the variability in response amplitude we have previously observed between animals in that type of experiment.
For each experiment the total number of animals is based on
- (group size x number of drugs to be tested x doses of drug)/estimated success rate
Note: for most experiments the estimated success rate = 1 but in a few instances (e.g. implantation of recording electrodes or installing indwelling iv cannulae) the success rate may be less than 1 but no less than 0.75.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have limited the number of drugs and number of doses of each drug that will be studied. This has been done on the assumption that from our in silico and in vitro work we will be able to group drugs of similar properties (e.g. way they bind to the receptor, intrinsic efficacy, lipid solubility, reversal by antagonists) and then select exemplars from each group for the in vivo experiments rather than study all possible drugs.
We will perform as few solvent and antagonist drug controls as sound scientific practice demands to exclude

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The design of our animal studies will be predicated upon the results from *in silico* and *in vitro* cellular assays

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will monitor drug-induced changes in respiratory parameters in awake, freely moving animals using plethysmography. Apart from the mild discomfort of drug injection this procedure does not cause pain or distress.
To measure changes in respiratory muscle electrical activity we will perform experiments on the *ex vivo* brainstem-lung preparation. This reduces the need for experiments on awake, freely moving animals in which the recording electrodes and telemetric devices have first to be implanted under general anaesthesia. There is a need however to ensure that the drug effects observed in the *ex vivo* preparation are also seen in the awake, freely moving animals but the number of such *in vivo* experiments will be kept to the absolute minimum as required to demonstrate scientific validity.
In the self-administration experiments drugs will be administered iv to freely moving animals via an indwelling cannula inserted under general anaesthesia. Access to drugs is limited by the experimental protocol to prevent the induction of dependence and thus associated withdrawal occurring between testing periods.
Analgesia testing will be performed using standard thermal techniques. To prevent pain, suffering and distress the stimuli will be mild with the animals having the ability to withdraw themselves from the stimulus at any time. Stimuli will be applied at appropriate, controlled intervals with limits of intensity and duration to ensure tissue is not damaged.
To induce drug tolerance, we will implant under general anaesthesia slow release devices that provide continuous drug delivery for up to 7 days. These devices remove the need to give repeated drug injections every day which may be stressful and avoid periods of drug withdrawal that may occur between repeated drug injections.
For all surgical procedures performed under general anaesthesia local anaesthetic agents will be injected into the area surrounding the wound and applied topically to the wound area at the end of the surgery. Following surgery analgesic drugs will be administered to alleviate any pain caused by tissue damage during the surgery.

Why can’t you use animals that are less sentient?

Rodents (mice or rats) are the least sentient mammalian species that are appropriate for the opioid induced respiratory depression, analgesia and reward work. The neuropharmacological characteristics of the respiratory depressant and antinociceptive effects of opioids have been extensively characterised in these rodent species and closely mirror that in humans. The anatomical distribution of opioid receptors in rodents is similar to that in man. Consequently, rodents are an ideal model in which to undertake these studies outlined.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Our institution has recently issued new advice for the handling of rodents and introduced improvements in the quality of their caging environment. We will continue to refine our procedures in light of any new advice that is issued.
Each of the proposed experimental procedures has been in use in our laboratory or that of one of our close collaborators at the same institution for the past 10 years. Over that time they have been refined extensively.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to the revised ARRIVE Guidelines 2019 (available at https://europepmc.org/article/ppr/ppr85606) and any updated editorials issued by relevant UK scientific societies (British Pharmacological Society, Physiological Society) and their journals (British Journal of Pharmacology, Journal of Physiology) as well as by grant funding agencies. Surgical procedures will be performed aseptically in line with LASA guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will
- attend the annual 3Rs conference organised by our institution

- monitor the updating of guidelines on animal experimentation as they are issued by relevant UK scientific societies and their journals, and by grant funding agencies.

Home Office

NON-TECHNICAL SUMMARY

103. Ischaemia Reperfusion Injury and Organ Transplantation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to characterise the mechanisms and consequences of ischaemia reperfusion injury in solid organ transplantation and to develop new therapeutic strategies using targeted drugs or cells.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Organ transplantation is a life-saving treatment for end-stage organ failure, but there is a growing disparity between the number of patients in need of an organ transplant and the number of suitable donor organs available. In January 2020, there were 6183 people in the UK currently waiting for an organ transplant, an increase in more than 1% on the previous year. Conversely, the total number of patients whose lives were saved or improved by an organ transplant fell by 2% in the same year. The total number of transplants performed also fell, ranging from a 3% decline for pancreas transplants to 20% for lung or heart-lung transplants. This is in spite of a 2% increase in the referral rate of potential donors, as well as a 1% increase in the overall consent rate for organ donation.

Between March 2018 and 2019, 400 patients died while on the active waiting list. A further 777 were removed from the active waiting list, mostly as a result of their deteriorating health and subsequent ineligibility for transplant, and many of these patients would have died shortly afterwards.

When an organ is donated for transplantation, it can spend several hours outside the body, without any blood or oxygen supply, before it is transplanted into the recipient. This interruption and restoration of oxygenated blood to the organ at the time of transplantation is known as ischaemia-reperfusion (IR) injury. This results in damage and death to cells, and ultimately can result in the organ being unsuitable for transplantation.

This project aims to improve our understanding of the cellular mechanisms that underlie IR injury and test the safety and efficacy of promising novel therapeutic agents. New treatments that reduce cellular injury and organ dysfunction will help overcome the national and international organ shortage by increasing the availability of organs suitable for transplantation. Improved rates of organ transplantation would have an enormous societal impact by shortening waiting lists, improving the quality of life of patients, and reducing complications and death from organ failure.

What outputs do you think you will see at the end of this project?

This project will generate academic outputs, new treatment products, and the basis of clinical studies which will have health and economic implications.

So far, our understanding of how cells and organs sustain injury during transplantation is from results of experiments in cells grown in special dishes in the laboratory, and in mice. We anticipate that project will not only confirm that what we know is also true in pigs, which are much more like humans in terms of size and complexity but will also extend to discoveries in the precise steps underlying IR injury. If our hypotheses are correct, the findings will enable us to design and test targeted treatments, and perform experiments to measure whether injury levels can be reduced this way.

The results of these experiments will be published in peer-reviewed journals and presented at national and international conferences. The treatments that come out of the project may be new intellectual property. From our experiments, we hope to learn what the best ways to deliver the treatments are, and how often and how much of the treatments need to be given. Altogether, these will generate a blueprint for clinical studies, which will bring successful new treatments to patients.

Who or what will benefit from these outputs, and how?

Throughout the project, researchers both inside and outside the field of transplantation will benefit from the above outputs. IR injury occurs in many human diseases, including myocardial infarction (heart attack) and stroke. The processes that occur in mitochondria, cells and organs are applicable to all of these diseases. Because the cellular processes underlying injury in transplantation, heart attacks and strokes are similar, we anticipate that our findings, including new drug treatments developed for use in transplantation, could potentially also be of benefit in treating heart attacks and strokes. Importantly, our raw data, publications and presentations will disseminate new knowledge to other researchers, who can then build on it.

The surgical and scientific techniques used in this project are very specialised, and therefore limited to a few experts who are able to carry them out. As this project proceeds, more researchers will be trained in these specialist skills. They will go on to apply them in collaborative or new studies in the future, ensuring the dissemination of good experimental practice and model refinement.

In the longer term, future clinical trials of the new treatments will be based on the results of this project. These trials will ultimately deliver safe and effective new treatments to patients with end-stage organ failure and patients undergoing organ transplantation. The new treatments may also be applied to diseases such as myocardial infarction and stroke, so a wider range of patients may benefit.

How will you look to maximise the outputs of this work?

This project represents an extensive multi-disciplinary collaboration involving multiple institutions. The knowledge created will be disseminated through presentations at national and international meetings and publications, which will include both successful and unsuccessful strategies investigated in the study.

Species and numbers of animals expected to be used

- Pigs: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Pigs that weigh approximately 40–70kg have been chosen as they closely approximate the anatomy, size, physiology, and function of human organs. Techniques for organ retrieval, supplying blood to the organ outside the body (ex vivo perfusion), and transplantation are transferrable between pigs and humans, allowing us to closely model how organs are affected when their blood supply is interrupted (ischaemia) and when the blood supply is restored (reperfusion). This project will allow us to confirm that our mechanistic findings from mice are translatable to larger animals. Once the large animal (pig) model has been developed it will be used to test the safety and efficacy of our new treatments prior to the treatments being using in humans.

Typically, what will be done to an animal used in your project?

We will use commercially-sourced adult pigs for all of our experiments. When possible, animals will be trained to eat the substrate in which a sedative is administered before induction of terminal anaesthesia. Animals will undergo general anaesthesia, they may then be treated with therapeutic agents or cells, and finally multiple organs will be retrieved for the study of ischaemia reperfusion injury. The animals used in this project will be humanely killed at the end of surgery whilst still under anaesthetic (non-recovery). This means that any given animal will undergo anaesthesia and surgery once, and will not experience any pain, distress or suffering as a result of any procedure.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will receive a general anaesthetic from the beginning of the experiment which will last to the end of the experiment after which they will be killed by the administration of an overdose of anaesthetic. The procedures do not involve reawakening the animal; therefore, no adverse effects are anticipated.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Pigs: 100% Non-Recovery. All animals will undergo non-recovery procedures, as described above.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ischaemia reperfusion injury in solid organ transplantation is a complex biological process involving crosstalk between cells, organs, the immune system and more. There is a gap in applying the knowledge we have generated using basic experimental models of ischaemia reperfusion injury to clinical transplant practices. We have used these basic experimental models to identify new therapies, but before these can be offered to patients, it is essential that we carry out clinical trials to ensure that these new therapies are both effective and safe. This project will provide us with a more complete understanding of the underlying pathological processes, help us shortlist the most promising new therapies, and inform the design of clinical trials in humans.
Which non-animal alternatives did you consider for use in this project?

This project has been preceded and informed by experiments using cells grown in special dishes in the laboratory (*in vitro*) and donated human organs that have been declined for clinical transplantation. Non-animal alternatives have, therefore, been extensively used as far as possible, in order to replace animal experiments.

Why were they not suitable?

Use of cells does not enable the complexities of organ injury during transplantation to be assessed fully. While we have and continue to make extensive use of human organs, these are very rare and access to them is very unpredictable. Moreover, because some of the human organs are of less-than ideal quality (which is why they were not used for transplantation), they are not always able to be used to generate robust and reproducible data.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals per group have been estimated based on the preliminary data obtained from previous experiments, which we have used to estimate the variance in the data and the anticipated effect size in the treatment groups. We estimate a group size of 5 per group, with a total of 20 experimental/control groups, requiring a total number of approximately 100 animals. This is likely to be an overestimate, as in our experimental design, group sizes of 4 per group are anticipated to generate biologically and scientifically significant data. The overestimate is included to account for cases when it is not possible to generate data for technical reasons.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have designed the experiments to maximise the number of organs and tissues that can be obtained for experimental use from every animal. For example, the heart, liver and kidneys, or biopsies from these organs, can be obtained from the same animal, enabling us to study mechanisms of injury (and response to therapy) to multiple organs in the same animal. In experiments using kidneys, we plan to use one kidney from each animal as a control and the other kidney as the experimental organ, thus reducing inter-animal variability and increasing the reproducibly of the data. By obtaining tissues under terminal anaesthesia, we will be able to ensure that the blood pressure and heart rate of the animals are consistent. This will reduce inter-animal variability, a key source of biological noise which can reduce the ability to generate biologically and statistically significant data.

We will continue to use the NC3Rs Experimental design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda) and the PREPARE guidelines (https://norecopa.no/prepare) for our ongoing experimental designs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The proposed project builds on a wealth of pilot data, generated from small animal (mouse) models and use of human organs. We will therefore only pursue hypotheses and progress the use of therapeutic agents that have been shown to demonstrate promise in pilot studies. Moreover, we will actively share tissues from the animals with other researchers in order to reduce the number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animals will be acclimatised to their new accommodation before the experiments, according to the guidance

of the Named Veterinary Surgeon at our establishment. Animals will receive a general anaesthetic from the beginning of the experiment which will last to the end of the experiment after which they will be killed by the administration of an overdose of anaesthetic. The animals will therefore not endure pain or suffering.

Why can’t you use animals that are less sentient?

Pigs are chosen for the proposed experiments because the size and anatomy of the organs closely resembles those of humans. The data generated from these experiments will therefore be directly applicable to humans and prime the design and conduct of human clinical trials. The research is using the least sentient model because all animals will be terminally anaesthetised in the experiments.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The Named Animal Care and Welfare Officer (NACWO) and animal technicians will be involved in sourcing animals, providing suitable acclimatisation and handling and environmental enrichment, all of which will improve animal experience. As housing and handling of the pigs, prior to the experiments, can contribute to contingent harm, we will monitor the pigs for any evidence of stress or adverse effects. If necessary, we will seek guidance and input from the Named Veterinary Surgeon (NVS) and explore measures to reduce such stress. For example, the acclimatisation period will be extended, or additional environmental enrichment will be provided as appropriate. Under the guidance of the NVS, palatable sedatives will be administered to reduce stress prior to terminal anaesthesia if necessary. During anaesthesia, the animals will be continuously monitored (heart rate, blood pressure, oxygenation and temperature) to ensure the depth of anaesthesia is appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The PREPARE guidelines and NC3Rs Experimental Design Assistant (EDA) have been used to design this project. These have aided in the comprehensive consideration of logistical, legal and ethical, quality control and experimental design and statistical analysis issues. Home Office Advice
Notes, Codes of Practice, and regulations for personal and project license holders will be adhered to. We use the Establishment's 3Rs search tool as well as the NC3Rs and other websites (e.g., www.thepigsite.com) websites to keep up to date with new techniques and refinements as they are published. We will also actively explore and adopt any experimental procedures and techniques reported by other groups that can help refine the conduct of the experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I have been actively involved in the ethical review of other scientific projects at the establishment. I actively engage with and keep informed about advances and developments in the 3Rs, including publications, conferences, meetings and new guidelines.

Home Office

NON-TECHNICAL SUMMARY

104. Lipid regulation of cardiovascular disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Cardiac disease, clotting, high fat diet, specialised fat molecules,

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The primary aim of this work is to determine the role that newly discovered lipids (fats) called "eoxPL" play in cardiovascular disease and abdominal aortic aneurysm, specifically through their ability to modulate blood clotting. It has been recently found that these lipids are made in the blood vessels of mice with both disorders, and that mice that are not able to make these lipids are protected from disease. Studies have shown these lipids can alter different aspect of vascular disease by modulating both clotting and underlying vessel wall

inflammation. We now need to better understand the molecular mechanisms involved in order to identify new ways to prevent or treat these diseases.
A retrospective assessment of these aims will be due by 02 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Cardiovascular Disease CVD causes 26% of all deaths in the UK; which equates to over 150,000 deaths each year or one person every three minutes. Along with this, abdominal aortic aneurysm is a complex silent disease, often co-existing with CVD (such as aneurisms and atherosclerosis), that has no effective treatments current, and is of high mortality. These diseases represent a massive public health concern, as well as a considerable economic impact.

The newly discovered lipids generated by enzymes (called lipoxygenases) appear to play a major role in the progression of cardiovascular disease and aneurysm formation, but the specific ways in which these lipids act still needs further investigation. The potential benefits of this work could include new treatments to prevent cardiovascular disease or aneurysms, or identify blood proteins that could be used to identify “at risk individuals”. We may also discover new drugs that could be developed for treatment of bleeding disorders.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Mice (wildtype and genetically altered strains) will be used, and the total number will not be greater than 12,500 in total. Only a proportion (3,500) of these will undergo complex biological testing, the rest will be for breeding purposes

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Of the 3,500 mice that undergo biological testing only a very small proportion, less than 35, may die as a result of complications that result from procedures.

1) Sudden death caused related to Ang II aneurisms.
For one of the knockout mice (or double knockouts) treated with an aneurism agent (Ang II), there is a risk of sudden cardiac death. Daily checks are conducted on the mice that are receiving Ang II, and mice showing adverse effects will be humanely killed. In addition, any mice found dead whilst under protocol 3 will be necropsied to evaluate whether an aneurism rupture has occurred

2) Breeding defects observed in knockout mice.
The knockout (ApoE) breeders show a reduced breeding pattern, compared to other knockouts and higher pre-weaning loss rate, for this reason animal care staff perform regular monitoring on mouse pups and license holders conduct weekly visual inspection on these mice.

3) Skin lesions induced by high fat diet in ApoE-/- mice
To assess this, daily health screening will be conducted on the mice. Should mice not respond to treatment over a course of 3 days then mice will be humanely euthanised.

4) Surgical procedure to implant minipump
Where surgical procedures are applied, additional appropriate control measures are in place for all adverse effects to ensure that all animals will be monitored closely, and appropriate action taken. All animals will be humanely killed if adverse effects cannot be treated.
A retrospective assessment of these predicted harms will be due by 02 March 2026

The PPL holder will be required to disclose:
- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement
State why you need to use animals and why you cannot use non-animal alternatives.

To study cardiovascular disease and aneurysm, the use of mice is unavoidable because this can only be studied properly in vivo.
Disease development involves the coordinated interaction of multiple cell types with the specific micro environment and physical stress/strain parameters which cannot be modelled faithfully with cell or computational models. We also extensively use non-sentient alternatives including cultured cells, human tissue obtained post-operatively from patients and healthy volunteer human blood.
A retrospective assessment of replacement will be due by 02 March 2026

The PPL holder will be required to disclose:
- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction
Explain how you will assure the use of minimum numbers of animals.

Based on previous work, appropriate group sizes that give a defined statistical power will be used. Results will be monitored as studies are undertaken to determine whether subsequent experiments could use fewer mice
Where possible, we will breed lines as homozygotes.
We will cryopreserve lines we are not actively using and provide tissues to both internal and external collaborators.
A retrospective assessment of reduction will be due by 02 March 2026

The PPL holder will be required to disclose:
- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We will minimise suffering by applying procedures which where possible are non-invasive, and only lead to short periods of minor discomfort and stress and ensure less than 1% of all mice experience more adverse effects such as aneurism related deaths. Further to minimise harm to the animals, animals will be monitored weekly and then daily (whilst undergoing procedures) and where there is any concern, advice will be sought from the Named Veterinary Surgeon and Named Animal Care and Welfare Officer, and prompt appropriate action taken. Pain relief and appropriate anaesthesia will be used as standard for surgical techniques or when needed to reduce pain. Habituation will be used to acclimatize mice to restraint stress. A Treatment plan for skin lesions is in place so that as soon as mice present with symptoms treatment can be started immediately.
Mice represent an excellent system in which to study cardiovascular disease and aneurysm, since they possess many of the same genes as humans and also display similar disease progression. Mice are also an ideal species due to our ability to genetically and environmentally modify them.

Mice with a gene mutation (*ApoE* gene, a protein that is important in handling plasma lipids/fats) are susceptible to elevated blood lipids and cardiovascular disease. As such these mice represent a robust mouse model of cardiovascular disease that have been extensively characterised over the last 20 years. This again makes them an ideal model to study the pathophysiology of this disease.
A retrospective assessment of refinement will be due by 02 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

105.

Macrophages as a cell therapy for liver disease Edin 003

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Liver fibrosis, Cell therapy, Macrophages, Cirrhosis

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to identify, develop, and test if a genetically-modified macrophage-based cell therapy candidate can serve as a treatment for acute and chronic liver injury. Currently, the prevalence of liver disease is increasing, and there are no effective therapies other than liver transplantation.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

If this project is successful, we will develop a genetically-modified macrophage for cell therapy for chronic liver disease, which would be the only treatment option for patients other than liver transplantation. The ultimate goal of this project is take a new cell therapy product into phase I clinical trials in patients with severe liver cirrhosis. Currently, there are no effective treatments for patients with cirrhosis of the liver, other than liver transplantation. Here, we hope to gain evidence that human macrophages, a type of white-blood cell, can serve as a cell therapy in animal models of liver fibrosis. We will genetically-engineer the human macrophages to vastly improve their anti-fibrotic potential by targeting certain genes, which we predict will make them very effective at treating liver disease. If successful, genetically-modified macrophages could then be the first approved therapy for chronic liver disease other than liver transplantation. A macrophage-based cell therapy could help improve liver function in patients with liver cirrhosis and prevent them needing a liver transplant.

What outputs do you think you will see at the end of this project?

The main outcomes of this project, if completed successfully, will be:

- a treatment for chronic, and possibly acute liver injury, to be further tested in patients in order to have it approved as a therapy for chronic liver injury by the relevant regulatory authorities

- patents to protect the intellectual property around new macrophage products generated during the duration of this project

- papers to ensure that the scientific community can scrutinise our results appropriately, and to ensure that our findings can be broadly utilised in basic research

- community and public engagement material to allow the general public to understand what cell therapy is and how it can be translated from the laboratory to the clinic

- abstracts to be presented at conferences in the form of posters or oral communication. This will: (i) ensure the professional development of early career scientists working with us; (ii) allow the establishment of new collaborations; (iii) disseminate the knowledge gathered thanks to the present project

Who or what will benefit from these outputs, and how?

Short term outcomes will be an increase in the public knowledge on cell therapy thanks to our regular involvement with public and community engagement projects. This is an ongoing commitment, with several events organised by our local public engagement office every year.
Mid-term goals will be: (i) the patenting of products that we may deem interesting to be brought forward for clinical assessment; (ii) the presentation of results around such products at conferences and meetings. We estimate that 2 years at least will be necessary prior to reaching these goals.
Long-term goals will be the approval for clinical trial of a macrophage product, and its testing in phase I/II trials. Further, we aim at publishing these results in well respected, peer reviewed international journals. We believe we can reach these goals during the last year of this project, and perhaps the year following the natural conclusion of the study.

How will you look to maximise the outputs of this work?

This project is the result of the collaboration between three research groups within the Company:

1. a **discovery** research group will identify and generate several genetically-engineered macrophage candidates

2. a macrophage **development** research group will pre-screen the cell candidates in vitro

3. an **in vivo pharmacology** team to test only best-in-class cell candidates in animal fibrosis models, thereby reducing the overall number of animals required

We will also look at maximising outreach of our data by presenting at conferences and publishing results (both positive and negative), thereby providing the scientific community as a whole with a blueprint to test this type of therapy using other cell types (e.g. cell therapy of liver disease using other cell types, e.g. hepatocytes).

Finally, we will ensure that our junior scientists are trained to design experiments that deliver reproducible and meaningful results; we will also ensure that they have received appropriate training to carry out complex procedures according to best standards, as set in the locally-approved standard operating procedures. This will maximise the chances of obtaining robust, reproducible and publishable results with the use of the minimum number of animals.

Species and numbers of animals expected to be used

- Mice: 6000
- Rats: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Inbred rodents (i.e. mice and rats that are almost genetically identical to each other) are the best choice for this project because they low biological variation between individual animals. Consequently, this will reduce the natural variability we observe in our experiments and means we require fewer animals to faithfully evaluate our new cell candidates. In this project, we will test the safety and efficacy of human macrophages in animal models

of acute and chronic liver disease. In most cases, we need to use immunodeficient rodent strains (i.e. rats and mice that lack certain immune cells) to allow the engraftment of human cells. Models of immunodeficient rodents are widely commercially available and are usually on inbred background strains to keep biological variation low. We propose to use adult rodents, not younger than 8 weeks, as the pathology we are experimenting a therapy for appears in the adult life of patients. Finally, inbred rodent housing and husbandry is highly standardised, ensuring consistent and robust results.

Typically, what will be done to an animal used in your project?

We will model several types of liver disease in animals: chronic liver fibrosis, acute liver injury, and liver ischaemia. We also intend to understand the distribution of the cells in animals in healthy and diseased animals.

1. Acute liver injury will be modelled by a single injection of a substance that is toxic to the liver i.e. induced acute liver injury. Mostly, we use a high-dose of paracetamol in mice (acetaminophen, APAP) due to its clinical relevance. Typically, mice with liver injury will receive the macrophage cell therapy candidate (or vehicle alone) via intravenous injection (tail vein) usually 16 hours following paracetamol administration. Mice will be culled at various times after macrophage treatment to understand how safe and effective our new cell therapy is. Liver and blood harvested from the mouse will be analysed in the laboratory to determine the effect of macrophage therapy on liver injury, inflammation, and liver regeneration.

2. Chronic liver disease will be modelled by repetitive treatment with carbon tetrachloride (CCl_4) twice-a-week for up to 16 weeks, depending the degree of liver fibrosis we wish to induce in animals (usually 8-12 weeks is sufficient). During the final weeks of treatment, animals will receive either macrophage cell therapy or vehicle alone (saline, control mice) via intravenous injection once-a-week. Mice will be culled at various times after macrophage treatment (from 1 day - 1 month after cell therapy injection). Another way to induce chronic liver disease is to administer thioacetamide (TAA) dissolved in drinking water. TAA treatment also may vary in length (6 - 22 weeks) depending on the degree of liver fibrosis we wish to induce. The TAA model is particularly useful because the resulting fibrosis is stable (especially in rat) whereas fibrosis automatically resolves in other liver fibrosis models (e.g. CCl_4). Therefore, the TAA model will therefore allow us to test macrophage cell therapy after stopping TAA treatment, and follow up its safety and efficacy for a number of weeks after injection (up to 12 weeks). This model will also allow us to model the injection of multiple doses of macrophages after the cessation of TAA injection (e.g. 4 doses over 4 consecutive weeks).

3. Liver ischemia is a useful model to reflect the injury processes that occur during liver surgery (e.g. when resecting cancer) where blood flow needs to be temporarily arrested. The mechanisms of injury differ to acute and chronic disease models and this model allows an alternative injury in which to test our cell therapy. Liver ischemia can be modelled in mice using a surgical procedure by stopping blood flow to the liver by gently clamping certain vessels for a fixed period of time. Once the clamps are removed, mice could receive macrophage therapy candidates (or vehicle) at different times, and though different routes to find the most effective treatment combination.

4. A small group of animals with liver disease will be subjected to non-invasive imaging to study where the macrophages go in the body after injection. This is important to determine any side effects, e.g. due to migration of cells to an unwanted site. During imaging, the mice will be under general anaesthesia for a short period of time to immobilise them. Their bodies will be scanned and images of the various anatomical compartments will be visualised on a computer to track the injected cells in real time. These studies will help us understand where the cells go in the body, and how long the cells stay there for. Data from these studies will allow us to better design future experiments and to know how many and how often macrophage cell therapy candidates need to be dosed.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals with chronic liver disease can develop weight loss and show temporary signs of illness, which can include: loss of appetite, piloerection (striking coat), reduced mobility, reduced response to external stimuli and general malaise. Very rarely, animals can develop liver tumours (hepatocellular carcinoma), most likely on the TAA protocol. Normally, general malaise develops after the injection of the substance used to induce liver injury, and for a short period of time afterwards (no more than 2 hours). The other side effects may develop over time (from 3 weeks of treatment onwards) in a minority of the mice involved in the experiment. Weight loss is a good proxy measure, together with behavioural changes (grimacing, withdrawal and subdued behaviour), for the development of liver tumour and it will therefore be monitored closely.
Mice with acute liver injury can develop weight loss, hypothermia, piloerection, general malaise, grimacing and withdrawn behaviour, which usually only lasts for 12-16 hours after drug administration and then quickly subsides. Usually, mice fully recover within 48 hours and regain full health.
Potential side effects of macrophage injections are infections (usually only in animal strains which are immunocompromised), pulmonary embolism (clot in the lungs caused by the injected cells) and a risk of increased inflammation. Leading up to this project, we have so far injected more than 100 mice with chronic liver disease with various type of macrophages, and we have never observed any of these side effects, which demonstrates that injecting macrophages is safe. Mice are to be observed for 15 minutes post-injection and then once every 24 hours to monitor for side effects.
During live imaging, mice undergo general anaesthetic. Animals can experience breathing issues, and an overdose of anaesthesia could potentially be fatal. To avoid this scenario, breathing will be monitored constantly during imaging, and percentage of gaseous anaesthesia carefully adjusted accordingly.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In this procedure project licence, the maximum expected level of severity is moderate.
The proportion of animals that reach moderate severity is protocol-dependant summarised in Table 1 and Table 2 for mice and rats, respectively.

Protocol Number	Protocol Name	Proportion - mild severity	Proportion - moderate severity
1	Breeding and maintenance of genetically-altered animals	100 %	0 %
2	Induction and resolution of liver fibrosis	10 % (healthy group, vehicle control only)	90 % (i.e. all animals entering liver fibrosis protocols)
3	Induction and resolution of acute liver injury	20 % (healthy group, vehicle control only)	80 % (i.e. all animals entering acute liver injury protocols)
4	Dose-finding procedure	40 % (mostly pharmacological agents)	60 % (mostly toxicological agents)

5	Ischemia-reperfusion injury	0 %	100 both receive	(controls and treatment groups surgical procedure)

Table 1: Mouse severity classification an d proportionality

Protocol	Protocol Name	Proportion - mild severity	Number	Proportion - moderate severity
2	Induction and resolution of liver fibrosis	10 % (healthy group, vehicle-control only)		90 % (i.e. all animals entering fibrosis protocols)
4	Dose-finding procedure	40 % - mostly pharmacological agent dose-finding		60 % - mostly toxicological agent dose-finding

Table 2: Rat severity classification and proportionality

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

When planning the use of a cell therapy, the first concern is safety. Whilst some safety tests can be carried out in a dish (in vitro), several adverse events commonly observed when using biological therapies depend on a number of complex interactions that happen within a living organism. Reproducing faithfully these complex interactions *in vitro* is still not possible. Therefore, the use of rodent models is still essential to study efficacy and safety of new cell therapy.

Which non-animal alternatives did you consider for use in this project?

The first part of the discovery 'screening' phase is to choose and test genes to genetically-engineer in macrophages to generate our new cell therapy candidates. All candidates will be thoroughly tested using a battery of in vitro measurements first to ensure:

1. the genetic engineering has worked
2. the genetic engineering is optimal and can't be further improved

3. the new candidate shows promise as an effective treatment for liver fibrosis in culture

This strategy will ensure that only the cell therapy candidates that have the best chance to work are tested on mice, thereby reducing the number of mice needed to carry out the experiments.
Some non-animal alternative models exist, including collagen degradation assays, and may be utilised in the development testing phase, however critical limitations exist meaning these alternatives do not faithfully model the true biology that underpins liver fibrosis.

Why were they not suitable?

In culture, we can use individual assays to separately test different aspects of macrophage behaviour and function. These include the ability to:
- eat pathogens and/or dead cells (phagocytosis)

- migrate through a barrier (similar to the migration through the scar in the liver that the macrophages have to do once injected in a patient/mouse)

- actively reduce the scar (collagen) by breaking it down

- keep a stable behaviour in the presence of inflammatory molecules

- produce molecules that can help to switch off inflammation and promote regeneration of the liver

However, in a fibrotic liver, the macrophage is likely to perform all these functions at once. Therefore, a mouse model in which the macrophage used as cell therapy can behave in a fully physiological manner is required. Finally, previous studies suggest that macrophages interact with many other cells in the liver, including scar-deposing cells (activated hepatic stellate cells) and biliary cells. These complex interactions are crucial to fully understand the therapeutic effect of the macrophages during liver fibrosis. Unfortunately, we are not able to recapitulate this complexity in a dish, and therefore we need a mouse model to do so.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

We have used a combination of approaches to determine the number of mice to be utilised in this project:
1. based on preliminary data, we have applied appropriate statistical analyses to predict how many mice per experiment we would theoretically need

2. for each experiment we have considered what the best experimental design could be, depending on the biological question we wish to answer with that specific experiment

3. based on the available scientific literature, and our previous experiments, we have selected the best models to answer our biological questions

4. we have used freely available online tools to help with the experimental design, to ensure it is optimised and tailored to our needs

5. we have follow the current national guidelines to design experiments, and we have kept in mind the recommendations for best practice during data analysis when designing the experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In order to optimise the number of mice utilised in the project, we have taken advantage of the NC3Rs Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-design-assistant-eda). This free online tool helps to achieve the best experimental design to answer one's question efficiently, minimising the number of subjects (mice) necessary. Moreover, we have considered the PREPARE guidelines (https://norecopa.no/prepare) to ensure we followed the best available recommendations when planning our experiments. The PREPARE guidelines are designed to help scientists consider all those factors that may help to achieve the most efficient experimental design. Finally, we considered what our goals were, and we planned how we would like to analyse data and report experiments, in order to guarantee an adequate experimental design. In order to plan the analysis and reporting phase of the project we followed the ARRIVE guidelines (https://norecopa.no/3r-guide/arrive-guidelines).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In order to further optimise the number of mice utilised, we will performed stringent in vitro screening of our genetically modified macrophages before testing them on mice. Therefore, not all candidate genetically modified macrophages will necessitate of in vivo testing, but only a small fraction of them. Moreover, we will share tissue between collaborating scientists. This will reduce the chance of needless duplication of experiments. Finally, live imaging procedure will allow us to follow macrophage cell therapy homing in various tissue over time. This approach will allow us to follow the same mice in time, without having to cull different mice at the different time points post-therapy injection. In some very specific cases, in experiments designed to understand how animals respond to a range of doses of a particular drug, it might be possible to re-use the same animal by re-testing a range of doses over a time period. This approach may reduce the number of different animals required for dose-finding procedures. In other dose-finding experiments with pharmacological agents/drugs, existing data from control treated mice in older studies (i.e. historical controls) may be used as the comparator group, but only when the drug effect is very reproducible, and does not change between different batches of animals. These additional measures can reduce the overall number of animals required in this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Acute and chronic liver disease models chosen for this project are very well characterised in the scientific literature. One of the advantages of using these methods is that the potential adverse events are very well known, and therefore we can efficiently monitor our animals, spotting them early at their onset and act upon them early to minimise animal suffering. Further, the high standardisation of the models means that we have already implemented stringent monitoring methods based on weight loss and clinical signs (hunching, squinting, withdrawn behaviour, etc) for models of TAA-induced, CCl_4induced liver fibrosis and APAP overdose. Plus, the

REDACTED have implemented state-of-the-art animal housing facilities, including environmental enrichment, which will

minimise stress for the animals during protocols. When we will work with immunodeficient mouse strains, it is necessary to provide antibiotics to reduce infection risk during certain procedures, which will reduce any unnecessary suffering, distress, or lasting harm.
Macrophage cell therapies have been administered in the past, in proof-of-concept studies, either in the spleen or through the hepatic portal vein. Both these routes of administration are invasive and require surgery. Instead, we use intravenous (i.v.) injection to deliver macrophages to animals. This way, we use models that faithfully reflect the design of the ongoing clinical trials where non-engineered macrophages will be injected intravenously in patients. Intravenous delivery is a safe and well-tolerated delivery route and will minimise the stress for the mice during injection. Further, mice will be carefully monitored after macrophage injection to ensure no severe side effects develop.

Why can’t you use animals that are less sentient?

We cannot use mice during embryonic development as they would not be a faithful representation of acute or chronic liver injury, pathologies that typically develop during the adult life in humans. We cannot use more primitive animals such as zebrafish and drosophila because they only partially recapitulate the complex environment in which macrophages will be injected when used as cell therapy. Finally, we cannot use mice that are permanently anaesthetised because we have to follow animals up for several weeks after macrophage cell therapy injection to determine how effective the treatment is. Induction and regression of liver fibrosis usually takes several weeks for detectable changes to occur.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In order to achieve the best results and minimise the welfare costs (harms) we will:

1 - As standard, house any animals subjected to anaesthesia in a heated cabinet to provide thermal support to aid recovery

2 - Provide thermal support to animals during any procedure that reduces body temperature (e.g. following paracetamol-induced liver injury) or if an animal becomes sick

3 - implement frequent checks, include weighing animals twice-a-week or more, as recommended by the local Named Veterinary Surgeon (NVS). Any animals about to exceed moderate severity will be humanely culled

4 - ensure adequate training of technicians and other personnel performing experimental procedures, so that they could be aware of the potential side effects and how to minimise pain and stress during the procedure itself

5 - administer analgesic drugs if recommended by the NVS

6 - implement a clinical scoring system that considers all aspects of the mouse behaviour that could indicate suffering, as advised by our NVS

7 - ensure that, whenever possible, the same person handles the mice when a protocol requires repetitive handling and manipulation (for example injecting CCl_4 twice-a-week for six weeks). This will decrease the stress for the mice, and will standardise monitoring after injection

8 - use appropriate anaesthetics and utilise them properly during surgical procedures

Importantly, the animal unit routinely uses appropriate environmental enrichment and handling techniques. These actions guarantee that the level of stress are kept at a minimum during the duration of the protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow constantly the NC3Rs and Norecopa websites in order to have the most up to date knowledge around experimental design, monitoring and minimisation of discomfort during experiments. We will also use databases such as PubMed or Google Scholar to search for the most up to date literature on our topic.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group will continuously refer to the NC3Rs website to stay informed on best practice in animal research (https://www.nc3rs.org.uk/). Further, we will participate to the local NC3Rs symposium, both actively by presenting our research and as delegates. Finally, we will participate to the personal licence holders' local annual refresher sessions organised by REDACTED at the establishment. We will implement any new recommendations by interacting with our local veterinary services, and by reading the relevant literature on the topic, in order to gain a better understanding of the practicalities around the change or refinement of a specific practice.

Home Office

NON-TECHNICAL SUMMARY

106. Mapping mechanisms for energy homeostasis in rodents

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Diabetes, Islets, Glucose, Homeostasis, Energy

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this research programme is to look at why and how diseases related to loss of control of energy balance- principally diabetes and obesity- develop. In this project, mouse models will be used to look at the contribution of a protein that is a fuel sensor, and the products of genetic variations that were identified as conferring disease risk in humans, in disease progression. Such studies are important as it is known the reasons behind disease is different between individuals so understanding the individual risk (by looking at the contribution of products of genetic variations) and more general risk (contribution from aberrant fuel sensor function) will provide a better picture of these diseases and how treatment may be tailored to the individual.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Our data indicate a fuel sensor is involved in regulating blood glucose levels and food intake/appetite. It is a particularly difficult protein to study and we have the necessary knowledge, experience and developed the tools that will allow us to study this potential drug target. Understanding the contribution of genetic variations that lead to disease will allow us to better tailor treatment for individuals based on which genetic variations they carry in their genome. This work is important as c.100 variations have been associated with diabetes/obesity, with more on the way, and we are very far behind in establishing whether/how these variations contribute/lead to disease. The work proposed in this project will chip away at this colossal work load

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project? We expect

to use mice (10000) and rats (500) over the course of the project licence

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

In brief we will be inducing obesity and diabetes with administration of diets with high caloric value and/or chemical/genetic manipulation. We will then try to reverse obesity and/or diabetes using drug treatment, and/or alteration of diet regiment. Treatment and monitoring of diabetes will require the use of procedures similar to those used in human patients. Animals will be humanely killed at the end of the project period. If the animal fails to respond to treatment or its condition deteriorates, it will be humanely killed.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The maintenance of normal energy balance requires the interplay between hormonal secretion from, and hormonal action on, different tissues. Neuronal outputs from the brain in response to changes in hormonal signalling and nutrient availability also modify the net effect on energy balance. Such complex interrelations cannot be reproduced in vitro and require a whole living organism. Although we do most of our work on cell lines and freshly isolated cells, we ultimately need to validate the systemic effects in the whole animal. Validation of the efficacy of drug targets can only be assessed in the whole animal.

Reduction

Explain how you will assure the use of minimum numbers of animals.

For most of the quantitative experiments, sample sizes will be set using careful statistical analysis. We will use the least number of animals to provide an adequate description, generally on the basis of previous experience (ours, or from other published reports). Usually 6-8 animals per treatment group are sufficient to obtain the required results

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Mice are the lowest vertebrates in which genetic manipulation can be successfully achieved and where diabetes studies are well documented. Rats give a better yield of blood and tissues per animal than mice and are preferred when we do not need to use transgenic animals. All the procedures in this licence are classified as either mild or moderate and are done under local, general or terminal anaesthesia, where appropriate, to minimise stress and suffering of the animals. Where appropriate, pain relief will be provided

Home Office

NON-TECHNICAL SUMMARY

107. Measuring brain activity of fish during humane slaughter

Project duration

4 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
● Tilapia (Oreochromis niloticus)	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The aim of the project is to develop and apply a method to measure brain activity of fish around the time of slaughter, to allow the development of stunners that render them unconscious immediately and until they are killed.

A retrospective assessment of these aims will be due by 24 February 2025

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In 2010 it was estimated that between 37 and 120 billion farmed fish were slaughtered. Ensuring humane slaughter of farmed animals, including fish, is an essential part of ethical food production. Humane slaughter requires that the animal is rendered immediately unconscious and does not regain consciousness until it is dead, this mostly requires some form of stunning. At present there is only effective pre-slaughter stunning for a small proportion of farmed fish. To ensure that the stunners are effective we have to measure the brain activity of the fish. This project will develop and apply methods to measure the brain activity of fish around the time of slaughter.

What outputs do you think you will see at the end of this project?

The project should result in new products leading to commercial opportunities and publications affecting worldwide improvements in animal welfare. It will produce a non-invasive (externally applied) system to monitor brain activity in a variety of fish species. It will facilitate the development of humane stunning equipment and allow evaluation of existing stunning systems.

Who or what will benefit from these outputs, and how?

The ability to monitor brain activity in animals around the time of slaughter is essential to ensure that the stunning is effective, and that they do not regain consciousness. The findings of the project can be rapidly implemented due to a rising demand in the sector. This project will benefit the welfare of farmed fish and farmers using the equipment and all those interested in the ethical production of farmed fish.

How will you look to maximise the outputs of this work?

This research proposal is a collaboration between industry, academia and the wider supply chain. The project will expand and refine our ability to humanely stun fish by widening the range of environments and fish species for which effective practical and objectively validated humane stunning systems can be supplied. Following scientific validation of stun parameters, full scale prototype stunning equipment will be installed in fish processing plants for additional commercially important species.

Species and numbers of animals expected to be used

- Other fish: No answer provided

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will initially use trout or salmon, since these are the species on which the majority of work has been conducted and published. Subsequently we will focus on the commercial target species: initially we will work with tilapia and subsequently if time and resources permit pangasius catfish.

Typically, what will be done to an animal used in your project?

Most of the fish will be anaesthetised and have their brain activity recorded. Some will then be stunned (rendered immediately unconscious) using an electrical field in water.

What are the expected impacts and/or adverse effects for the animals during your project?

We anticipate that the vast majority of the fish will experience no more than routine handling before being anaesthetised or stunned. Anaesthesia is a common husbandry practice based on addition of anaesthetic to the water. While this does cause a mild stress response it does not appear to cause any pain, suffering, distress or lasting harm. The fish that are stunned will be rendered immediately unconscious (<1 second) and will not regain consciousness before they are killed. However, in order to identify the effective lower limit of stunning it is possible two fish may suffer a brief electric shock before being humanely euthanised.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the test trout or salmon 100% will be sub-threshold or mild.

For each of the two target species (tilapia (n=150) and Pangasius (n=100)):
Non-recovery 33% (Tilapia), 50% (Pangasius)

Mild greater or equal to 63% (Tilapia), 44% (Pangasius)

Severe not greater than 4% (Tilapia), 6% (Pangasius)

All the fish will be humanely killed by a schedule 1 method at the end of the procedures.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 24 February 2025

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to develop methods to measure brain activity around the time of slaughter to make the slaughter of fish more humane. This can only be achieved through the use of live fish.

Which non-animal alternatives did you consider for use in this project?

Where possible we will use dead fish for testing our equipment but once we reach the stage of measuring brain activity, we need to revert to live fish.

Why were they not suitable?

Brain activity can only be measured in live animals.

A retrospective assessment of replacement will be due by 24 February 2025

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

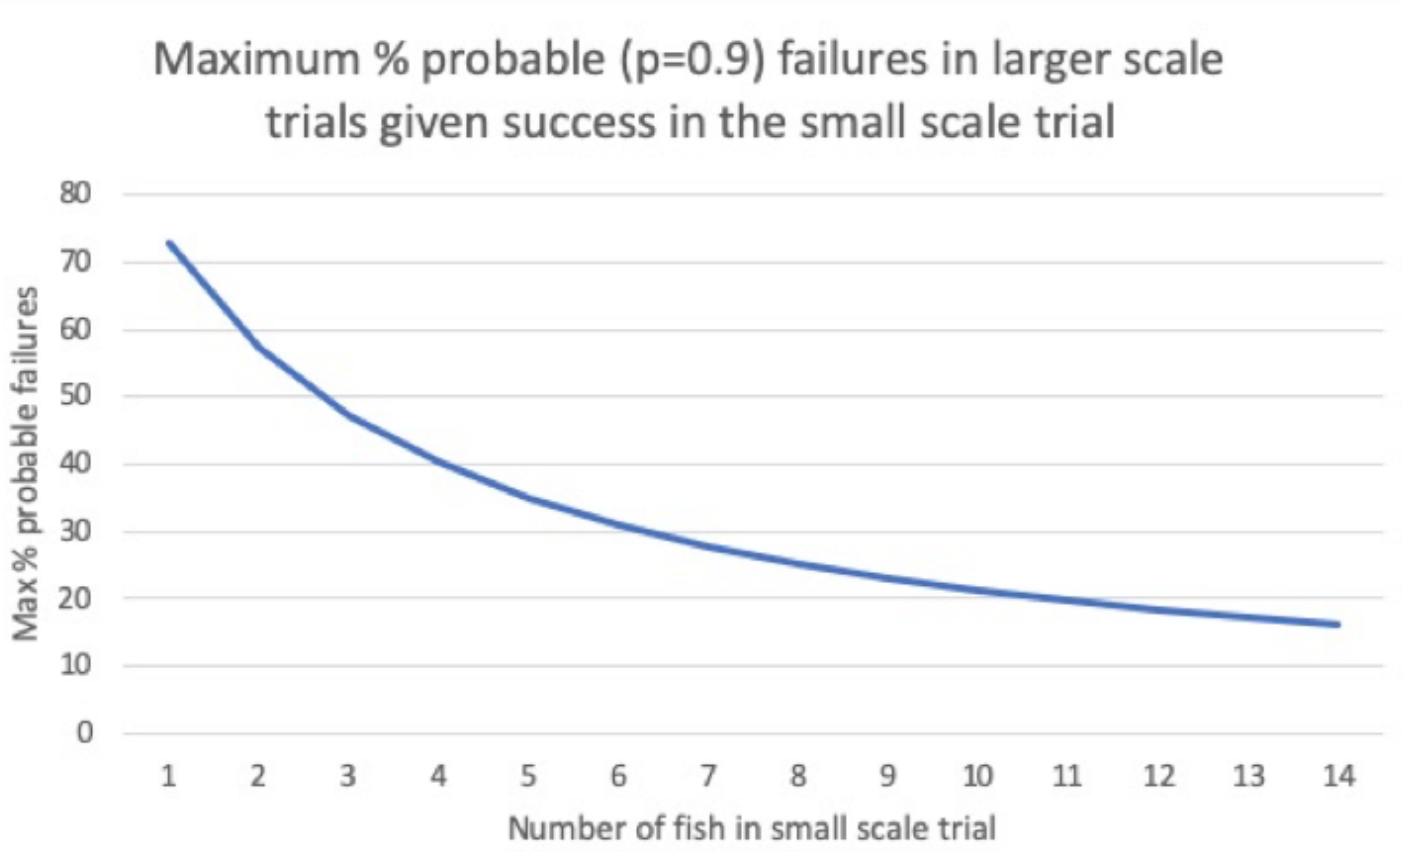
Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

the UK Animals Scientific Procedures Legislation (ASPA), Development of systems and procedures will be conducted with individual fish. Once we have systems or which appear robust at the individual fish level, we will use 6 fish per trial.

Success in 6 fish gives a reasonable compromise between power and numbers of animals used. Success in 6 fish suggests that failure rate in larger scale studies will be less than 31% (p=0.9), see graph.



Proportion in a single sample using Wilson's method (Altman, D (2000) Statistics with Confidence: Confidence Intervals and Statistical Guidelines, 2nd Ed. BMJ Books, 254pp.)
Eventually experimental trials will result in stunning parameters that will be used to inform commercial processes. At this stage although the activities will not be controlled under the UK Animals Scientific Procedures Legislation (ASPA), we will continue to monitor the efficacy of the stunning system to detect low prevalence problems that are unlikely to be detected in small scale experimental studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There is an inevitable compromise between reducing the number of animals and improving confidence in the results. We worked with a professional statistician to reach such a compromise. When using stunning equipment prior to slaughter there are some problems that only occur very rarely. We will not try to detect such problems under experimental conditions, since this would require the use of a very large number of fish most of which would not produce any useful information. Rather we have another phase of the project which will monitor large numbers of fish in commercial systems (outwith the UK). This will not be experimental and therefore will not covered by ASPA but will allow us to detect issues that only occur very occasionally e.g. 1 in 1,000 fish or even less frequently.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The research group has a great deal of expertise in all the key areas, minimising the need for developing new methods or equipment. In addition, we have an agreement with international groups which will allow us to exchange information and work in each other's laboratory. As a result, we will avoid duplication of effort in the two sites and both groups will benefit from advances made by either group.

A retrospective assessment of reduction will be due by 24 February 2025

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use the external application of electrodes to the head of fish to measure brain activity. This is far less harmful or distressing than the alternative surgical implantation of electrodes.

Why can't you use animals that are less sentient?

We are developing systems for monitoring the slaughter of commercially important species and therefore need to work with those species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Humane slaughter is an essential part of ethical food production and Electroencephalography (EEG) or measurement of brain activity is essential for determining if methods of stunning are humane. Currently accurate EEG measurement in fish requires surgical implantation of electrodes. The insertion of electrodes directly into the brain of fish, may result in pain and discomfort, requires surgical anaesthesia, delicate surgery, and that the animals are restrained post-surgery. The method being developed and applied here will simply require the application of a suction cap to the head of the fish. While the fish's activity will then have to be restricted, they will not have to be tightly restrained. This not only drastically reduces the severity of the procedure but will also allow data to be collected under commercial conditions.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will apply the NC3Rs guidelines - Institutional framework for the 3Rs, and Responsibility in the use of animals in bioscience research.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The hosting institution runs a compulsory program of training and refresher courses to ensure all staff using regulated procedures are aware of current developments. The Animal Welfare and Ethical Review Board and Named Information Officer also circulate any relevant information on a regular basis. The licence holder will also maintain a watch on the relevant literature. **A retrospective assessment of refinement will be due by 24 February 2025**

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future

work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

108. Mechanisms and treatments of eye disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Eye disease, Blindness, Retina, Photoreceptors, Gene therapy

Animal types	Life stages
Mice	adult, neonate, juvenile, pregnant, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the proposed project is to develop treatments for eye disease, especially those that affect the function and/or survival of the retinal pigment epithelium (RPE), neural retina (including the optic nerve) and retinal vasculature.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to find novel treatments, and improve the current ones, to beat sight loss. Partial sight and blindness in the adult population impose a large economic cost on the UK economy. Eye diseases become more common with the ageing population, vision impairment associated with conditions such as age-related macular degeneration (AMD) and retinitis pigmentosa (RT), where the retina, the light sensitive layer of tissue at the back of the eye, degenerates with age, compromises the quality of life and limits social interaction and independence. It has also been shown to interfere with the person's ability to care for themselves and others indicating a need for community and vision-related support. Aside from these socio-economic considerations, it has been reported that after cancer, people fear losing their sight more than any other medical condition. Besides, the degree of debilitation that sight loss can have on societies is important to consider, especially when effective treatments for many ocular conditions are limited. Vision loss can affect one's quality of life, independence and mobility and has been linked to falls and injuries, which in turn can have a big impact on mental health and wellbeing.

What outputs do you think you will see at the end of this project?

The main output of the project is the development of new and improved therapies for diseases and disorders of the eye. This will contribute to the current understanding and applications of treatments and therapies in the field. Our group has an established track record of successfully translating laboratory work into clinical trials. it is expected that any positive results of this project will be used to perform human clinical trials. In the future, this will lead to new or improved therapies for diseases and disorders of the eye and would therefore provide direct benefit to patients with eye disease.

Work under this project will also produce new information in the field which will be published, contributing to expanding knowledge in the field.

Also, the treatments assessed under the project will result in the development of gene and cell replacement therapies for the eye

Finally, products such as novel vectors for gene therapy will be generated for use in clinical trials. We are currently working on two novel viral vectors used for gene therapy in the eye, one for treatment of *CDHR1* gene mutations in the retina called (AAV8.CDHR1), and another on RNA editing of the *USH2A* gene. We are also planning to generate a novel Base Editing construct for the treatment of ocular conditions caused by single nucleotide mutations.

Who or what will benefit from these outputs, and how?

This project will develop new and improved therapies for diseases and disorders of the eye, providing a real benefit to human health and wellbeing, and also to fellow scientists and researchers in the field. Work in animal models has already been very successful in understanding the mechanisms of eye disease and in the development and testing of new treatments.

Benefits from the work under the project may be seen in the short-term as well as the long-term. Knowledge and information in the field produced by publications will be realised in the short-term and will benefit the scientific

community. Treatments and therapies discovered under the project will be taken to human trials and it might take several years to see the final result, however, if successful, this will provide a real benefit for people who suffer from debilitating eye conditions and it could have a big impact on their lives.

How will you look to maximise the outputs of this work?

We aim to explore novel therapeutic approaches of gene editing in the eye using molecular biology tools, such as clustered regulatory interspaced short palindromic repeats, known as CRISPR, and validate its efficiency and specificity as a gene editing tool as well as its safety as a therapeutic agent. We aim to achieve this by establishing collaborations with experts in the field of in vivo application of CRISPR tools. These collaborations will help to validate effective treatments of ocular diseases that are caused by mutations in specific genes. Current knowledge of efficacy and safety of such therapeutic approaches is limited, especially in the eye, and validation of any approaches, including unsuccessful ones, will vastly contribute to disseminate knowledge, expand our understanding of treatments and help to achieve our main goal of developing new and improved therapies for diseases and disorders of the eye.

Species and numbers of animals expected to be used

- Rats: 500
- Mice: 36 000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice, and rats, are the species of lowest cognitive ability that are suitable for eye research and are highly appropriate because they are well defined model organisms and well characterised disease model strains with inherited ophthalmological dystrophies already exist. We use animals at different stages of development to model different ocular disorders. For example, for ocular conditions that have a developmental origin, such as nystagmus, a significant eye disease with uncontrolled eye movements, it might be necessary to use neonates to study potential causes of the disease. For other diseases, especially those with late onset retinal degeneration, adult animals will be a scientifically more appropriate model to study the disease.

Typically, what will be done to an animal used in your project?

Typically, we aim to assess efficacy and safety of different therapeutic approaches to treat eye disease, such as gene therapy, by injecting animals with novel recombinant vectors that carry a correct copy of a mutated gene or a therapeutic reagent with a specific pharmaceutical property, injections normally performed in the eye. Changes in ocular behaviour/phenotype are normally assessed by a combination of techniques, such as eye imaging and visual electrophysiology, two weeks after injections or treatment. The imaging/electrophysiology can continue for a period of time (up to 12 months sometimes) to assess changes in the ocular behaviour and/or eye or retinal morphology, which can indicate efficacy and safety of the therapy applied.

What are the expected impacts and/or adverse effects for the animals during your project?

Adverse effects of the techniques used in the project can differ according to the technique used. The main impact on animals in this project is visual impairment/blindness, which in itself is not known to affect the animal's welfare and ability to thrive. the visual impairment/blindness once it starts, it will last a lifetime. The techniques performed in the project involve injecting therapeutic reagents into the eye so there is a risk of inflammation and infection in the site of injection. Such adverse effects, if occurred, are not expected to last a long time (a few hours).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In general, the expected severity of the protocols performed in this project is mild, this is for the majority of animals (approximately 95%). A small proportion of animals (less than 5%) might experience a moderate severity due to performing more than one procedure during their lifetime.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals must be used for this project since the development of therapies requires an assessment of efficacy and safety in live animals. The eyes of lower, non-mammal species are quite different from those of humans and so do not make good models to use to test potential clinical therapies in.
Wherever possible, treatments will be initially investigated in non-animal alternatives such as cells and tissue from human donors.
Which non-animal alternatives did you consider for use in this project?

We considered using human retinal tissue for retinectomy (surgical removal of small retinal tissue during routine surgery) as an *ex vivo* alternative approach. We also considered using isolated cells from patients skin biopsies as an *in vitro* alternative approach. We also routinely culture immortalised rodent and human cells lines of retinal or otherwise neuronal origin.
Why were they not suitable?

Animals must be used since the development of therapies requires *in vivo* assessment of efficacy and safety. For instance, in the case of intraocular/retinal inflammation (which occurs as part of retinal degeneration, in response to retinal gene therapy, or as part of uveitis), the systemic (humoral) immune system plays a central role in driving the inflammatory response. Therefore, a whole organisms-based model is required to study the mechanisms of retinal inflammation and test potential therapies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers have been estimated according to previous experience from previous licences.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal numbers will be kept to a minimum by using the most appropriate experimental design and statistical analysis. Wherever possible we will use technologies, such as imaging, to enable longitudinal studies in the same animal. Avoiding systematic error/bias and using adequately powered, multi-factorial experiments will help to reduce the final number of animals that are used. We use our experience of procedures and protocols to enable reliable estimation of the likely experimental and biological variation to be used in power calculation for determination of appropriate sample size (using http://statpages.org/). We also perform experiments that are 'proof of principle' and/or qualitative descriptions (e.g. test if a vector is capable of transducing particular retinal cell types). In this case, statistical analyses need not be applied and a very small number of animals (2-3) will be used.
Pilot/feasibility studies are also used, especially where from novel treatments or techniques.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have reduced animal use by establishing an *ex vivo* culture of mouse retinal tissue. This will never be able to fully replace in vivo studies and does not completely remove the requirement for animal use, as the mouse line/s used to generate tissue must be maintained. However, procedures on live animals are reduced (animals humanely killed before extraction of tissue) and several retinal tissue preparations can be made from one eye, allowing for experimental replication and/or multiple treatments to be assessed.

Using ocular imaging in mouse lines in which subsets of retinal cells are genetically fluorescently labelled means we can to non-invasively quantify retinal cells in vivo. We can longitudinally assess cell numbers in the same individual, quantify ongoing retinal degeneration and evaluate the effectiveness of therapies to prevent cell loss. Repeated measurement in the same individual dramatically reduces the number of animals used compared to histological techniques and does not suffer from inter-animal variability. More generally, we can often apply treatment to one eye and use the other as an untreated/sham-treated control. This reduces animal numbers, by abolishing the need for a separate cohort of control animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice, and some extent rats, will be used during this project. Rodent models, and particularly mice, have become the most widely used models of human disease. These small mammals are easy to manage in a laboratory environment, and multiple mouse mutants of retinal disease are already recognized or can be generated relatively easily for investigations. Also, in vivo transfection or silencing of specific genes in mouse retina or in vitro transfection of retinal explants, using electroporation (Matsuda and Cepko, 2004) allows rapid examination of genes and variants.
Why can't you use animals that are less sentient?

For treatments to have biomedical relevance and applicable to humans, a mammalian model organism must be used. Mice are the species of lowest cognitive ability that are suitable for eye research and are highly appropriate because they are well defined model organisms and well characterised disease model strains with inherited ophthalmological dystrophies already exist.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For models of retinal degeneration, such as the Rhodopsin knockout strain, the loss of rod photoreceptors is the main cause of visual impairment/blindness, which is caused by a faulty rhodopsin gene. One effective route to slow down the loss of the rod photoreceptors, or stop it completely, is treatment with cell replacement therapies. Recent advances in gene therapy in the eye, particularly the applications of CRISPR gene editing, meant that targeting disease causing mutations is achievable by injection of therapeutic agents into the retina. Subretinal injections is a well-established technique that provides effective delivery at the target site of the disease. To minimise potential harms to the animals as far as possible, we use the best possible equipment for experimental eye surgery and assessments. We often use clinical grade equipment that has been modified for animal use. We make sure our methods are conducted within the internationally recognised guidelines for animal eye research, laid down by the Association for Research in Vision and Ophthalmology (ARVO). We also make sure anyone conducting complicated procedures is highly skilled and adequately trained. Many people working on the licence will be clinical ophthalmologists, specialised in human eye surgery and transferring those skills for use in animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- The Laboratory Animal Science Association (LASA).
- The guidance on aseptic surgery (LASA).
- Guidance on the Operation of the Animals (Scientific Procedures) Act 1986 NC3Rs
- ARRIVE guidelines.
- NC3Rs responsibility in the use of animals in bioscience research guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We aim to periodically follow guidance on advances in the 3Rs from the 3Rs website. Also, at a local level, we regularly attend a departmentally arranged 3Rs meeting where different aspects on the applications of 3 Rs are discussed with local experts of animal research in the university.

NON-TECHNICAL SUMMARY

109. Mechanisms in very early mammalian embryos

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (e) Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work **Key words**

fertilisation, gamete-to-embryo transition, preimplantation development, biotechnology, biomedical model

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the process by which the gametes transform into an embryo during fertilisation using the mouse as a model.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Today, there is no comprehensive model of the gamete-to-embryo transition in any species, so this work addresses a fundamental biological question: how does embryonic life begin? The model we use is the mouse owing to its biomedical relevance and because many of the key processes occur too rapidly in other models (*e.g. Xenopus*, flies or zebrafish) to be captured.

What outputs do you think you will see at the end of this project?

In general terms, the work addresses the mechanisms underlying the extraordinary change that occurs when the gametes (sperm and egg) transform from cell death into a one-cell embryo during fertilisation. This work is fundamental in nature but promises to impact human and veterinary clinical medicine because it links so many important biomedical processes. These include cancer, the regulation of body mass, the new idea that acquired traits can be inherited (highly clinically and economically relevant to the inheritance of acquired obesity), and regenerative medicine. For example, tomorrow's regenerative medicine requires that we have a good understanding of how cells control their fate, but no such understanding exists today. The potential of regenerative medicine to revolutionise certain areas of health-care is recognised internationally. The approaches we adopt contribute to this and promise to reduce animal use by streamlining genome manipulation and illuminating mechanisms of reprogramming. Advances in genome manipulation should be applicable to larger animals, such as pigs that are favoured by active collaboration in this area by sharing knowledge obtained in the mouse. Early embryonic pathways and components may suggest new explanations of idiopathic human infertility. As the outputs relate to specified Objectives, they are as follows:

Objective 1. To determine chromatin changes in mouse one-cell embryos. Outputs:

1. Identification of chromatin remodelling activities required in one-cell embryos for full-term development.

2. Determination of altered chromatin remodelling in atypical embryos to help delineate normative remodelling following fertilisation.

Objective 2. To determine transcriptome changes in mouse one-cell embryos. Outputs:

1. Determination of the precise kinetics of embryo genome activation (EGA).

2. Identification of genes participating in EGA.

3. Identification and characterisation of factors that activate EGA genes and their interactions.

4. Characterisation of epigenetic inheritance as manifest in preimplantation embryos.

Objective 3. To study how changes in mouse one-cell embryos are integrated. Outputs:

1. Demonstration of how cell cycle progression (meiotic exit) impacts chromatin remodelling.

2. Evaluation cross-talk between embryo processes; for example, how the protein Emi2, maintains ensures that cell division occurs normally.

3. Evaluation of components that regulate the normal cell division.

Objective 4. To harness processes in mouse one-cell embryos for new methods of genome and proteome manipulation. Outputs:

1. Refined genome editing using next-generation editors and base and prime editors.

2. Refinement of homology-directed repair-mediated editing.

3. Establishment of a protocol for genetic code expansion for inducible protein expression *in vivo*.

Who or what will benefit from these outputs, and how?

The work covered during the lifetime of the license will help to fill a fundamental knowledge gap concerning how one-cell embryos are formed. This is expected to have broad implications that will impact academic and commercial research communities including post- and under-graduate students (*e.g. via* the revision of text books) whose interests include embryology, cellular potency regulation, development, bioinformatics, epigenetics and stem cells. In the near term, the project will impact research communities studying fundamental aspects of gene regulation in human one-cell embryos, but it will subsequently contribute to greater awareness of human development locally, nationally and internationally. Over the longer period, extending from the duration of the work to years beyond it, knowledge generated here will also inform new healthcare messages, interventions and treatment regimes, with beneficiaries that include health care professionals, private and public health institutions (NHS, social services), policy makers (Department of Health, Health Authorities), charities (*e.g.* WHO, Diabetes UK, BHF), pharmaceutical and biotechnology companies. Overall, this potentially includes all groups whose work touches upon healthy development, since all development begins with a one-cell embryo. It will directly impact assisted reproductive technology (ART) by suggesting new diagnostic markers and treatments. Mechanisms underlying non-classical inheritance may operate in multiple (or potentially all) circumstances at the one-cell embryo stage, so this work will accordingly be relevant to those working on the inheritance of acquired traits. The work will illuminate mechanisms of embryo formation, thereby informing practical improvements to cellular (regenerative) medicine strategies that involve changes in cell fate potential. Information gained by the proposed work may provide vital information for human genome editing.

How will you look to maximise the outputs of this work?

Outputs will be maximised by publication in high-profile journals. Seminars, policy-makers and the commercial sector will be used to communicate to academic and clinical stake-holders. International meetings will grant the work a broader scientific audience that includes clinicians, those engaged in translational research. Wherever possible, the media will be asked to promote awareness of human early embryonic development and its healthcare policy implications. New technical advances applied to human early embryos are likely to affect everyone in the coming decades, so the work pays attention to communicating often impenetrable jargon by engaging broad publics, for example at TEDx and the Progress Educational Trust internationally. Outreach will be extended by contact with post-graduate and final year undergraduate students in seminar series, lecture courses to final year undergraduate students and as a recent STEM Ambassador with frequent presentations to A-level students. Research news will be disseminated to local, national and global audiences via university communications and events offices as well as communication through the internet.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Since very early embryonic development (the subject of this work) is distinctive in mammals such as humans, the choice of model species is restricted, and commonly-used model systems such as frogs, zebrafish or invertebrates such as flies are not applicable. In these non-mammalian models, the start of embryonic genome activity (known as EGA in mammals and the mid-blastula transition, MBT in nonmammals) occurs in embryos comprising many hundreds of cells, whereas in human and mouse it occurs much earlier. There are other differences. For example, in frogs, nuclear size scaling contributes to the timing of EGA, but no such scaling is reported in mammals. Multiple differences also exist between mouse and frog one-cell embryos. The mouse (*Mus musculus*) is a model because it is a genetically and embryologically tractable system enabling micromanipulation, genetics, embryology, transgenesis, gene targeting and imaging. These are some of the reasons why the mouse is a widely accepted model of health and disease in livestock and other larger mammals that may be biomedically important (*e.g.* pigs), as well as humans. Indeed, the mouse is a model of human pathobiology that will allow disease traits produced by embryo interference to be mapped onto human conditions. The mouse system is likely to be particularly amenable to revealing links between the early embryo, body mass control and cancer, opening new avenues to their study. The outcome is expected to enhance not only disease modelling but provide a clear line of sight to clinical diagnosis and therapy.

Typically, what will be done to an animal used in your project?

Most will be used for the production of sperm and eggs (gametes); this project is mostly concerned with manipulating and monitoring gametes and preimplantation embryos. For a comprehensive analysis of these early processes, it is necessary to show how they are manifest later in development, including in adults.

What are the expected impacts and/or adverse effects for the animals during your project?

The vast majority of mice used in the work of this license are expected to be healthy. Phenotypes of a subset are not predictable, but we anticipate that some may develop tumours or experience metabolic abnormalities (*e.g.* weight gain). Animals will be carefully monitored by ourselves and staff, and any signs of poor health will trigger the involvement of the NVS.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority (>99%) of animals are expected to be healthy and not to experience any enduring discomfort. The small proportion exhibiting ill-health are expected to belong to the GAA (moderate) category, expressing transgenes corresponding to transcripts present in early embryos.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Wherever sound alternatives to animals are available they are taken, including predictive computer algorithms and cultured cell lines. However, there is no accepted in vitro source of mouse gametes that are central to the proposed work. Recent studies have reported 'in vitro' gametogenesis, and whilst these studies are extremely impressive, spermatozoa have not been produced (post-meiotic precursors, spermatids, were obtained). The production of eggs required *ex vivo* material and the resulting oocytes produced abnormal offspring. Moreover, the efficiency of full-term development supported by either set of gametes (combined with naturally-produced counterparts) is very low - a maximum of ~4%. These features of *in vitro* gametogenesis make it unacceptable for the work of the current proposal; it introduces unknown and non-trivial variables. It is therefore unavoidable that gametes for the proposed work are recovered *ex vivo*.

Which non-animal alternatives did you consider for use in this project?

We have considered gametes produced from cells cultured *in vitro* as described above. The proposed work is complemented by other, non-animal approaches, but they are not alternatives: if there were alternatives, they would be used.

Why were they not suitable?

There are no alternatives. The recapitulation of sperm and egg generation in mammals *in vitro* has never been completely achieved and what has been done is extremely inefficient. The use of normal, healthy gametes completely capable of supporting full-term development is a *sine qua non* in the present work.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimation is based on extensive experience on early embryogenesis, accommodating consultation with statisticians and input from experts in this area. It assumes that there are two postdocs whose main occupation is performing micromanipulation. For experiments in particular requiring oocytes and embryos produced following *in vitro* manipulation, it assumes an average of ~20 oocytes are obtained per female and that over the course of five years, there are two phrase or equivalent, requiring 25 mice per week (48 weeks per working year) to produce oocytes mainly for *in vitro* maturation (IVM) and/or micromanipulation such as intrcytoplasmic sperm injection (ICSI) and/or *in vitro* fertilisation (IVF). Oocyte and embryo manipulation and analysis are

central to the work of the laboratory. In many cases the oocytes and embryos will be genetically modified (GAA), for full cell biological and developmental evaluation of genes expressed in early (especially one-cell) embryos. The number of GAA required reflects a combination of factors, including their utility (*e.g.* Venus-Tubulin, or histone H3-mCherry mice can be used in multiple lines of work), fertility (some GAA do not breed well, requiring greater numbers), the efficacy of the mutation where it is generated *de novo* (*e.g.* by genome editing) as, for example, edits often do not inactivate their target gene, and developmental phenotype (some homozygotes result in embryo death, meaning that the mutation has to be maintained in heterozygotes, increasing the animal number required). This last point is germane because we are studying the roles of genes in early development. There are fluctuations in GAA mouse colony numbers due, in part, to the specific nature of the work focus at a given time. By way of example, we might expect one post-doctoral researcher (pdra) to average ten colonies (each of ten GAA) including genome-edited mice and transgenic lines including reporter lines (*e.g.* ubiquitously expressing fluorescent proteins); at 100 GAA/week, this totals 15,600 mouse weeks for one pdra over a typical three-year project grant.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The transgenesis and editing protocols that will be used minimise animal numbers by producing improved models containing fluorescently-labelled gamete proteins and utilising a highly efficient method, or by genome editing via a highly efficient method. The work promises novel and improved methods of genome manipulation in mice and larger mammals, and it can realistically be hoped that they will reduce requisite numbers of both. The genetically altered animals here will be mice. Where suitable lines already exist, animals will be obtained from the relevant supplier or re-derived by embryo transfer (Protocol 2) from our previous work. Otherwise, we will generate the required lines ourselves or, in the case of gene-targeted lines, in collaboration.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will institute an efficient breeding programme for Protocol 05, the best estimate of precisely how many animals is comprised of two components: numbers required for the production and consolidation of GA mice, and the number of GA mice required for the expansion of desirable lines. The Production estimate assumes 10 lines per year, each of which derives from 5 founders (F0). Crossing with C57BL/6 will generate 20 transgenic F1 and 40 transgenic F2 offspring, the minimum for analysis to yield transgene-expressing lines for brother-sister mating, to generate 12 F3 offspring. This yields 77 GAA/line/year. Expansion is necessary for a thorough analysis of transgene behaviour or where transgenes encode markers. The estimate again assumes that an average of 10 lines are maintained at any one time. We share tissue where possible and perform strain storage and archiving.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The vast majority (>99%) of cases will cause no pain, suffering or lasting harm to the animals. This is because

the methods are either non-invasive (*e.g.* breeding GAA) or standard protocols that are brief (*e.g.* superovulation) or refined and which would not succeed if distress and suffering had not been minimised (*e.g.* embryo transfer; efficiencies of >80% per transferred embryo are obtained). In the unlikely event that lasting distress becomes possible (e.g. because interference with a given gene unexpectedly produces a disease phenotype), the experiments are all set up to detect it at the earliest juncture, so that, with guidance from one or a combination of the HOI, NVS and NACWO, the appropriate response can be made and if necessary, the animal killed by a schedule 1 method.

Why can't you use animals that are less sentient?

In general, the phenotypic effects of altering components involved in early embryogenesis are not expected to exert adverse effects on adults - they are active far earlier in development - and cannot be studied except during healthy development to adulthood. Most of the animal experiments will be performed in preimplantation embryos .

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Methods will be adopted that have improved efficiency in mouse transgenesis and refined mouse genome editing. In addition, challenging research areas that are in error will terminate wasteful lines of animal research and help to refine the mouse model of early development.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will closely follow the new ARRIVE reporting guidelines (ARRIVE 2.0) published recently in PLoS Biology, which build on previous guidelines already accommodated in our approach and with respect to the NC3Rs (<https://arriveguidelines.org/news/new-arrive-guidelines>).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are in contact with our regional NC3Rs Office and monitor the NC3R website (<https://www.nc3rs.org.uk>).

Home Office

NON-TECHNICAL SUMMARY

110. Mechanisms of diabetes-associated heart disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants.

Key words

Diabetes, Heart diseases, Heart attack, gene function

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to determine the fundamental role of genes involved in diabetes-associated heart

disease, in particular the effects of diabetes on the development of heart dysfunction. The objective is to develop the treatment strategies of heart dysfunction, particular in diabetes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Diabetes affects 10% population worldwide. Approximately 57% diabetic people will develop some degree of damage to heart function. Diabetes not only affects structures and function of heart muscles, but also causes poorer prognosis after heart attack. This project will benefit diabetic patients suffering from heart disease by identifying new treatments to improve heart function.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The designed work will be conducted in mice for the duration of 5 years, which includes five thousand animals. Genetically modified mice will be used to study the role of genes in the heart.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Mouse models will be used to study the effects of both types of diabetes on heart disease. With both models, animals will have raised blood sugar levels, eat and drink more, and urinate more frequently than control mice. Animals are regularly checked, and cages are changed daily. We typically use streptozotocin to develop Type 1 diabetes on mice, in which loss of body weight may occur. Type 2 diabetes will be induced by high calorie food, obesity or skin irritation may occur. At any stage, if the mice display any distress or lose a lot weight, they will be killed humanely.
When checking blood sugar in models of diabetes, we may remove food from the cage for 6-18 hours, which may irritate the animals though water will be always provided. A small amount of blood will be collected under local anaesthesia to reduce stress in the animals.
Administration of pharmacological agents by injection or oral route (gavage) may cause transient stress. Where appropriate pain relief medication or local anaesthesia will be provided. The animals will be carefully monitored to ensure effectiveness.

Post-heart attack injury will be induced under terminal anaesthesia by ligation and subsequent untying one of the major blood vessels of the heart (coronary artery). These mice will not recover after surgery.
To assess cardiovascular function, mice will undergo a series of tests, including ECG for heart rate and rhythm, blood pressure which are not performed under sedation and cause little stress to the animals. Cardiac ultrasound will also be performed under general anaesthesia. These tests may be repeatedly performed, in which the animals will recover from general anaesthesia and be reused. The welfare of the animals in these longitudinal studies will be carefully monitored.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The anatomy and physiopathology of the heart in mouse is similar to the human heart. Diabetes is a whole-body disease, affecting hormone, immune and cardiovascular systems, which cannot be effectively tested in non-animal systems. Hence, there are currently no alternatives to the use of mice.
Cultured heart cells or isolated heart complement our understanding of gene function and treatment dose or efficacy. If any relevant non-animal alternatives become available during the course of the work, we will incorporate these in our projects.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will use statistical Power Calculations based on our previous experiments and experience, which allows us to minimise the number of animals.
We will use efficient and optimised breeding protocols to minimise animal number. In addition, the use of control animals can be reduced, because the variation between these mice is lower. Where possible control data from previous experiments may be used to minimise controls.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Gene changed mice are well-established models for studying the cause of heart diseases in human. Although gene changes may result in unexpected suffering, these occurrences are rare, and the mice will be monitored at all stages.
To minimise the harm to the mice, we will continue to use/improve these refined approaches and techniques, causing the least pain and distress whilst being able to meet our objectives.
Blood collection and administration of pharmacological agents by injection or oral route (gavage) will be performed with pain relief medication or local anaesthesia. Mice will be carefully monitored. We are familiar with the methods, and no adverse impact on animal welfare is expected.
Induction of post-infarction injury by ligation and subsequent untying of coronary artery will be carried out under general anaesthetic to ensure that the mice do not feel pain. The mice will not recover.
Echocardiogram will be performed under general anaesthesia, while ECG and blood pressure check are performed on conscious mice, which is free of stress. In the majority of cases, heart function tests will be performed under terminal anaesthetic from which mice do not recover.
At any stage, any mice showing signs of distress will be evaluated in consultation with the veterinary surgeon and killed humanely if the distress cannot be averted.

Home Office

NON-TECHNICAL SUMMARY

111. Mechanisms of Immunoglobulin G-related autoimmunity in chronic primary pain conditions, and pharmacological solutions.

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Chronic primary pain, auto-antibodies, epitopes, mechanisms, therapies

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

To understand the cellular and molecular mechanisms underpinning the pain phenotype in passive transfer models of chronic primary pain, and to establish potential pharmacological solutions.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic primary pain conditions, including FMS (Fibromyalgia) and CRPS (Complex Regional Pain Syndrome) are amongst the most severe and disabling unexplained chronic pain conditions in humans, causing severe suffering and dramatic economic losses. In either condition only few patients attain long-term benefit from available drug treatments. New solutions are desperately needed.
Pain-sensitising serum autoantibodies in these conditions, can explain for the first time why patients get such pains. There is the potential for drug-, and diagnostic test development. However, to develop new solutions we now need to understand the cellular and molecular mechanisms by which the antibodies have their effect

What outputs do you think you will see at the end of this project?

Outputs will include a better understanding of these conditions, for example outlined in publications, novel leads to the development of diagnostic serum tests, and novel leads to drug developments
Where distinct epitopes are identified we hope that patents will be another output.
The respective UK and international Guidelines on information for patients with both conditions will be updated as appropriate (Royal College of Physicians and others) **Who or what will benefit from these outputs, and how?**

Patients and relatives, and employers will benefit as there will be better understanding of these conditions, which will facilitate diagnosis and acceptance - acceptance is still often an issue because many doctors, relatives or employers don't understand why patients would have pain without having a destructive problem – this is causing substantial suffering.
Patients and their relatives will further benefit as this research should lead to the development of diagnostic serum tests, likely within the 5 years of this license period, or at least to a clear pathway towards the development of such tests. Currently diagnosis relies on clinical criteria and is often severely delayed up to several years, leading to inappropriate treatment and suffering from not understanding what is wrong.
Patients, their relatives and the wider society may also benefit from the development of effective treatments arising from leads identified in this research. Current drug treatments are poorly effective, resulting in reduced activity, lost work days, and missed opportunities for personal development for many patients.

How will you look to maximise the outputs of this work?

We will work with various charities, patient organisations and Royal Colleges to enhance dissemination. We will also use the University Press Office and as appropriate approach national and international press to disseminate our findings.
We would publish unsuccessful approaches to avoid futile duplication - we have a good track record of doing this.

It is possible that by the time of the end of this license period commercial entities are being involved who can help promote new tests for example.

Species and numbers of animals expected to be used

- Mice: 3000
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The use of rodent models for the assessment of chronic pain is the most appropriate scientific approach as rodent responses to a large number of pain stimuli have been well assessed in the literature and assessment methods have been shown reliable and valid; such data does not exist for any other species.
Excepting specific questions around paediatric pain, the use of adult rodents is the accepted method; in younger rodents the pain-sensing system is immature and any results cannot be translated into a better understanding of adult human pain mechanisms.

Typically, what will be done to an animal used in your project?

Animals will be habituated and will have at least one set of baseline tests of their sensory-motor function, in some cases they will be trained to perform some sensory-motor tasks to allow accurate recording of their sensory-motor function, no longer than 1 month before the operation (in the case of the CRPS protocol only) and/or start of human IgG injection (next step). They will all-together experience no more than very mild discomfort from such testing (optional step -most animals will undergo this step). Overall habituation and baseline testing are expected to *reduce* any distress the animals will experience in the establishment, and with later sensory-motor testing.
Animals in the CRPS protocol will then have a small, shallow hind-paw incision (obligatory step) under general anaesthesia (skin and muscle fascia), which will be sutured or glued. Most mice will exhibit some transient discomfort post-operatively (moderate). The wound will heal rapidly. In rare cases of wound dehiscence this will be repaired under GA.
In both protocols, either starting before the operation or after, animals will receive intra-peritoneal injection with human IgG or vehicle, maximally once a day. They may further receive application of a compound, either per subcutaneous/intraperitoneal/intravenous injection, or orally (no more than twice a day).
Both types of applications (IgG and compound) may be done on the same days and may continue daily for no longer than 3 weeks after the operation. This will cause no more than mild discomfort.
The animals may provide tail-vein blood, maximal frequency every two days not exceeding recommended withdrawal amounts, causing no more than mild discomfort.
The animals may then again be subjected to sensory-motor testing repeatedly - after the operation and/or first IgG injection - (no more than three tests per day), for maximally 21 days. These postoperative tests will cause no more than very mild obvious discomfort, although since this protocol is instituted to mimic a chronic pain condition (if human IgG is also injected), then if any mild behavioural abnormalities are seen their discomfort may be considered moderate with only mild signs.
At the latest 21 days after the operation and/or first IgG injection the animals will be killed, either with a schedule 1 method, or under terminal anaesthesia where blood may be drawn/paraformaldehyde intracardially injected.

What are the expected impacts and/or adverse effects for the animals during your project?

Operation

1. Animals which have undergone plantar incision may develop varying degrees of lameness. The hind paw on the operated side may be withdrawn into a protected position. The animals may walk with a limp. Recent studies have shown that the incision is fully healed in mice within 2-3 days, such that the wound is difficult to discern. The animals should be weight-bearing within 4 days; if they are not they will be killed by a schedule 1 method.

2. There is a small risk of dehiscence of the wound as animals will remove sutures (usually within one day) and as such wound glue may be employed. Wound dehiscence will be repaired once only under anaesthesia; animals with serious or repeated wound dehiscence will be killed. There is a minimal (less than 1%) risk of inflammation or infection after surgery.

3. Adverse effects from General Anaesthesia include hypothermia, dehydration, overdosing of the anaesthetic agent, however we will adhere to BSU standards for anaesthetic drug delivery and perioperative care, and the procedure is short, therefore we do not expect more than moderate effects. If signs indicating severe adverse effects unexpectedly emerge which cannot be rectified, the animal may be humanely killed - this will be decided in consultation with the NVS as appropriate.

Injections

Rarely injection site reactions or injection site inflammation may occur.
Mice may become irritable with repeated injections over time
In our experience repeated treatment with human IgG for less than 14 days does not cause more than mild adverse effects. Repeated treatment with human IgG for longer than 14 days can occasionally result in serum sickness (a reaction of the mouse immune system against the human protein), characterised by signs of general un-wellness.
Rarely systemic adverse events may arise from other compound treatments with, particularly novel substances. The effects of such novel test compounds are difficult to predict, but any compound for which no safety data in mice or rats exists may first be tested in non-protected species. We will consult the NC3r toxicology resource hub as appropriate.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity grade for all animals in the CRPS protocol is *moderate* because all animals (100%) will undergo a surgical operation, (1560 mice, 400 rats)
In the FMS model, the severity for those animals receiving IgG from patients is per definition moderate because they develop sensitivity that resembles a chronic pain condition although their behaviour on observation to the naked eye is normal or only mildly affected (e.g. moving/ rearing may be mildly reduced).
The expected severity for animals in the FMS model receiving healthy control IgG injection for mechanism research (n=440 mice, n=200 rats), or healthy control IgG plus saline vehicle injection for compound research (n=150 mice) are considered mild, i.e. a proportion of 41% of mice (i.e. of a total of 1440 mice), 50% of rats (i.e. of a total of n=400)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We presently don't know how autoantibodies cause disease in FMS or CRPS but we have found that these human pain disorders can be reproduced in mice by 'passive transfer' of the patients' autoantibodies, i.e. the antibodies are taken from the patients' blood, purified, and then injected to the mice. This finding indicates that autoantibodies are responsible for the human disorders, and that they interact with the mouse organism similar as in humans, causing these pain disorders.
We need to use animals to achieve the first aim of our project, 'to better understand the mechanisms of autoantibody action', to understand at least the starting point of the autoantibody-related biological processes leading to disease.
The alternative would be to try and guess the relevant processes and hope that research using cell lines based on such guesses can identify the relevant mechanisms; such an approach has - to our knowledge - never been successful in any autoimmune disorder research where the antibody-target was unknown - posing risk that no new solutions for patients will be found. For example, we have identified specific autoantibodies against autonomic receptors in a substantial subgroup of patients with CRPS, using primary rodent cells. However while interesting, it remains unclear whether/how these antibodies specifically contribute to the disease process, or (more likely) whether they represent epiphenomena. This is hindering progress towards the development of novel therapies - this type of in vitro work has therefore reached its limitations.
We will pursue our second aim, to identify drugs that can ameliorate or abrogate the disease processes, only after we have been able to identify important disease mechanisms (as above), and only after - following appropriate advice, alternative methods (use of non-protected species or cells) to identify potential safety problems have been applied. At that point, the alternative to using animals would be to use these drugs in humans *without* efficacy or safety data in animals, which is not feasible. We will only use animals for as long as is required to understand that a particular drug is truly effective in the model, thereafter experimental approaches in humans will be more appropriate.
We have considered to develop an in vitro/ex vivo screen, after antibody mechanisms are identified in the epitope/cell function experiments, before using animals to assess compounds. For example, if we can find that (hypothetically) a novel cytokine is involved in mediating the downstream effect after antibody binding to a satellite glia cell in the DRG, and if effects of novel compounds to directly block the production of this novel cytokine are not well described in the literature, then instead of using animals it would appear more appropriate to develop either a primary cell line or if possible an immortalised cell line to first establish that a particular drug actually affects that pathway. *Therefore, for any identified mechanism that we will address with compound testing, we will carefully weigh whether the information available about the action of that compound is adequate to justify use in the model directly, or rather whether first assessment in cells should be evaluated* to clarify whether this pathway is actually sufficiently interfered with by the compound. Only the most efficacious drugs would then be tested in the animals.

Which non-animal alternatives did you consider for use in this project?

We did consider using human tissue either derived from biopsies, or from human tissue harvest after death in order to achieve part of our first aim, to identify epitopes. For clarity, in such research human tissues could be put in contact with the patients' autoantibodies. As autoantibodies 'bind' to tissue, it may be possible that such binding could be identified and from there the binding structures ('epitopes'), and mechanisms could be explored.
With regards to the use of non-animal alternatives to assess the effects of drugs, we will in part use nonanimal methods.

Why were they not suitable?

Human tissue: firstly our preliminary research has already indicated that the likely target tissues in humans are dorsal root ganglion cells, sub-groups of immune cells, or brain/spinal cord cells; these cells are not generally ethically accessible using biopsies in humans. Additionally, even if it was possible to take biopsies from these tissues, this process would not be useful to achieve our objective because it would not generate sufficient tissues to identify epitopes (see also below).
With respect to the use of tissue from human tissue banks, in the case of CRPS, binding is likely only possible if the patient has sustained a limb injury - we have tried previously to identify binding by using tissue from naïve mice (and checking whether the human antibodies bind to it) - this was not successful. Similarly it is hence unlikely that we would find binding in *human* tissue unless a distal limb injury has occurred shortly before tissue harvest - so that in order to have sufficient material we would likely require tissue from a large number of patients who died shortly following a distal limb injury, which is not feasible.
In the case of FMS, we will in parallel pursue an avenue of trying to identify staining with human IgG using suitable tissues derived from tissue banks (DRGs to start with). However, while this approach may eventually support the validation of animal research, it is not suitable for the identification of epitopes with currently available methods, because not enough human cell material would be available to make it possible to detect the molecular structures to which the antibodies bind.
Tissue from tissue banks is not alive and is therefore not suitable for the identification of cellular mechanisms.
Non animal alternatives to assess drugs: We will reduce the use of animals by first screening, where possibly, cell lines for compound effects after antibody exposure as described above. However the human organism is a complex system, and many molecular processes cannot be modelled in cells because many different cell types and sub-types are involved to produce the phenotype. This is particularly true for chronic pain. Therefore only using cells to assess compounds before human testing is not suitable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Overview details about number of animals are given in the Action Plan section.
All numbers are maximal numbers. Animal numbers were discussed with an expert in statistics for rodent experiments. There are two protocols, A) Fibromyalgia, B) CRPS. Both protocols use the same approach: a mix of blood proteins ('immunoglobulin G antibodies' (IgG)) will be purified from the blood of patients suffering from either condition, or from healthy controls and will then be injected into groups of mice. Within that mix, some proteins are thought to cause the respective pain disorder.
Each of the two protocols has two components – component 1 relates to the objective of better understanding the mechanisms by which the proteins cause disease. No power calculation was considered appropriate for this section. We and others have conducted and published experiments before, outlining the typical number of animals needed. Component 2 relates to the objective of evaluating therapeutic substances.
component 1 – better understanding of disease mechanisms
Tissue binding studies will be conducted to understand to which tissues the human proteins bind – harvested tissues will be sliced very thinly; this will be followed by experiments investigating cell function.
To identify the molecular structures to which the IgG bind, methods will be refined in accordance with the cell type identified, and then sufficient mass of bound protein needs to be generated to allow analysis; this process is the central method to identify the exact binding; up to 10 animals need to be used to generate enough tissues for one experiment; note where the use of rats is required because use of mice is found to not provide sufficient

tissue, then fewer mice are needed; further where use of mice will provide sufficient tissue no rats are used. For all the above studies, we will in all cases first optimise the methods of preparing harvested cells by using primary cells not involving regulated procedures. We will only use mice that undergo regulated procedures as and when the preparation methods appear fully optimised. Grand total 1200 mice, 800 rats.
component 2 - compound testing
These experiments will be carried out only as and when the experiments above produce relevant information about molecular structures and mechanisms.
Testing of drugs (always mice) will generally be conducted by including 3 control groups, a healthy volunteer-IgG injected group that receives the therapeutic compound, plus disease- and healthy volunteer-IgG - injected groups that receive saline vehicle, i.e. generally 4 groups per compound will be tested; we pragmatically assume that we will need an average of 6 mice pre group. We intend to treat the animals in either the FMS- or the CRPS models for a maximum of 3 weeks, and we anticipate on average performing 1 repeat and one dose adaptation experiment/ compound. grand total n=1200 mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Randomisation and blinding, and limitation of the number of operators will reduce variability and animal numbers. Animal numbers and study design were discussed with an expert statistician and adapted - specifically it was confirmed that first pilot studies should be performed with each IgG preparation as appropriate and that for compound testing experimental numbers per group can be reduced to n=3 per group if outcomes are supportive.
Feedback was also received from an RRR specialist, and several design steps were streamlined reducing animal numbers, for example a previously planned step to elucidate epitopes for extreme FMS phenotypes was removed reducing the animal number needed by n=200; further the validity and strength of the mechanism in question for various compounds will now be tested first by first using cellular models and then taking forward the best-effective compound, where possible.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- preservation of tissues in the staining experiments where appropriate, so that other tissues will be available at a later time, and mice are not just used for harvesting/assessing one single tissue type

- early switch from using mouse to rats for the epitope experiments, if needed, to avoid futile use of mice in cases where tissue harvest will be sub-optimal

- pilot studies for all compound testing experiments to elucidate effect sizes, power calculations then in communication with a statistician with experience in this field

- cellular studies to elucidate compounds with maximal efficacy

- use of non-protected species where this is possible in case of new compound testing not tried in rodents taking into account 3R toxicology advice

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare

costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A) CRPS is a post injury condition and the pathogenicity of antibodies cannot be shown without setting an injury. We therefore need to use a model in which injury is induced, but our model is the most refined model available – it occurs immediately and is of short duration (right hind paw incision of plantar skin and plantar muscle) under general anaesthesia).

B) Transfer of human immunoglobulin (a blood protein) to rodents - the human antibodies are the core pathogenetic factor to be examined; we have refined our experiments for the FMS model by first examining both antibody binding and binding epitopes without using any model, instead using primary cells. Only if this does not render usable results will we transfer human immunoglobulin. Similarly, in the CRPS model in order to elucidate binding tissues and epitopes we will first try to avoid human immunoglobulin transfer all-together. This approach is the most refined approach as it minimises additional suffering from receiving the sensitivity-inducing human immunoglobulin antibodies

C) Similarly, when cell functions have been assessed in either the FMS or the CRPS models, we will attempt to move to the refined approaches of using either primary cells harvested without procedure (FMS) or cells harvested without human immunoglobulin transfer.

Why can’t you use animals that are less sentient?

We are using the lowest neurological model (mice) for the majority of our work. Rats only to be used when necessary.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Because we are interested in pain research any analgesics (outside the peri-operative period) are not appropriate but we will monitor the animals regularly (twice daily) including weight and any surgery will have a 7 day post-operative assessment as standard.
For the CRPS work, we will first use the Brennan model to identify tissue staining and epitopes, which does not need injection of IgG. Only where needed will we use additionally IgG injection.
All animals that will be involved in behavioural tests will be habituated to these tests to reduce any distress.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow “LASA best practice guidelines” for administration of substances and Home Office and LASA guidelines for aseptic techniques.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will check the NC3R website regularly. We are in regular contact to the responsible officers within the establishment's biological services unit and will enquire about advances (e.g. 3-6 monthly), and similarly have been offered support through the NC3Rs Regional Programme Manager and are grateful to take this up in a similar way.

Home Office

NON-TECHNICAL SUMMARY

112. Mechanisms of neuronal plasticity in psychiatric and neurodegenerative disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Schizophrenia, Alzheimer's disease

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall objective of this project is to understand the molecular mechanisms of the brain's synaptic plasticity

(changes in the efficiency with which brain cells communicate with each other), and hence to facilitate the treatment of neurodegenerative and psychiatric diseases where synaptic plasticity is impaired. In particular, this project aims 1) to identify the signalling mechanisms involved in synaptic plasticity that are compromised in psychiatric or neurodegenerative disease; 2) to ascertain how dysfunction of these mechanisms affects neurochemical, functional and behavioural parameters relevant to psychiatric or neurodegenerative disease; and 3) to assess the efficacy of novel treatment strategies to ameliorate the disease-relevant changes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Brain diseases represent an enormous and increasing burden on health care resources and inflict great suffering on patients and their carers. For example, Alzheimer's disease affects 10% of the population over 65, 33% of the population over 85 (WHO). The only currently available treatments delay deterioration, but are not effective in the long term, as they do not interfere with the neurodegenerative process. Total societal costs are estimated at £26 billion/year in the UK. Similarly, for schizophrenia, the lifetime risk in the general population is 1%, with the majority of patients affected for most of their lives, with an onset in late adolescence. Current drug treatments (dopamine antagonist anti-psychotic drugs) are effective against some symptoms, but not at all against others (and are associated with unpleasant side-effect profiles). Total societal costs were recently estimated at £12 billion/year. Hence novel pharmacological treatment strategies are urgently needed for these diseases.

What outputs do you think you will see at the end of this project?

The research will improve our understanding of the mechanisms allowing synaptic changes in the brain, and provide insight into how the processes go wrong in diseases such as Alzheimer's disease and schizophrenia. As a result, the research may also illuminate novel ways of alleviating these neurological diseases.

Who or what will benefit from these outputs, and how?

The short-term impact will be increased understanding of the biological basis of psychiatric and neurodegenerative disease. This will be evident as soon as the results are published, and will hopefully stimulate follow-on research in other laboratories. The longer-term output will hopefully be improved treatments for these diseases. Improved treatments will only be identified through rational drug development programmes based on an understanding of disease aetiology and testing of drug candidates in translational models. Our research will contribute to, and enable, this process.

How will you look to maximise the outputs of this work?

The intention would be to communicate the results of this project to as wide an audience as possible. Communication with the scientific community would be facilitated by peer reviewed publication of results in the highest-profile and widest-interest journals, as well as the usual specialist literature. We also have an extensive network of contacts in the pharmaceutical industry, and communication and collaboration with industry colleagues will be an important way to maximise the long-term output. An additional aim would be to disseminate results to the general public via open access lectures (e.g. during Brain Awareness week), articles in general, wide-distribution science periodicals, and also via Press interviews.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the only species used in this programme of research. Mice are widely-used to study the mechanisms underlying learning and memory. Their neuroanatomy is similar to that of humans, and behavioural tests are available which match closely with those used in humans. Animal use occurs only where it is not possible to test important hypotheses using in vitro systems.
The majority of studies use adult mice, since most psychiatric and neurodegenerative diseases affect adults. However, the onset of some very common psychiatric diseases such as schizophrenia, is during adolescence; hence juvenile mice are used on occasion. In addition, most of the environmental risk factors for schizophrenia operate prenatally or antenatally. Hence some studies will look at the effects of reproducing the environmental risk in pregnant females and in their embryos and neonates.
The use of genetically-modified mice is frequently the only viable strategy for studying the in vivo function of gene products which cannot be manipulated pharmacologically.

Typically, what will be done to an animal used in your project?

Mice, in some cases with genetic manipulations to elevate or reduce the level of expression of specific genes related to neurodegenerative or psychiatric disease, will typically receive injections of current drugs used to treat these diseases, or of potential future improved drug treatments. Often, mice will be identified by implantation of a subcutaneous microchip, so that non-invasive behavioural observation can be conducted.
Pregnant female mice may receive an immune mimetic agent to induce an immune response, in which case offspring will have been exposed to the maternal immune response prenatally.
In some cases, mice will receive intra-cerebral injection of an optogenetic or chemogenetic viral construct, or of a gene expression viral construct. In this case, the mice will later undergo surgery for electrophysiological recording under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

The abnormal behaviour that may be observed due to manipulation of a gene relevant to psychiatric disease, with or without environmental manipulation, is expected to be very subtle. Psychiatric disease-relevant phenotypes due to the manipulation of individual genes or genetic loci are invariably restricted to slight changes in the amount of locomotor activity, along with subtle cognitive and affective changes that can only be detected using sophisticated techniques. Neurodegenerative disease relevant phenotypes due to the manipulation of individual genes or genetic loci are also relatively mild, with behavioural change typically limited to small reductions in cognitive abilities.
Pregnant female mice are expected to experience weight loss due to the immune response following injection of immune mimetics. However, this is expected to be transient, with mice rapidly recovering their initial weight. No

more adverse effects such as abortion, post-natal health issues or maternal rejection are anticipated.
The drugs used are expected to produce only subtle pharmacological effects. Some transient minor discomfort due to injection is expected.
The surgery involved in intra-cerebral injections will produce post-operative pain, which will be mitigated with analgesics. Rarely there may be post-operative wound infection, which will be treated with antibiotics.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice - mild severities anticipated in 81% of animals, moderate severities in 18% of animals, 1% of animals are non-recovery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cell cultures have limitations in modelling the complex network nature of the CNS, and there inevitably comes a stage where the theories obtained from the cultured cells have to be tested in vivo. To study the function of the novel genes we have identified, we have felt that the information to be gained justifies the use of genetically-modified mice, although we still favour the use of in vitro and cell culture studies wherever possible. Moreover, whilst cellular level assays are used to test whether pharmacological and genetic interventions can rectify pathology at the single cell level, it is only by testing these at the whole brain/organismal level that one can truly assess whether these translate to improvements in paradigms reflecting cognitive function.

Which non-animal alternatives did you consider for use in this project?

We have been able to develop cell culture models which allow us to pursue many aspects of our studies in culture rather than in the whole animal. This involves the use of immortalised cell lines in many cases, and also the use of primary neuronal culture prepared from mouse tissue. We have taken the opportunity to divert most of our studies into the cell culture system. We are optimistic that we will be able to continue studying the molecular basis of neurological disease mainly in cultured cells.

Why were they not suitable?

Cell cultures have limitations in modelling the complex network nature of the CNS, and the subtle and multi-faceted dysfunction in these networks that underlies psychiatric and neurodegenerative disease. There inevitably comes a stage where the theories obtained from the cultured cells have to be tested in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken

to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The proposed experimental designs and methods of analysis of the results have been optimised over a number of years, and discussed with statisticians where appropriate. Many of the mice are involved in breeding programmes, and we have extensive experience in optimising breeding strategies to minimise the numbers of mice involved.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Much of our research is conducted using ex vivo materials (electrophysiological, biochemical and morphological assays and genetic and pharmacological interventions). Furthermore, the use of cultured systems (organotypic and dissociated cell culture) enables the preparation of multiple cell based assay systems from a more limited number of animals.
Since much of our work utilises either ex vivo neurochemical and genomic investigations of tissue samples, or primary culture approaches, only a minor proportion of animals generated by breeding are then studied in subsequent protocols.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use efficient breeding strategies, so that generation of surplus mice is avoided wherever possible. We will obtain tissue from mice used in behavioural studies, rather than generating separate groups of mice for tissue collection. We will use pilot studies employing minimal numbers of subjects, where poorly characterised drugs are being used., and we will use within-subjects designs for drug studies in general, to maximise statistical power and reduce numbers of subjects used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are widely-used to study the mechanisms underlying learning and memory. We will use genetically-modified mice, as this is frequently the only viable strategy for studying the in vivo function of gene products which cannot be manipulated pharmacologically. However, manipulation of the genes associated with psychiatric and neurodegenerative disease in general produces only very subtle phenotypes (we have studied more than 20 of these genes in transgenic and knockout strains). Genetic manipulation of these genes in mice is therefore not expected to produce overt pain, suffering, distress or lasting harm.
We will also study the responses of mice to the administration of drugs/agents expected to affect plasticity processes. The agents that will be administered are also generally well-characterised in other contexts, and are not expected to produce overt pain, suffering, distress or lasting harm.

We will also study the effect of reproducing environmental risk factors for psychiatric disease. In humans, and also in mice, exposures to these factors have no lasting effects on their own, and, when combined with genetic risk factors, produce a subtle enhancement of the effect of the mutation. No overt pain, suffering, distress or lasting harm is anticipated.
In some cases, where there are no alternative means to manipulate the CNS expression of these genes, we will also inject agents to affect local gene expression in the CNS. Pain and discomfort due to surgery will be controlled with analgesics, and subsequent studies will be performed under terminal anaesthesia.

Why can’t you use animals that are less sentient?

Psychiatric and neurodegenerative diseases are, in general, not apparent in humans until the CNS is mature. In many cases, increasing age is a risk factor. The use of immature life stages is therefore not appropriate for this work. While the mouse CNS is similar anatomically and neurochemically to the human CNS, and mice have a behavioural repertoire with clear parallels to human behaviour, the same is not the case for lower species. hence mice represent the minimum species that can be studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will monitor new strains of mice very carefully to assess their phenotypes. Post-operative care will include close monitoring and the use of analgesics.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the ARRIVE guidelines throughout.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to monitor advances in the 3Rs, and look for opportunities to improve our research strategies.

Home Office

NON-TECHNICAL SUMMARY

113. Mechanisms of seasonal rhythms in physiology and behaviour

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

chronobiology, neuroendocrine, genomics, epigenetics, behaviour

Animal types	Life stages
Siberian hamster	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify the genes involved in timing seasonal physiology and immune function. Understanding predictable oscillations in seasonal genes will help inform management and welfare of human and domestic animals.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

All animals, including humans, show long-term rhythms in health and disease. For example, acute and chronic illnesses (e.g. seasonal affective disorder) have annual peaks and declines in incidence and severity of pathology. Our understanding of predictable, long-term rhythms at the genetic, molecular and cellular signalling level, and across internal organs is poorly developed. By using well characterized day length manipulations, the work can easily replicate robust seasonal changes in physiology and immune function by simply placing animals in rooms that mimic summer-like long days and winter-like short days. The work described in the licence will help us uncover the genome plasticity that underlies long-term changes in physiology, immunology and behaviour.

What outputs do you think you will see at the end of this project?

The primary benefit of the work is the advancement of scientific knowledge on the role of seasonal genes and hormones for the control of long-term changes in physiology, behaviour and immunity. The knowledge gained will be directly relevant for human and animal health and welfare. By discovering new ways in which genes are in control, the work might help identify new light mediated approaches for human and animal care. It is anticipated that 10-15 publications will be achieved.

Who or what will benefit from these outputs, and how?

The short-term benefits of the outputs will be for academics interested in how long-term rhythms (e.g. seasonal) in physiology, behaviour and immunity are controlled. In the long-term, medical and veterinary practices will be interested in which genes and hormones are involved in timing seasonal changes in physiology and immune function.

How will you look to maximise the outputs of this work?

Outputs of the work will be maximised by dissemination via publication in open access and international sources. The findings will also be presented at public engagement events and communicated to the national media. Real-time updates on research progress are readily provided on social-media. The training provided will facilitate the development of the next generation of cutting-edge scientists and communicators.

Species and numbers of animals expected to be used

- Other birds: No answer provided
- : 1010

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Hamsters and quail models have been valuable examples of mammalian and avian species due to the well characterized annual change in reproduction, energy metabolism and immunity. Only hamsters and quail have robust, reliable and repeatable changes in seasonal physiology in response to a simple change in laboratory light conditions. Moreover, these animal models benefit from over 50 years of scientific literature, provided a solid basis to advance our scientific understanding of the genetic of seasonal rhythms. The combination of breadth in scientific knowledge and robust seasonal physiology in laboratory conditions make hamsters and quail the ideal animal models.

Typically, what will be done to an animal used in your project?

Most animals will experience manipulated changes in day length as a cues to mimic seasonal rhythms in physiology. To better understand how hormones and genes control seasonal rhythms in physiology, some animals may receive injections of melatonin, thyroid hormones, gonadal steroids or prolactin. In few cases, some animals may experience surgical procedures that will allow the function of precise seasonal genes to be controlled. Surgical procedures will be limited to a single brain injection into the middle of target brain regions involved in timing seasonal rhythms. Animals will only experience one procedure and the duration is never longer than 32 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

There are few to no expected adverse effects for the animals during the project. All studies will use manipulated changes in day length to induce seasonal changes in hormone concentrations. In the few instances, some animals may show weight loss, infertility and reduced immunity that parallels what the animal would experience in the wild. Pain and suffering is minimised by good surgical and aseptic techniques, suitable anaesthesia, good peri-operative care and adequate provision of pain relief. Any animal showing any signs of ill health will be closely monitored, receive veterinary treatment or will be humanely euthanized.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities range from mild to moderate. The approximate proportion of animals are for mild (66%) and moderate (34%).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are the only model for the proposed licence because it is not possible to study the brain using cultured cells or computer modelling. At present, to understand how external factors such as light affect behaviour, the brain, and immune interactions requires the use of live animals. The research programme seeks to identify means to replace gene-behaviour studies by incorporating mathematical modelling when available.

Which non-animal alternatives did you consider for use in this project?

Unfortunately, non-animal alternatives do not exist at the moment. To understand how the brain detects and integrates external information and internal hormonal signals requires the use of live animals. The only potential alternative to consider for the licence would include artificial intelligence.

Why were they not suitable?

The use of artificial intelligence is limited due to the lack of knowledge of how the brain times long-term rhythms at a genome, molecular, and physiological level. It will likely be decades before such artificial intelligence can be used. Artificial intelligence would be welcomed because of the replacement in animal usage.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimation of numbers of animals used are determined from several sources. The sample sizes for each protocol are derived in part, from decades of published literature that use hamster and quail models. These numbers are also shaped due to several years' experience working with these models.
Lastly, statistical models are employed to limit the number of animals used for each protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Tests that are regularly conducted to assess statistical significance and power include multi-factorial ANOVAs and Repeated measures ANOVAs. Appropriate advice is taken from qualified statisticians. Sample sizes are based on statistical power analysis from several prior experiments and power calculations conducted with a statistician. When power values are observed to be consistently high (>0.8); sample sizes will be reduced to include the minimum number of animals necessary. Built into the experimental design and dissemination of the results are the ARRIVE guidelines established by the
NC3Rs.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To reduce the use of animals, all tissues are collected at the end of the experiment and shared with colleagues or archived for future use. By engaging in the sharing of tissue we reduce the animals used for research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Hamsters and quail are the best species to study seasonal rhythms in physiology, behaviour and immune function. There is a large scientific literature on this species and alternative models (for example mice and chicken) do not exhibit the large brain, physiological and immune changes over long-term, seasonal time scales. The methods used will allows the identity of genes that generate seasonal rhythms to be characterized and discovery how sex steroids, melatonin, thyroid and prolactin hormones regulate the timing of gene expression. The methods used, such as hormone injections or removal are the best suited to minimize harm while allowing the role of hormone action to be uncovered.

Why can't you use animals that are less sentient?

Unfortunately, to uncover the genetic and physiological signals that provide long-term timing requires adult animals. Moreover, only Japanese quail and Siberian hamster show robust, reliable and repeatable changes in

seasonal physiology and are supported with scientific literature that span 50 years of research. Common biomedical and domestic animals have a significantly reduced seasonal rhythm and are not optimal to study the objectives of the research programme.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements for injections include good technique (e.g. rotation of injection site, single use of needles, sympathetic handling) and the minimization of the number of injections (never more than daily for 6 weeks). In terms of surgery, pain and suffering is minimised by good surgical and aseptic techniques, suitable anaesthesia, good peri-operative care and adequate provision of pain relief. Pilot studies that use alternative procedures (e.g. apple bits, pellets) will be used to optimize as these potentially new procedures may result in minimal or complete elimination of current approaches.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The National Centre for the Replacement, Refinement and Reduction of animals in research website is readily checked. The resources available, such as literature on experimental design and ARRIVE guidelines are reviewed and incorporated into experiments to maintain the most refined procedures are conducted.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The scientific literature is continually reviewed and veterinarians consulted for alternative surgical treatments and novel means to alleviate adverse effects. In addition, we will keep abreast of local guidelines developed by our local AWERB and seek their advice where appropriate. To prevent duplication of experimentation and facilitate sharing of tissue material, scientific conferences are attended and discussion held with colleagues.

Home Office

NON-TECHNICAL SUMMARY

114. Mechanisms of structural and functional plasticity in cortex

Project duration

5 years 0 months
Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to understand the mechanisms of functional plasticity and structural plasticity in the healthy and diseased brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

By understanding which behavioural, sensory deprivation and activity paradigms induce or prevent plasticity, we can begin to understand potential mechanisms that are critical for the initiation and maintenance of synaptic plasticity, or the changes associated with memory formation and learning. The experiments outlined here are an important first step in determining the mechanisms of plasticity, which will be critical in the future development of treatments for a number of neurological disorders that have disrupted plasticity.

What outputs do you think you will see at the end of this project?

At the end of this license, we expect to have several publications on the mechanisms of plasticity as they relate to behavioural paradigms, spatial scales, and cell type specificity. We expect to have collaborative publications on plasticity mechanisms in disease states, particularly Alzheimer's disease.

Who or what will benefit from these outputs, and how?

By understanding the mechanisms of plasticity, we can begin to understand the conditions that are critical for the initiation and maintenance of plasticity. Then, using animal models for diseases, we can determine which of these mechanisms are faulty in the disease states and may serve as potential targets for future treatments. We expect that in the next five years, we will have 1) established a list of important plasticity mechanisms that can be tested to determine if they are perturbed in disease states, 2) established the disease models, particularly for Alzheimer's disease and 3) tested the degree to which some of the synaptic plasticity mechanisms are deficient in these disease states. Any important plasticity mechanisms that we find in healthy animals, will then be tested by ourselves or our collaborators to determine if they are perturbed in disease states. We have collaborations with scientists based in pharmaceutical companies and as we find plasticity mechanisms that are perturbed in the disease state, we will work in collaboration with these colleagues to establish potential treatments that target these plasticity mechanisms.

How will you look to maximise the outputs of this work?

We have several collaborations with scientists who are working on diseases of plasticity around the world, and we will share data, analysis tools and resources between these laboratories. We are a part of two large worldwide consortia for learning and plasticity, which involve sharing data and analysis tools between dozens of laboratories. This will reduce the number of replicated experiments in the field and the number of experiments that we need to do in our laboratory. All of our findings are made public with open access and our analysis tools are freely shared on public forums. We will give public talks about our new findings related to plasticity and diseases and work with public partners to make this new knowledge known.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will do these experiments in mice because of the number of available mice that are transgenically altered

and the comparison with previous studies in the scientific literature. Using transgenic mice has the distinct advantage that we can use mice with the phenotypes for diseases, such as Alzheimer's disease, Parkinson's disease and epilepsy that have disrupted brain plasticity. We will use adult mice, since these experiments are most viable in adult mice and the diseases of plasticity are largely associated with ageing.

Typically, what will be done to an animal used in your project?

Typically, a transgenic animal will undergo a surgery, where a small part of their skull is replaced with a glass coverslip to give us repeated optical access to the brain. They will then have four weeks to recover from that surgery. After that time, they will have a number of non-painful behavioural tests, some of which will also involve measuring from the neurons in their brain using light. These tests may be repeated several times over the duration of typically up to one month. Part way through the tests, the animals could either learn a new task or undergo sensory changes (like being in the dark) and we will measure the neurons' changing responses to the changing environment. At the end of these behavioural measurements, the animals will be humanely sacrificed and their brain tissue will be used for post-hoc histological or electrophysiological measurements.

What are the expected impacts and/or adverse effects for the animals during your project?

The animals will undergo surgery of moderate severity. This means that the mice will be quiet and move less for a day or two after surgery. The animals will be given multiple types of pain relief after surgery. Animals might lose up to 15% of weight, but will typically lose 5% or less and animals will regain weight loss within two to three days. In the event of infection or at the end of the procedures, the animals will be humanely sacrificed in consultation with the veterinary staff.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 1000 mice will undergo a surgery of moderate severity, which means that they will have a one or two surgeries. Approximately 300 mice will undergo non-recovery procedures, where they are given terminal anaesthesia at the beginning of the procedure. Approximately 2000 mice will be bred transgenically, which is a mild severity. These animals will then enter one of the other two protocols.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our objective is to characterise the mechanisms of plasticity in the healthy and diseased brain. The field of in vivo plasticity is relatively new and the current understanding of basic mechanisms of plasticity is poor. Furthermore, many of the disease models have only recently been developed and basic characterisations are still underway. Thus, there are currently too many unknowns to use exclusively computer models to determine the expected mechanisms of structural plasticity in either the diseased or healthy brain.

Which non-animal alternatives did you consider for use in this project?

We have considered both computational models and human plasticity studies. We will work with computational collaborators on models to test potential hypotheses and limit the potential outcomes, which will help us with our

experimental design and limit the number of animals necessary. We also have collaborators working on human plasticity and will work closely with them to design mechanistic animal experiments in a way that will be most quickly and directly beneficial to human health.

Why were they not suitable?

As stated above, there are currently too many unknowns to use exclusively computer models to determine plasticity mechanisms. For human experiments, we cannot measure the mechanisms of plasticity without animal results first.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated these numbers using a power analysis of group size for each set of experiments we have planned. We estimated effect size based on our pilot experiments, past work and expected effect sizes from the literature.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In our experimental design, we always collect as much data as possible from each animal. With longitudinal experiments, we repeatedly measure the same synaptic structures, synaptic activity or cellular activity over a long period of weeks. This approach allows us to directly compare the structural/functional plasticity in the same synapses, cells and animal before and after sensory deprivation or alterations in behaviour. Furthermore, in each animal, we can collect data from hundreds of synapses and dozens of cells, increasing the amount of data from each animal used and reducing the overall animal number necessary. Additionally, our experiments are designed over the same time course for all paradigms, thus we will use shared controls whenever scientifically feasible, to reduce the number of animals used in total.

The proposed experiments will generally use factorial experimental design, which will maximise the data collected from each animal. We will use the appropriate statistical methods for analysing the data and seek statistical advice as necessary from the Bio statistics group at our university.

We have also made methodological advances, based on technologies that have emerged in our field, which now allow us to collect more detailed data using the same surgical approach. Specifically, we are able to measure the functional properties of synapses, not just their structural changes levels over time. This helps reduce the variability that arises in our data and means that we need fewer overall experiments. This is reflected in our overall animal numbers, which are fewer than half of the total number of animals on our last project license application.

In all experiments, we will use the following guidelines to ensure that data collected from our animals is viable:

1. All surgeries will be performed in aseptic conditions in a designated surgery space with SEP status

2. Groups will be randomised and blinded

3. All data analysis will be done blindly

4. To reduce the effects of inflammation following surgeries on experimental results, we will give the animal sufficient time to recover from surgeries (typically 4 weeks).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will test hypotheses using computational models in order to refine the parameter space of the experiments before starting animal experiments and thereby reduce the number of necessary animal experiments. We always do pilot studies with a few animals to ensure the correct time course and experimental paradigms for our experimental purposes before larger scale studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of species:

We will do these experiments in mice because of the number of transgenic mouse lines available. Using transgenic mice has the distinct advantage that we can use mice with the phenotypes for diseases, such as Alzheimer's disease, Parkinson's disease, and epilepsy, which have disrupted plasticity. These mouse lines allow us to test potential mechanisms of plasticity and their role in these diseases.

Choice of method/minimise suffering:

By using chronic imaging in combination with cranial window surgery preparations, we can follow the same synaptic structures or cells over period months. This preparation is ideal for examining plasticity, because it allows us to examine how the same synapses are changing their structure and function over time. Because changes in plasticity in response to sensory changes can take up to several days to occur, addressing these questions in acute slices or slice culture is not possible. Additionally, to examine the role of plasticity in behaviour, we need to do these experiments in intact animals that are capable of learning and behaving. We are committed to refining the protocols and in the past five years have made many refinements to our methods to reduce the number of animals necessary (and as a result, have more than halved the number of animals in our project license). For example, we have used technological advances in the field to increase the yield of neurons recorded from 10s per animal to 100s and 1000s per animal, and to use viruses and transgenic animals, rather than in utero electroporation, which reduces the number of animals necessary and decreases the complications from the procedure. We have developed new methodological approaches that allow us to measure the functional responses from many synapses over many days, where previous work was only able to measure at a single time point. This approach allows for within animal comparisons and reduces the number of animals necessary in total, as well as increases the amount of data collected per animal without any further painful procedures. Past work that records simply the presence and absence of synapses (rather than their functional responses), requires far more data per study, since averages are across a large number of synapses with different properties. By being able to sort the synapses by their response property, we are able to see effects with far fewer animals.

Furthermore, by collecting behavioural data (novel object recognition, open field, foraging and nesting behaviours) in our mice that have undergone imaging, at a later date when we move into studying disease models of plasticity pathology, we can test rescue approaches on the known affected behaviours to determine if plasticity rescues have worked without surgical interventions necessary for chronic imaging. We can then focus our in vivo imaging experiments on rescues that have a behavioural effect.

By using chronic imaging, we can make comparisons within an animal, which increases our statistical power and allows us to use many fewer animals. Furthermore, this protocol minimises suffering, as the initial surgery is the only one in which any pain may occur. All imaging sessions afterwards will only require either light anaesthesia or no anaesthesia.

In addition to chronic imaging, we plan to prepare acute slices from mice. These terminal experiments will take place entirely under anaesthesia and therefore will have minimal suffering. We plan to use these experiments to test a number of potential mechanisms before testing them in vivo, which will help reduce the number of animals undergoing the in vivo paradigm and that may suffer as a result.

Why can’t you use animals that are less sentient?

A number of our experiments are done in animals that are terminally anaesthetised, but in order to look at behavioural outputs, the animals must be awake and behaving. Our recent work has shown that plasticity mechanisms in the intact brain are not the same as those measured in reduced preparations, therefore, we must do some of our experiments in an intact system. Animals that are at a more immature life stage are unable to perform the behaviours associated with plasticity and there are major differences between plasticity in young and older animals. Given that many plasticity diseases are associated with ageing, we need to work in adult animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have made many refinements since our last project license. We use refined holding techniques for the animals, as well as group housing and enrichment. We use post-operative analgesics and will refine these with advice from the NVS to ensure that we are using the best possible option given our experiments. The animals will be given multi-modal peri-operative analgesics and allowed to recover for typically four weeks after surgery before undergoing any further procedures. We have also moved to not using anaesthesia during our imaging experiments. A majority of our repeated imaging experiments (>75%) are done in awake animals.

We have also refined our sensory deprivation approaches and always use the intervention that requires the least surgical intervention.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are constantly reading the most current advice on refinement in the literature, which is brought to our attention by our local animal staff. We have local holding for the animals, and thus they are housed with littermates and with enrichment. We will also use refined animal holding techniques, specifically tube handling. We will also consult recommendations on the ARRIVE and NC3Rs websites, regarding animal welfare. Regarding refined injections of substances, we will consult the LASA guidelines and recommendations from the Working Group, together with published guidelines for substance volumes and routes of injection.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs from several sources. We are in regular contact with our animal care staff, as they come directly into our laboratories to care for the animals daily. They, together with our NAWCO, make suggestions for 3Rs refinements and develop approaches to implement them in our animal holding area. Additionally, since our animal area is a part of our laboratory, we are able to locally implement any 3Rs advances immediately, without consultation from other laboratories. We also have a 3Rs Regional Manager

that works with our animal staff, with whom we will consult and annual meetings that highlight the 3Rs advances. We will also view the NC3R's Website periodically.

Home Office

NON-TECHNICAL SUMMARY

115. Mechanisms underlying circadian and visual responses to light

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Circadian rhythms, Vision, Light, Optogenetics, Sleep

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Light detected by the retina plays a key role in setting our circadian clock to the external environment, as well as regulating sleep and alertness. This project will characterise the photoreceptors driving these responses, determine how our environment may influence them and use our understanding of these mechanisms to treat retinal disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Light is detected by the mammalian retina by specialised cells called photoreceptors. However, the photoreceptors mediating visual and circadian responses to light are different. Work on circadian responses to light has identified an additional retinal photoreceptor system, based on a blue-light sensitive protein called melanopsin. As a result, light which is suitable for vision may not be ideal for our circadian physiology. The circadian effects of light are of increasing concern in our modern 24/7 society as the majority of the populace are exposed to artificial light at an inappropriate time of day. This includes artificial lighting in the work and home environment, as well as from light-emitting devices such as smartphones, tablets and computers. In addition, ~20% of the workforce perform work at night, on fixed, rotating, or irregular schedules where irregular or inappropriate light exposure is unavoidable. Aberrant light exposure has the potential to disrupt our circadian rhythms and sleep. Long-term circadian rhythm and sleep disruption has been linked with a wide range of adverse health outcomes, including impaired concentration and performance, mood disturbances, metabolic disease, cardiovascular and neurological disorders and even cancer. Understanding the underlying biology is therefore essential if we are to ensure that our light exposure is optimum for both circadian and visual function. In addition, ~20% of the US and European workforce perform work at night, on fixed, rotating, or irregular schedules Approximately 20% of the US and European workforce perform work at night, on fixed, rotating, or irregular schedules.

As well as responding to changes in the light environment, many organisms such as flies and birds are also sensitive to magnetic fields which they use for orientation and migration. Recent work has shown that the mammalian retina may respond to magnetic fields, influencing both circadian and visual responses. Given the prevalence of man-made magnetic fields - for example from power lines and mobile networks - understanding how they affect our physiology is clearly important.

Finally, understanding the mechanisms of light signalling provides opportunities for treating vision loss. Expressing light-sensitive proteins is sufficient to make neurons respond to light - a method termed optogenetics. Using optogenetics in cells which survive retinal degeneration provides a promising avenue for restoring visual function. The circadian photopigment melanopsin has been shown to provide an ideal candidate for such optogenetic approaches to visual restoration.

What outputs do you think you will see at the end of this project?

A primary outcome of this project will be an increased understanding of the contribution of different retinal photoreceptors (rods, cones and melanopsin pRGCs) to circadian and visual responses. This will particularly focus on regulation of circadian rhythms, sleep and alertness, but may also benefit many other aspects of physiology. As these photoreceptors differ in their sensitivity to the intensity, colour and timing of light exposure, this will enable us to design lighting that is optimal for both circadian health and visual function. This

fundamental scientific knowledge will provide the basis for future studies in human subjects to test the efficacy of such interventions. In this way, the development of optimised lighting strategies also has potential commercial application in circadian effective lighting. This will benefit the general populace and will be of particular relevance to shift-workers. The identification of new strategies to improve circadian lighting are expected to occur within the timeframe of this project.
Secondly, work on the role of the retina in magnetoreception will provide a mechanistic understanding regarding how magnetic fields influence retinal signalling in mammals. Whilst responses to magnetic fields have been widely studied in other animals, evidence from mammals is critical if these findings are to be relevant to humans. Moreover, such data will enable the power of mammalian genetics to be used to study the precise molecular and cellular mechanisms involved in magnetoreception. A key output of this work will be the necessary data to allow testing in humans to determine if environmental magnetic fields influence our visual or circadian physiology.
Finally, work on optimising retinal optogenetics provides an essential step in improving treatments of human retinal disease. Optogenetic treatments are already undergoing clinical trials. However, improving the cell-specificity and timing of these treatments has the potential to improve the degree of visual restoration achieved. Such data may provide the basis of subsequent clinical trials on optogenetic therapy.
At all stages, outputs will be published in peer-reviewed journals. Key outputs of this work will be in improving existing therapeutics - in particular improved light and optogenetics. These outcomes are likely to occur within the timeframe of this project. However, understanding the signalling pathways underlying these responses also has the potential to identify new targets for regulating circadian rhythms (for example in jet-lag or shift work). Development of these targets to new treatments is likely to occur beyond the timeframe of this project.
Translational work in humans will be conducted in collaboration with other research groups with expertise in human circadian and visual research, particularly in the case of clinical trials for optogenetics.

Who or what will benefit from these outputs, and how?

The use of artificial lighting is prevalent throughout the world - in both home and workplace lighting as well as from light-emitting electronic devices. With the increasing use of LEDs, light is now cheap and be easily optimised in terms of intensity, colour and timing of exposure. This work therefore has the potential to benefit a large proportion of the populace due to the widespread use of artificial lighting. In the short-term, over the course of this project, many basic scientific questions relating to the optimisation of circadian lighting can be addressed. For example, this will include optimising the intensity and colour of evening lighting to minimise circadian responses. These findings will then be translated to human studies before dissemination to lighting specialists and the wider public in the mid- to long-term.
Whilst the responses of animals to magnetic fields has attracted interest from biologist for decades, evidence for effects in mammals has always been lacking. This is of particular concern as our modern built environment contains numerous sources of magnetic fields, which have the potential to affect our physiology and health. Again, outputs from this project will provide key mechanistic data on the biological processes that are affected by magnetic fields, which are essential for properly designed human studies. Key mechanistic data is likely to be obtained within the timeframe of this project, and will form the basis of human studies that may occur beyond this project.
Finally, due to increasing lifespan, visual loss from retinal disease affects an increasing proportion of the populace. For example, in the UK age-related macular degeneration (AMD) affects 5% of those over 65 years of age and inherited retinal diseases such as retinitis pigmentosa affects 1 in 4000 people. Such vision loss can be irreversible. Optogenetic strategies provide a promising approach to treating retinal disorders, restoring light sensitivity and visual function. Internationally, clinical trials using optogenetics for retinal disease are already underway. Whilst data obtained within the timeframe of this project will benefit the design of future clinical trials, the clinical translation of this research is expected to occur beyond the timeframe of this project.

How will you look to maximise the outputs of this work?

We have extensive collaborations with other groups at our establishment, throughout the UK as well as internationally. This includes collaborative funding as well as acting in an advisory capacity - particularly in the

areas of light and circadian rhythms. As well as primary scientific publications, my lab has a strong track record in the development and dissemination of new methods. This has included non-invasive methods for measuring sleep, circadian rhythms, pupil responses and body temperature, as well as resources for measuring the effects of light and using existing genomic data in metaanalyses. As part of this work, we routinely make all published data accessible to other groups. I have also been involved in specialist training schools and developing online resources to help disseminate expertise and help others use the methods we have developed.
In addition, our group has a strong track record in public engagement. Our research was featured at a major museum exhibition and has been the basis of animated videos explaining the importance of circadian rhythms. We plan to continue such outreach work as part of this project to maximise the outcome of this project.

Species and numbers of animals expected to be used

- Mice: 20,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will exclusively use mouse models. Mice have well studied circadian and visual systems which have been shown to be highly relevant to humans. The availability of extensive genetic and transgenic resources provide ideal tools for studying the mechanisms underlying these aspects of physiology and behaviour. The majority of studies will be conducted in adult animals, though tissue may occasionally be collected from neonate or juvenile mice.

Typically, what will be done to an animal used in your project?

The majority of animals used in this project (75% of all animals) will be in the breeding of specific genetically altered mice for subsequent tissue collection or testing visual or circadian responses.
Subsequent testing may involve:

- Circadian testing (~15% of all animals). A typical experiment will involve housing genetically altered and control animals under different environmental lighting conditions over an extended period (typically 2-8 weeks), whilst monitoring voluntary home cage activity via cameras, sensors or voluntary wheel-running. During this time, animals may be exposed to light of different intensities or colours, or low frequency magnetic fields.

- Visual testing (~5% of all animals). This typically involves a battery of simple behavioural tests involving brief restraint to measure pupil responses or exposure to a novel environment to measure visual function. Animals may be briefly anaesthetised to study electrical responses from the surface of the eye or to image inside the eye.

- Behavioural testing (~5% of all animals). This will include exposure to a novel environment to study learning and memory or anxiety. Occasionally, tasks may require food restriction so that food can be used as a reward.

- Administration of substances (~10% of all animals). Substances (drugs or viral vectors) may be administered to modify visual or circadian responses. This may involve systemic injections as well as targeted injections to the eye. More rarely (~1% of all animals), stereotaxic injections to the brain may be

required. Implanted devices to allow the controlled release of substances may also be used (~2% of all animals). These animals will then undergo circadian, visual or behavioural testing.

- Implantation of devices. In a small proportion of animals (~1% of all animals), a device may be implanted to measure body temperature, heart rate (electrocardiography) or brain activity (electroencephalography).

NB: As specific phenotyping screens are not mutually exclusive, the proportions provided will not total 100%.

What are the expected impacts and/or adverse effects for the animals during your project?

A common adverse effect will be impaired visual or circadian function. This may involve using mice which are blind or have impaired circadian rhythms and sleep. Blindness in laboratory mice is not associated with any additional health effects, as they use their other senses - particularly smell - to navigate their home environment. However, circadian defects may result in changes in metabolism or behaviour. This may involve increased or decreased weight, as well as changes in the level and distribution of normal activity. Rarely, changes in social behaviour may also occur.
Circadian and visual testing are non-invasive, but may be stressful due to exposure to an altered environment. Some forms of visual testing may require repeated brief anaesthesia. Appetitively motivated behaviour may require food restriction, which will result in weight loss. Administration of substances may involve transient pain at the injection site. Where intraocular injections are used, brief anaesthesia is required, though animals rarely show signs of ocular irritation. Stereotaxic injections to the brain and implantation of devices require surgical interventions that are associated with pain during the recovery period, and a small chance of wound breakdown or infection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Breeding (75% of all animals). Mild 20%, Moderate 55%.
Circadian and visual testing (15% of all animals). Mild 5%, Moderate 10%.
Administration of substances (9% of all animals). Mild 5%, Moderate 4%.
Telemetry (1% of all animals). Moderate 1%.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This work involves the study of the mechanisms underlying complex physiology and behaviour. This includes neural, hormonal and behavioural mechanisms, all of which interact. As such, no alternatives to animal models are available.

Which non-animal alternatives did you consider for use in this project?

We have considered the use of in vitro cellular models, mathematical models as well as the use of human

participants and patient groups. Whilst basic cellular processes, such as molecular rhythms and light responses can be studied in cellular models in vitro, these cannot recapitulate the full range of physiological processes that occur in vivo - particularly with regard to whole organism behaviour. Similarly, mathematical models allow key variables to be studied in detail, but are dependent upon detailed in vivo data. Predictions from mathematical models also typically require validation in vivo. Finally, human studies enable the translation of basic science data, but are not suitable for detailed mechanistic studies on the genes and pathways underlying these responses. However, the alternatives described above will be used in addition to the animal studies described in this project.

Why were they not suitable?

The alternatives described above are not suitable for studying the complex mechanisms underlying visual and circadian light inputs and the regulation of behaviour. Whilst we still use such approaches in conjunction with the work described in this project, the study of in vivo animal physiology and behaviour is essential.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used is based upon extensive previous experience of similar work over the last 20 years. For the breeding and maintenance of transgenic animals, we would maintain up to 10 different genetically altered lines. Each line typically results in the generation of ~200 mice/year, or 1000 mice over the 5 year project. However, with the use of conditional and inducible transgenics with multiple alleles, more animals may need be bred to obtain the necessary genotypes (~400 mice/year or 2000 over the 5 year project). We would expect to maintain 5 knockout/mutant lines (1000 mice/year or 5000 over the 5 year project) and 5 conditional lines (2000 mice/year or 10000 mice over the course of the project). This gives a total of 15000 mice over the course of the project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals used during the course of this project, we maintain a close oversight of all GA lines and plan and sign off all experiments in advance to ensure that appropriate sample sizes are used to optimise statistical power. As well as the NC3Rs Experimental Design Assistant, we routinely use G*Power for sample size and power calculations. We have weekly meetings with all PILs at which planned and ongoing experiments are discussed. These meetings also reduce the number of animals used by allowing multiple questions to be addressed simultaneously as well as optimising tissue harvesting.
Where certain allele combinations are required, we calculate the necessary breeding strategies well in advance. This planning phase may result in some experiments not proceeding where the number of animals required to produce the necessary genotype is inefficient. We routinely cryopreserve lines to minimise the need for maintenance breeding of lines that are not in active use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We practice efficient breeding and routinely archive our GA lines when not required to minimise unnecessary breeding. Where data is not available in the literature to determine appropriate sample sizes, we conduct pilot studies. Where possible we also use within group experimental design and counterbalancing to increase statistical power and therefore reduce necessary sample sizes. We also routinely use mathematical modelling to determine the optimum distribution of sample sizes across different time points. We also take advantage of genomic resources to be able to address research questions using existing deposited data rather than using new animals. Our regular lab meetings optimise tissue sharing and banking. Finally, where possible we optimise reagents using in vitro cellular models prior to using them in vivo - for example, when using siRNA or AAV vectors.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will exclusively use mouse models. Mice are the species of lowest neurophysiological sensitivity that are appropriate for this research, and have well-characterised visual and circadian physiology. Extensive genomic data coupled with a wide range of existing transgenic, mutant and knockout models make mice the only viable model for this work.
Methods primarily involve non-invasive monitoring of physiology and behaviour, which includes home cage activity monitoring using passive-infrared movement sensors, capacitive sensors, infrared cameras, voluntary running wheel activity and thermal imaging. In addition, we routinely use simple non-invasive assessments of vision, including head tracking to visual stimuli, pupillometry and novel object recognition. Some tests - such as electroretinography or retinal imaging - may involve brief reversible anaesthesia. Where magnetic fields are used, these will be generated using a Helmholtz coil around the home cage. A smaller number of studies may involve delivery of substances to the eye or brain, such as AAV vectors or siRNA, to modify visual or circadian responses. These studies will always use the most refined method of delivery and the smallest devices possible, as well as appropriate anaesthesia and analgesia. At the end of experiments, tissues are collected for ex vivo analysis.

Why can’t you use animals that are less sentient?

In mammals, the photoreceptors regulating circadian physiology are confined to the eye. In nonmammalian vertebrates, photoreceptors may also be found in the pineal organ and deep brain, as well as other tissues throughout the body. As such, to be relevant to human physiology, the study of mammals is essential. As the mammalian visual system continues to develop after birth, using earlier life stages is not possible. A key output of our research are empirical measurements of behaviour, which precludes the use of terminal anaesthesia. However, we do routinely study ex vivo tissues, minimising the need for live animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

A key feature of our work is to minimise disturbance to animals, so constantly seek refinements in physiological and behavioural monitoring. To this end, we have already developed and validated many non-invasive methods of studying vision and circadian physiology, including simultaneous activity and sleep monitoring and thermal imaging to study body temperature. These monitoring tools also provide ideal welfare indicators, enabling us to

accurately monitor disturbances of activity, sleep and body temperature throughout our studies. We also have extensive experience in behavioural procedures, and the use of habituation and counterbalancing enables us to minimise any effects of treatment order. We have worked closely with the vets and other collaborators across the Establishment to optimise in vivo substance delivery. For example, for intraocular substance delivery, we use an ophthalmic microscope to enable us to see inside the eye during injections and have optimised our setup to allow inhalational anaesthesia for faster recovery. We routinely use pre-, peri- and post-operative analgesia for surgical procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We have recently published guidelines for the effects of light on mouse physiology and behaviour. We also routinely use published standards for experimental design, such as the ARRIVE guidelines. We also have a track record in data deposition and sharing to allow others to benefit from our data and improve reproducibility.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As chair of the Establishment's 3Rs committee, I am well aware of developments in the 3Rs across the University as well as nationally and internationally. This role involves working closely with the NC3Rs as well as many other welfare researchers. My lab has played a key role in the development of a wide range of 3Rs advances, including many non-invasive approaches to studying physiology and behaviour as well as methods of using existing genomic resources to address new scientific questions. For example, we have developed non-invasive methods for measuring sleep based upon home cage movement and have recently validated the use of thermal imaging to measure body temperature in mice. We have also pioneered methods of combining existing gene expression data in the form of meta-analyses.

NON-TECHNICAL SUMMARY

116. Memory in the rat

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

No answer provided

Animal types	Life stages
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the capability of rodent memory, and in particular the role of context in mediating such memory.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

With an increasingly old population, problems with memory are becoming increasingly common. We know different types of memory rely on different structures and systems in the brain, but we still have a relatively poor understanding of what system underlies what type of memory and (as importantly) how it supports that memory. To understand this we need to understand whole systems where different memories can be learned, stored and retrieved in order to be able to help those with memory problems.

What outputs do you think you will see at the end of this project?

The lab has a strong track record of publishing high profile outputs (journal articles, reviews etc) from such work. The aim of this project (to understand the capability of rodent memory) is of broad and timely interest at the moment and therefore a strong track record of publications is expected to come out of this project.

For example, context plays a key part in the control of clinically relevant forms of memory. Episodic memory (for example) can be thought of as the memory for what happened, where it happened and which occasion it happened on, and the contextual factors which separate one occasion from another appear to be critical in sparing memories from confusion and interference. Therefore understanding the nature of context in rodent memory is critically important to understand its relevance to clinically relevant forms of human memory.

As a result, outputs will include new publications (relevant to a wide audience of researchers in different fields), information to improve research methods and reliability and behavioural tasks which may improve the reliability and translatability of research with significant clinical focus.

Who or what will benefit from these outputs, and how?

In the short and medium term the project will deliver high profile journal publications for the academic community. We have a track record of highly cited work in this area and the work in the current project is likely to continue to deliver outputs of broad interest to a wide community of researchers (including those interested in human memory as well as animal memory).

In the short and medium term we would continue to work with commercial partners to adapt our novel tasks into commercially available tasks (if appropriate). This apparatus has significant 3Rs potential, and increasing the market through novel tasks has the potential for further reduction in animal use in the medium and long term.

In the long term objective 2 will deliver clinically relevant tasks of memory in rodents, allowing improved translation of work in animals to the clinic.

How will you look to maximise the outputs of this work?

As well as typical academic publishing routes, the lab has a track record of dissemination to different populations (clinicians, pharmaceutical industry, behavioural testing industry) and the same would be true of the current project. The work will be discussed at a wide variety of meetings, attracting different types of audience. In addition the work will be communicated with existing industrial partners to ensure the maximal impact of the knowledge gained.

Species and numbers of animals expected to be used

- Rats: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are interested in how different systems in the brain work to give rise to different types of memory. To do this we need to use whole animals - other systems can show that memory is present but only measuring the behaviour of animals shows what type of memory is affected. Therefore we need to use animals that have a brain structure similar to humans, but also that can perform tasks which are relevant to the problems that humans face in the clinic when they present with memory difficulties. For that we use mice and rats, where the brain structure is well understood and has a high degree of similarity with humans and where tasks have been specifically developed to show comparability of their behaviour with human memory. To fully understand how different brain systems support memory we also need to understand how these systems change over the lifespan of an animal. We need, therefore, to look at how these different types of memory and change as animals grow up and grow old, to make comparisons to the problems humans face with memory as we grow older.

Typically, what will be done to an animal used in your project?

Most animals on this project will be tested on behavioural tasks of memory, and to encourage them to work on these tasks they may on occasion have a slightly reduced diet to motivate them to eat food rewards they can achieve in the tasks themselves. Some animals will do these behavioural tasks after they have had surgery to remove a system in the brain related to memory. This allows us to see what the role of these systems is in normal memory performance. These animals will have surgery under a deep anaesthetic and would only have one surgery in their lifetime. No juvenile or aged animals would have surgery, though some animals that have had surgery may be kept for study as they age.

What are the expected impacts and/or adverse effects for the animals during your project?

Behavioural studies are unlikely to cause any ill effect to the animal. Reduced diets to motivate the animals on some tasks cause problems only very rarely, and when weight drops below specified amounts. Animals will be weighed very regularly and so such changes will be spotted before they become problematic and irreversible.

Animals' time in any behavioural test apparatus will be limited (typically 2 hours and no longer than 3 hours) and for the number of tasks learned will be relatively low (e.g. typically around 3-4 tasks over approx. 6 months, although there will be fewer tasks over a longer period where learning is difficult).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals run only on behavioural experiments (with or without reduced food diets) are likely only to experience mildly adverse effects.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

There are many different types of memory, and different systems in the brain are likely to support each different type. Therefore, demonstrating the presence or absence of memory (such as whether changes happen between single cells) cannot tell us about the type of memory being affected. To understand that we need to observe behaviour in whole animals where different types of memory can be detected through different tasks.

Which non-animal alternatives did you consider for use in this project?

Because of the need to observe behaviour only whole animal systems can be used, though this can include humans.

Why were they not suitable?

The need to link the behavioural changes to specific brain systems requires surgery to remove those systems before observing the behaviour. As a result such studies would not be possible in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For most studies (whether behaviour alone or using lesions) to understand differences in memory we need to compare one group with another where each group either performs a different task or has a different type of surgery. The numbers here then are arrived at through determining the number of groups that would be run and the number of animals in each group needed to provide reliable and reproducible information in the behavioural tasks (i.e. too few animals wouldn't be enough to demonstrate differences between groups, whilst too many may show effects that are so small as to not be reliable).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will always run an animal on many different tests where possible. This means that we do not need to use different animals for every test (reducing numbers) but it is also a more powerful experimental design which allows us to be more confident in the data we get. Design assistants such as NC3R's experimental design assistant can be helpful in informing the best design to minimise numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are also very experienced in using tasks and lesion methods that reduce the number of animals needed, by making tasks collect more data more reliably and by reducing factors that can impact on the tasks other than the measure we are trying to observe.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Behavioural testing is unlikely to lead to significant pain or distress. Our surgical techniques are refined to minimise the risk of post-operative effects.

Why can't you use animals that are less sentient?

We need animals that can complete tasks which are relevant to humans. Without this we face a problem where what we learn from animals may not be relevant to problems in humans. Rodents provide us with a level of behaviour which we have evidence relates to human performance.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Post-operative care and pain management are carefully monitored throughout and surgical procedures allow us to minimise these (for example by giving pain relief before as well as after surgery). We also have experience in refining the behavioural tasks to minimise handling and the stress associated with it.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The project will ensure that ARRIVE guidelines are followed at all times. The lab is well aware of these guidelines and follows them in its current practice. They will be continued to be followed and all researchers working on the project will be committed to understanding these guidelines and the relevance of them to experimental design and running.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The lab has developed several projects funded by NC3Rs and is closely linked to current advances in 3Rs as they apply to this work. All people working on the project will continue to develop their skills and working methods through the sharing of best practice within the lab and the wider community.

Home Office

NON-TECHNICAL SUMMARY

117. Metabolic and Endocrine Pharmacology

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Metabolic, Endocrine, Diabetes, Pharmacology

Animal types	Life stages
Rats	adult
Mice	adult
Guinea pigs	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To evaluate the effects of both pharmaceuticals and other substances (e.g. Industrial Chemicals) on Metabolic and Endocrine function. This may be both for efficacy and safety purposes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In the case of efficacy, there are numerous conditions in humans that are caused by diseases or dysfunction of metabolic and endocrine systems (e.g. obesity, diabetes, high cholesterol) with either an unmet clinical need or drugs that are not wholly effective and have undesirable side effects. This project will seek to help in the development of better, safer therapies with less side effects.

In terms of safety, industrial chemicals (for example) have been shown to affect both male and female reproduction, and evaluating their safety is required by law, to ensure the safety of the public from their effects. It is also possible that new drugs for other indications may have undesirable effects on the metabolic and endocrine systems, and we may undertake testing of such drugs, to determine their safety in this programme of work.

What outputs do you think you will see at the end of this project?

The benefits of this programme will be two fold. Firstly it will contribute to the development of new drugs that help alleviate metabolic and endocrine disorders (such as diabetes and obesity). These new drugs may work better in the clinic, relieve or cure diseases and have better side effect profiles. We may, by our work, also contribute to better knowledge and understanding of these types of disease, and that knowledge may be used to develop further new drugs.

Secondly, this programme also allows for the assessment of various chemical classes regarding their ability to produce endocrine disruption (e.g. industrial chemicals, agrochemicals and industrial solvents.) Found in many household and industrial products, endocrine disruptors are substances that interfere with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body that are responsible for development, behaviour, fertility, and maintenance of homeostasis (normal cell metabolism). These hormones include both oestrogen and testosterone. In recent years global regulators (who oversee the quality and safety of chemicals and pharmaceuticals) have increased their interest in such chemicals and have issued directions for the testing of already marketed chemicals . The scope has also been widened to include certain classes of chemical e.g. pharmaceuticals.

On some occasions, where previous studies have shown that a compound may affect metabolic or endocrine function, the models on this project maybe used to assess the safety of a test material and find a dose that causes no effect. This is important when planning future trials in humans, to make sure any starting dose in a clinical trial is safe for the patients taking it.

Who or what will benefit from these outputs, and how?

In both the medium and long term, patients will benefit by having newer, modern and safe drugs that are more effective than the current options. Humans will also be safer knowing that certain chemicals have been risk assessed and classified as safe or not, as potential disruptors of their endocrine function.

How will you look to maximise the outputs of this work?

The work will be shared with customers who will use it to determine their future strategy, or for submission in documents required by regulatory authorities. Whilst we have no direct control over what happens to the data after we have shared it, we trust from information given to us that it is used for regulatory purposes or to support regulatory purposes (e.g. to support drugs progressing to clinical trials, or to show that a certain chemical is safe for human exposure). Previously however, we have collaborated with customers and shared data we have produced in the form of Scientific publications that are in the public domain.

Species and numbers of animals expected to be used

- Rats: 7500
- Mice: 1500
- Guinea pigs: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Most of our experiments will be carried out on mice and rats as these are the smallest relevant species that we can use that have a metabolic and endocrine system that is comparable to humans. In some specialist cases we may use other animals (the guinea pig) because what we are trying to find out is better done in that particular species rather than in the rat or mouse.
The only other time we would use a species other than a mouse or rat is to continue work that has been previously done in that species. For instance if previous work, and results gained, had been carried out in a guinea pig, it would make no scientific sense to start the next stage of a programme of work in a rat or a mouse.

In some protocols we may use genetically altered animals to investigate some types of metabolic disease like diabetes and obesity. This because these alterations mean the animals produce symptoms and characteristics of these diseases that we see in humans like higher than normal levels of blood sugar in diabetic mice. The use of genetically modified animals is rare.
We will be using adult animals in our studies, as we do not expect to be investigating either metabolic or endocrine disease in young animals or children.

Typically, what will be done to an animal used in your project?

Typically on this project, animals are dosed over a period of time with test materials, and sampled (e.g. blood or urine) before having tissues taken after they have been humanely killed. Most studies would last a matter of days (much less than a month) although some, occasionally may last for longer than that.
Dosing of animals is commonly done orally using a flexible tube, or by injection using a syringe and needle, maybe directly into a vein, or into a muscle into the arm or leg, or just under the skin.
Blood samples are usually taken from easily accessible veins in the neck or the tail of rats or mice. We are limited to how much blood we can take at once or over a month. If we need a large blood sample, we would do this when the animal is anaesthetised and we would not let them recover consciousness.
Where possible, we try and take as many of the tissues and samples we need after the animals have been humanely killed.
Some animals we used are genetically altered, so they better represent disease states like diabetes in humans.

Sometimes we need to induce a metabolic condition in animals to test if a new drug can alleviate the condition. This can be done with diet or maybe by injection. When this happens we monitor the animals closely to check they don't get ill.
In some protocols we also have to surgically prepare animals for testing by removing their ovaries or testes. These tests are specialist to check for the potential adverse effects of chemicals and other substances on male and female sex hormones, and are required by law. To measure glucose levels in rats, sometimes we surgically implant an electronic device which means we can monitor blood glucose levels continuously without having to take many blood samples.

What are the expected impacts and/or adverse effects for the animals during your project?

When dosing an animal by injection or taking blood, The amount of pain an animal feels is similar to what a patient would feel having an injection done by a doctor. If we have to repeatedly inject animals using a needle and syringe, we would choose different sites to do this where possible. If we can take blood samples when an animal is deeply unconscious then we do. If we need to take repeated blood samples or need to dose repeatedly then we try and use different sites. Of course everyone who performs these procedures are trained to a high standard.
Animals undergoing surgery receive the same sort of care as a patient would in hospital. We discuss their pain relief and use of antibiotics with a vet before we start. We administer drugs as necessary and give them plenty of time to recover from surgery before we use them in experiments.
The genetically modified animals we use are usually models of type II diabetes. These animals are heavier than normal, urinate more frequently, and are more sedentary than normal animals. They don't look or behave like they are ill however.
Very occasionally we may need to take a urine sample for analysis, so we would then put an animal into a special cage which is smaller than their normal cage. The animal can still move around however, and we'd normally introduce an animal to this cage to acclimatise them to it. Virtually every animal will get used to their new cage within about 15 minutes and are fine.
Dosing with drugs and chemicals may cause adverse effects in some studies, although this is rare. We do observe our animals at least twice a day, and the people who do this know the signs when an animal is ill. If an animal is ill, we would check it more frequently, and get more senior staff involved in its care for advice, including vets. We also help sick animals out by giving more bedding, more heat and special food to make them more comfortable.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

On the last project, about 80% of animals were classified as having displayed moderate severity. This is because legally, all surgical procedures carried out on an animal must be classified this way. the rest of the animals were classified as having displayed mild severity.
It's impossible to predict the proportion of severities expected on a service licence, as this will be dependent on what study types we are asked to perform.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The endocrine system and other systems influencing metabolism are complicated and perform a wide variety of functions essential to life, like maintaining blood glucose levels, or keeping hormone levels correct for normal daily life. There are no adequate models to replace the whole animal experimental model, as the complexity of the human body cannot be fully replicated in a test tube.

In many cases the protocols listed in this Project will be used later in the life cycle of a test substance and in many cases, particularly for pharmaceuticals, tests in test tubes will have been conducted previously (often by the Sponsors) to ensure the drugs do what they are meant to, and are safe, before we expose them to testing in animals.
For some protocols the licence, the tests are legally required by regulators around the World to make sure certain chemicals and other substances don't have ill effects on male and female sex hormones, if you are exposed to them by accident or otherwise.

Which non-animal alternatives did you consider for use in this project?

There are no other non-animal alternatives for the work being undertaken on this project.
For some protocols, there are tests carried out in test tubes that determine whether or not chemicals and other substances may pose a hazard to male and female sex hormones. It's only when this hazard has been identified, that the next step in the testing tiered process (in animals) is triggered.

Why were they not suitable?

Although there are test tube tests that can model some parts of how drugs or chemicals get into our bodies, and how our body deals with them, for example, there is no one test tube test that brings all these complex happenings together, like we see in animals and humans.
That's why we need to test some substances in animals, as they have similar physiology and endocrine/metabolic processes as humans, and that testing gives us a good idea what may happen if they were ever tested in, or exposed to humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers we have used are based on figures of previous usage from previous projects, or a projection thereof (based on estimated incidence) based on requests received from customers in the past. It is, however, impossible to accurately predict the number of studies that may be performed, in the circumstances.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments will be designed in order to achieve the scientific objectives using the minimum numbers of animals. For study types that are less well established and for which historical data may not be available, the literature will normally be consulted to help establish the group size. Alternatively, there may be other data to aid this process. The Department of Statistics and Data Management are often consulted to assist in this process particularly where the study type is not routine.

Whenever possible, common control groups will be used in order to minimise the numbers of groups used.

For less established study types, preliminary pilot studies may be conducted whereby smaller numbers of animals may be used to generate data in order to ensure that the experiment operates to expectations and to generate some data which may be used to optimise the study design.

Experience has shown that occasionally, Sponsors have a preference with regard to their design and numbers of animals to be used. Rationale for the design will be requested from the Sponsor and such designs (particularly where they are at variance with EU requirement or studies usually conducted here) will be discussed internally (and the Home Office as appropriate) and forwarded to the Department of Statistics for advice. Such advice will be taken into account when determining the design/numbers to be used in the study with the goal of using the least number of animals to achieve the scientific objective.
In addition, the regulatory test guidelines used for testing in some protocols, stipulate group sizes (a minimum of 6). These are safety tests to evaluate whether chemicals and other substances have any effect on male and female sex hormones.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For studies where a new drug is being tested in animals for the first time, we would often test that in a small group of animals (usually 3-5) to give us confidence that the dose levels we chose are safe, and the drug affects the system its designed to, without making an animal ill. These are called pilot studies.
We will try and get as many outputs as we can from a single animal where possible, without adversely affecting its welfare. So if we need to get a blood glucose level in the blood , or if we need to find blood borne markers of diabetes, for example, we will often do that in the same animal, rather than use separate ones, when possible.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Most of our models involve dosing animals with test materials, and sampling them, with many outputs taken after the animals have been humanely killed. This is generally the least invasive set of procedures that can be done to give meaningful outputs to make scientific decisions about further tests.
In some tests we use animals that are genetically altered, to mimic conditions seen in humans we are investigating like diabetes and obesity. Sometimes we alter the existing conditions of animals by introducing a

drug, or changing their diet. This doesn't cause harm on its own, but the consequences of these may cause a mild degree of suffering to the animals.
We also use some surgical models to investigate the effects of chemicals and other substances on male and female sex hormones. For male animals this surgery (castration) or female animals (removal of the ovaries) are both the best ways to determine if a test material has an effect on male or female sex hormones, even though surgery is involved. The use of non surgical models (using immature animals who don't have fully developed testes or ovaries) was also considered, but these models are not always accepted by regulatory authorities for reasons of female endocrinology , and their timelines for dosing are so exacting (specific dosing dates after birth must be used), than to use them would mean us having to use more animals than if we used surgical models.

Why can’t you use animals that are less sentient?

Rodents (rats, mice and guinea-pigs) will be used in all of the studies conducted under this licence. Rodents are considered to be of the lowest neurophysiological sensitivity that will allow us to achieve the study aims and are considered suitable for the predicting what's likely to happen in humans

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is of utmost importance and Good Surgical Practice will be observed for any animal undergoing surgical procedures. Surgery will be conducted using aseptic techniques (to prevent infection) which meet at least the standards set out in the Home Office Minimum Standards for Aseptic Surgery. before we start surgery, we agree with a Vet what pain killers or antibiotics the animals need both before and after the surgery. When recovering from surgery, we give the animals extra heat and monitor them closely until they start behaving normally again. We then check them at least twice daily before they go on study.
In addition, care is taken to provide as much environmental enrichment as possible . This is things like plastic shelters in their cages, blocks to gnaw on, extra bedding for warmth and if they need it, food supplements after surgery.
With glucose measurements as over the counter glucose monitoring devices have increased in accuracy, it has been justified, in most cases, to switch to the use of such devices when measuring glucose level. These are the devices that humans use to measure their own blood sugar, given to them by a doctor. This has allowed the volume required for a glucose measurement to be drastically reduced from approximately 0.3 ml to as little as 0.01 ml. In addition to the obvious benefit to the animal whereby far less blood is required for an individual sample. It also means that we can use the same animals to get a time-course of action of any drug, instead of having to use several groups. We can sample on multiple occasions by removal of the scab from the initial wound on the tail and analysis of the small drop of blood that results which is sufficient for the analysis thereby not necessitating further needle stick penetration into the blood vessel.
  The use of a surgically implanted telemetry transmitter in rats, means that blood glucose levels can be tracked electronically, and that no blood sampling is required during the course of a study.
Dosing and sampling procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm and will be the minimum consistent with the scientific objectives. In addition, suffering will be further minimised by implementing clearly defined humane endpoints
.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For any surgical interventions, then the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017) will be followed.

For blood sampling and dosing then the following guidelines/literature will be followed:

First report of the BVA/FRAME/RSPCA/UFAW joint working group on refinement, Laboratory Animals, 27, 1-22 (1993).

A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes, Journal of Applied Toxicology, 21, 15-23 (2001).

Regulatory guidelines

OECD 440 Uterotrophic Bioassay in Rodents:
A short-term screening test for oestrogenic properties.
EPA OTTPS 890.1600 'Uterotrophic Assay'.

OECD 441 Hershberger Bioassay in Rats: A Short-term Screening Assay for (Anti)Androgenic Properties.
EPA OCSPP Guideline 890.1400 Hershberger
Assay.
ICH Topic M 3 (R2)
. Non-Clinical Safety Studies for the Conduct of
Human Clinical Trials and Marketing Authorization for Pharmaceuticals.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

This will be achieved by regular discussions with our Named Information Officer, colleagues in Animals Technology, and by attending appropriate training courses and conferences, or getting feedback from such events.

Home Office

NON-TECHNICAL SUMMARY

118. Mice with adaptive human immune systems and their application for drug and vaccine discovery

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Antibody drug, Vaccine, Cancer, Covid 19, T cell

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to genetically alter mice to humanise their immune system and subsequently use such mice to identify and develop novel drugs for treating diseases and vaccines for disease prevention in humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work so that we can discover new drugs and better vaccines for treating and preventing many different diseases in people.
Mice with human immune systems respond to vaccination just like people do. Therefore, by testing different vaccines in mice with human immune systems we can identify better vaccines that are much more likely to work in people.
We can also isolate human antibodies from these mice. These can be developed as drugs to treat diseases like those caused by coronaviruses such as Covid 19 or cancers like leukaemia and prostate cancer.

What outputs do you think you will see at the end of this project?

New medicines, namely vaccines and drugs.

- Drugs that offer potential new treatments for a form of leukaemia.
  Vaccine candidates that offer improved protection against malaria
- A second generation Covid 19 vaccine, improving on the proportion of vaccinated people who become immune to the virus following vaccination and improving on how long this lasts.
- **Basic Science benefits**:

- Publications in the peer reviewed scientific literature
- Genetically engineered mice that can be widely used by the scientific community to pursue related projects in other disease areas.

- Grants to support continuity of the work for an additional funding period.

Who or what will benefit from these outputs, and how?

- All countries of the world could benefit from the discovery of new information that supports the development of vaccines for Covid 19.

- Societies in countries where malaria is endemic could derive benefit (in the long term) if we are successful in identifying a better vaccine for malaria, recognizing that it can take many years for a result in the laboratory to be shown to provide long term benefit in humans.

- Society will benefit from knowledge generated as this provides better understanding of diseases and methods to treat and/or prevent them.

- Research institutes, pharmaceutical companies and non-governmental organisations will be able to take information produced by such studies and use it to support the development of drugs or vaccines that ultimately provide benefit to patients.

How will you look to maximise the outputs of this work?

We will collaborate with experts in the field, for instance our work on vaccines is a collaborative endeavour with a variety of laboratories.
We will publish scientific papers, thereby disseminating knowledge.
We will file patents, thereby placing in the public domain detailed knowledge of the discoveries we have made.
We will raise money so that the development of promising medicines can continue.
We will out-license promising drugs in situations where we cannot afford to develop these drugs ourselves, thereby allowing the benefits to emerge.

Species and numbers of animals expected to be used

- Mice: 38,550

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse was selected for this project because of the availability of advanced technologies to make "transgenic" mice. Transgenic mice are mice in which their genome has been genetically altered. This is accomplished by adding or removing genetic information at very early embryonic stages. The methods used to do this are very efficient and extensive changes can be made. The refinement of these techniques mean that many fewer animals are needed compared to achieving the same goals in another species.
The immune system of the mouse is similar to that of humans so we can replace mouse genes with the equivalent human ones to make mice that have a more "human relevant" immune system. Although very large stretches of mouse DNA has been replaced with the human equivalent the human genes substitute for the mouse ones. The resulting mice do not exhibit any signs of suffering or distress. The other genetic changes we will make in this project involve removing genes for drug targets from the genome, which should not adversely affect the mice either. Adult mice are used for vaccinations because their immune systems are mature.

Typically, what will be done to an animal used in your project?

To produce transgenic mice fertilised embryos are collected which are manipulated under the microscope. These are transferred to foster mothers who become pregnant, give birth and rear their pups.
The embryo transfer is done under general anaesthesia as we need to make a small cut in the skin to place the embryos in the uterus or oviducts. Typically, the mice recover very quickly from surgery, they are actively running around, eating and drinking after 1 hour and are fully recovered within a few days.
A small number of male mice are vasectomised, which are used to mate with foster females.
Vasectomy is conducted on anaesthetised males by making a small scrotal incision and cutting the thin tube carrying the sperm. The incision is closed and the mice recover from the anaesthetic within 60 minutes or so. A week or two later the wound will be healed and the mice can be used for mating with females.
Transgenic mice in this project will be bred and weaned. Where the line is not pure bred a small piece of tissue from the ear is taken for genotyping the mice to identify the genetic alterations they carry.
Transgenic mice are used for vaccinations also known as immunisations. Vaccination involves injecting a purified foreign substance into the mice, which is known as an "antigen". The vaccinated mice develop antibodies against the antigen and a types of cell known as a T cell begin to divide too.
Immunisation is usually conducted with a very fine needle and a small volume as this is the least painful method. To get a good immune response usually we conduct several vaccinations over a few months, similar to the "MMR" vaccinations we give our children. To check if the vaccination is working a small drop of blood is collected during the immunisation which we check in the laboratory to see if we can find antibodies that recognize the target. In the final stage, the mice are killed and the blood, spleen, bone marrow and lymph nodes collected for analysis.
In some cases instead of purifying a foreign substance from a virus or bacteria for immunisation, it is more efficient to take the gene and put this in the mouse. This is like gene-therapy in that we inject DNA encoding the foreign substance into a blood vessel which then ends up in the liver where it expresses the foreign substance for several weeks, resulting in a strong immune response. This is similar to the famous Covid 19 vaccine trial from Oxford, in which the DNA that makes a Covid 19 protein is used to vaccinate human subjects.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the animals in this project should not experience any adverse impact as they are used for mild procedures like breeding and vaccination.
The procedures used for immunisation involve needle pricks for vaccination and to collect small amounts of blood for analysis. Other procedures used for immunisation may be involve injection into a vessel which may involve anaesthesia. In either situation the mice are subdued and lethargic for an hour or two but then recover fully as the affects of the injection and/or anaesthesia wear off.
Some of the animals will experience transient pain from the minor surgery required for embryo transfer and vasectomy. Both of these procedures which will be conducted under anaesthesia and managed with drugs to relieve pain.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mouse : Mild severity : Greater than 98%
Mouse : Moderate severity: less than 2%

What will happen to animals at the end of this project?

- Used in other projects
- Killed
- Kept alive

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune system is extremely complex. We have two main types of cells that recognize and kill bacteria and virus infected cells known as B cells and T cells.
B cells make trillions of different antibodies which are released and circulate in the blood. When they find an infected cell they attract other cells to the site of infection to begin an immune response to kill the virus or bacteria. Each B cell makes a different antibody, but if it encounters a foreign substance on the surface of a virus or bacteria (known as a foreign-antigen) and it is able to bind to it, the antibody produced evolves so that its binds more and more tightly. By the end of an infection the antibodies our B cells produce bind very tightly to their target and are therefore much more effective at killing it.
T cells roam around the body looking for infected cells which they recognise through a unique structure on their surface known as the T cell receptor - which has some similarities to an antibody. Like B cells, every T cell has a different receptor and we have trillions of different T cells receptors too. T cell receptors recognize and bind to foreign antigens, but only do after these have been chopped up into much smaller pieces and presented on the surface of the infected cell. When a T cell encounters an infected cell it starts to divide, it releases chemicals to attract many other types immune cells - such as B cells - and they can also directly kill the infected cell.
The immune response is highly complex. It matures over many months. It involves the interaction of many different cell types and migration of cells to a variety of sites in the body. The interplay between the different cell types simply can't be emulated in the laboratory. This project uses immunisation with foreign antigens to explore the maturation of the immune response, it is not possible to use experimental vaccines in humans.

Which non-animal alternatives did you consider for use in this project?

Some artificial methods using bacteria can be used to discover antibodies in the laboratory, the most well-known of which is a technology known as phage display. In this technology viruses that infect bacteria are modified to carry antibody fragments. Large collections of these, known as "phage libraries “, can be generated using the genes from human antibody producing cells. Similar technologies have been developed using yeast.
Phage and yeast libraries can be examined to find individual members which bind to a drug target but the antibodies in these libraries are **immature**. They don't bind to their target strongly and they can lack specificity because they bind to other targets, which would cause side-effects.
Antibodies isolated from immunised humanised mice are different - they are **mature**. The difference comes about because the mouse derived antibodies have been induced to evolve into a mature form by immunization. **Mature** antibodies make much better drugs because they bind much more tightly (1000- times or more) to their target - such antibodies can be developed as drugs without further modification.
Artificial methods can also be used to make libraries of T cell receptors from human T cells. However, these libraries will not have T cell receptors that bind to human targets as these are normally removed from the body when a T cell matures otherwise we would all suffer from autoimmunity. However, human T cell receptor genes that bind to human targets can be found in mice with human T cell receptors.
Although these artificial methods provide some options, they can only be experimentally used in isolation. As summarised (and simplified) above, the immune system matures a response, selects and matures ideal antibodies and unique T cells though a highly complex series of interactions involving many different cell types that naturally evolve in an animal over many months. Simply, there are nonanimal alternatives that can adequately emulate this highly complex process.

Why were they not suitable?

Artificial display systems can be used to discover antibodies, but in practical applications, these methods have several severe limitations which restricts their usefulness. They are:

- They can bind to several targets, rather than just one.
  They bind weakly to their targets.
- It is difficult to make large quantities and concentrate them.
  It's very hard to find antibodies or T cell receptors which bind human targets.
- These issues have to be resolved in the laboratory. This is a slow, error prone, unpredictable and often fruitless process. As a result, despite huge effort only 5% of almost 100 approved antibodies for human
- clinical use have been derived from phage libraries.

Similar issues have been encountered using phage-based methods to turn human T cell receptors (TCRs) into drugs. Powerful and uncontrollable off-target toxicities and human fatalities have resulted.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals estimated to be used for this project are based on 35 years of experience in generating mice with altered genes. They are also consistent with the usage in the existing project license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

More than 90% of the animals used in this project will be used for establishing and breeding complex combinations genetic alterations.

- Where possible we establish mice which breed true. In these mice both copies of each genetic alteration will be the same.

- As our genetic alterations are made step-wise, we try to completely finishing one before crossing them together.
- We test the function of each genetic alteration before breeding them together.
  The construction of large humanized alleles requires many cycles of genetic engineering. We use
- embryonic stem (ES) cells for this purpose. We constantly select for ES cell clones that perform well, thereby reducing mice used for donor embryos and recipients.

The other use of mice in this project is for the immunisations required to deliver the core scientific objectives. To reduce mouse numbers we:

- Use standard operating procedures for immunisations and tissue harvesting, ensuring that we get the maximum amount of useful biological materials from each mouse.

- We consult widely to identify and where appropriate integrate improvements in methods to maximise the recovery of data from every mouse

- We have invested in technologies which enables us the sequence the antibody and T cell receptor genes in single cells. By using this technology we get much more information from every immunized mouse. Some years ago we would recover a handful of useful antibodies from each mouse. Today we are able to recover 100-200, which means the mouse numbers required are much lower than they were previously.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

There are four measures we take to reduce mouse numbers:

- We use colony management software to keep track of mice in the animal room, set up just the right number of breeding pairs to produce the mice we need. The data base will record pedigrees and procedures - keeping an electronic health record.

- We conduct pilot immunisations with antigens we have not used before to assess their performance before initiating larger experiments or not conducting them at all in cases where the pilot does not provide a good basis for continuing.
- We stop breeding and preserve mouse lines in cryogenic storage if they are no longer required

- We use contemporary methods to make genetic mutants which avoids numerous cycles of mouse breeding.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice with human antigen receptor loci

The genetic alterations that we have introduced into our mice are mostly mouse/human gene replacements. The mouse genes are exchanged for the human ones which are very similar. Although the resultant mice have a human immune system it is fully functional and consequently the mice are totally healthy. They do not experience any immunological deficiencies.
We also genetically remove the genes for drug targets from the genomes of these humanized mice. This improves the immune response against the drug target. To minimize any unexpected consequence of this type of genetic modification, we carefully check the literature and databases and will not proceed if the mice are not expected to develop normally.

Immunisation Methods

The immunisation methods we use are highly refined and are widely used. We use standard operating procedures and state-of-the-art downstream methods to get the most out of every immunized mouse.

A significant amount of work is performed in the laboratory to maximize the chance that an antigen is able to elicit a good and meaningful immune response. This includes ensuring that the antigen is pure, free of toxins and has not been damaged during its preparation - for example it is has not been degraded or aggregated together. A significant amount of animal use from repeat immunisations is avoided by rigorous application of these principles.

Similarly, carefully preparing the antigen so that it is free of toxic or inflammatory agents avoids unnecessary suffering and focuses the mouse's immune system on the relevant target.

Why can't you use animals that are less sentient?

The immune systems requires several months to develop a robust immune response against a target. The immune system is not mature at an earlier stage (immature life stage).
Lower organisms can't be genetically engineered to the extent possible with mice, the mechanisms of an immune response are different and the structure of the antigen receptors are also different.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I don't anticipate many refinements to transgenic methods as these are already very standardised and efficient, though where these are reported we will test and implement them.
Where possible we will employ highly experienced animal care staff who are familiar with the specific strains, experimental activities and careful handling of the mice. Familiarity with the balance between welfare and experimental needs, observing recording and reporting expected and unexpected outcomes at the cage-side with score sheets is another essential aspect of minimizing welfare costs. An important balance needs to be struck between to much disturbance of the mice while allowing time pre- and post-procedures for acclimatisation and recovery.
Where possible the mice will not be disturbed unless required for routine husbandry, daily checks or experimental purposes. Environmental enrichments like tubes and nests will be provided.
Where possible mice will be acclimatised, for instance when moved between facilities or animal rooms before any experimental procedures are conducted.
We consult existing literature to ensure we use the latest refinements in experiments. Work will be carried out in state-of-the art facilities by highly trained technicians and scientists, all of whom are dedicated to the highest standards of animal welfare.
The scientists and technicians work closely with the trained and highly experienced personnel in the facility and the veterinary surgeon to ensure that animals experience minimal adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I use guidance from the following sources:

- The National Centre for the Replacement Refinement and Reduction of animals in Research (NC3Rs) https://www.nc3rs.org.uk

- The International Mouse Phenotyping Consortium (IMPC) https://www.mousephenotype.org.
- The International Society of Transgenic Technologies (ISTT).
- Some of my team members are members of The Laboratory Animal Science Association (LASA) and attend an annual conference where information on best practice is often exchanged

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I periodically check website for The National Centre for the Replacement Refinement and Reduction of animals in Research (NC3Rs) https://www.nc3rs.org.uk which has many excellent standard operating procedures and videos.
I'm also a member of an international society where there is frequent technical "chatter" regarding technical advances in the field observations and experience implementing these.
Implementation of a technical variation will usually be conducted with a pilot experiment to gain confidence in the actual method and its reported advantages, ideally with suitable controls. Once this has been assessed and shown to be an improvement then this will be introduced in the standard operating procedure and then implemented as a routine.

NON-TECHNICAL SUMMARY

119. Mice with human antibody genes: Drug discovery and vaccine assessment

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Therapeutic human antibodies, Vaccines, Infectious diseases, Cancer, immunology

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Therapeutic human antibodies will be isolated and vaccines tested using mice with human antibody genes.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Antibodies have been used as medicines for more than 125 years. For most of this time antibodies from immunized horses and cattle has been used. This has provided effective treatment for some indications and is still used today as anti-venom for snake bites.
With the advent of modern molecular methods it has been possible to isolate individual antibodies and develop them as drugs for a wide range of diseases. Isolated antibodies can have a very high specificity and are very stable drugs, requiring dosing just once per month. The problem, however, is that if one needs to administer the antibody more than once, it can't come from an animal source as its foreign nature will be recognized by the human immune system and it will be strongly rejected.
To overcome this problem it is necessary to use a human antibody. Several methods have been used to make human antibodies. In some cases bits and pieces of an antibody from a mouse or rat antibody have been stuck together with parts of a human antibody to make them appear human. In some cases this is effective but its not easy to make a mouse antibody look like a human one. One of the best sources of human antibody drugs are mice in which the mouse genes which encode for antibodies have been replaced with ones from humans. Some mouse strains have very complete coverage of the large human antibody genes.
We use these mice, which can make trillions of different human antibodies, to discover antibodies which we can develop as drugs for a variety of serious diseases like cancer, autoimmunity and infectious diseases.
Mice with human antibody genes, have immune response that mimic those of a human. This is useful for testing experimental vaccines to make sure they work before they are used in humans.

What outputs do you think you will see at the end of this project?

The main output of this project will be new medicines, namely therapeutic human antibodies and vaccines.
The discovery, development, clinical testing and approval of therapeutic antibodies and vaccines typically takes ten years or more. Thus, at the end of the project, antibodies for treating several diseases and protective vaccines will have been identified, tested in preclinical models and some will be in advanced stages of clinical testing. For many of these antibodies and vaccines we anticipate publishing pre-clinical and clinical results in the peer reviewed scientific literature.
Antibodies emerging from our work on SARS-Cov-2 and the vaccines that we are currently evaluating will likely progress much more rapidly through clinical trials and hopefully will be approved on an accelerated time scale.

Who or what will benefit from these outputs, and how?

The long-term benefits are drugs and vaccines which will directly benefit human health**.** These benefits will play out over a longer time scale than the temporal envelope of this project. Human therapeutics typically take 10 or more years from concept to approval. Vaccines can take longer.
The scientific community will benefit from the new knowledge that emerges from the pre-clinical and clinical studies around each of the projects.

How will you look to maximise the outputs of this work?

We will collaborate with experts in the field, for instance our work on vaccines is a collaborative endeavour with a variety of laboratories.
We will publish scientific papers, thereby disseminating knowledge.
We will file patents, thereby placing in the public domain detailed knowledge of the discoveries we have made.
We will raise money so that the development of promising medicines can continue.

We will out-license promising drugs in situations where we cannot afford to develop these drugs ourselves, thereby allowing the benefits to emerge.

Species and numbers of animals expected to be used

- Mice: 71,200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse was selected for this project because genetic technologies have been developed in the mouse over the last 35 years to an extraordinary degree of sophistication and efficiency. The refinement of the experimental design and techniques for genetically manipulating mice mean that many fewer animals will be needed compared to reaching the same goals in another species.
The immune system of the mouse is similar to that of humans and we know that we are able to replace mouse genes with their human counterparts to make a mouse that has a more human relevant immune system. This is a relatively benign change to the mouse and should not introduce any suffering or distress. The other genetic changes we will make in this project should not adversely affect the mice. Where possible we will search databases to find out how a change in a gene might affect the animal before we do our experiments. If the change is likely to cause problems, we will change our work to try to avoid welfare issues.

Typically, what will be done to an animal used in your project?

To produce transgenic mice females will be mated and 1-3 days later killed and their embryos collected. In some cases, the females will be stimulated with hormones to produce larger numbers of embryos before they are mated. This will require two injections spaced 2 days apart. The embryos that are collected are manipulated under the microscope and then transferred to foster mothers (previously mated to vasectomized males) who become pregnant, give birth and rear their pups until they are old enough to be weaned.
The embryo transfer is done under general anaesthesia as it involves a small incision in the skin and body wall to access the uterus or oviducts. Following the embryo transfer, the incision is closed with sutures and the skin is closed with surgical clips. Typically, the mice recover very quickly, they are actively running around after 1 hour or so and the clips usually fall out spontaneously after a few days, or if not they will be removed within a week.
A small number of male mice are vasectomised, which are used to mate with foster females for embryo transfer. Vasectomy is conducted on anaesthetised males by making a small scrotal incision and cutting the thin tube which connects the testes to the penis. The incision is clipped or sutured and the mice recover from the anaesthetic within 60 minutes or so. The clips usually fall out after a few days if not they are removed. A week or two later the mice are used for mating with females once or twice each week.
Transgenic mice in this project will be bred and weaned. Where the line is not pure bred a small piece of tissue from the ear is taken for genotyping the mice.
Transgenic mice are used for immunisations so that they develop antibodies. This requires a few injections spaced a few weeks or a month apart typically extending over a period of 2-4 months. A small drop of blood will be collected at several time points during an immunisation to monitor the response to the immunization. In the final stage, the mice will be killed and the spleen, bone marrow and lymph nodes collected for analysis.

A small number of immunised mice will be challenged with an infectious virus to test if they are immune or not.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the animals in this project should not experience any adverse impact as they are used for breeding and immunisations. These procedures used for immunisation cause minor transient pain from a needle prick or a small cut to draw blood.
Some of the animals will experience pain from minor incisions, for instance for embryo transfer and vasectomy which will managed with analgesics. The pain in these cases is not expected to be severe or long lasting.
A very small number of mice will be challenged with influenza or another virus. These viruses induce weight loss in mice over a period of several days to one week. Generally, the mice will recover and regain the lost weight during the following week.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority [99%] of mice in this project will experience mild severity procedures.
A minority [less than 1%] may experience a procedure with moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The immune system is extremely complex. It begins to develop before birth and continues to develop throughout adult life. The components have been shaped by exposure of our ancestors to pathogens over millions of years. The development of antibodies that emerge following exposure to a target antigen over many months of an immune response, is a feature that simply can't be emulated in a laboratory as this involves the interaction of many different cell types and migration of cells to a variety of different sites in the body.

Which non-animal alternatives did you consider for use in this project?

Some artificial methods using bacteria been proposed that can be used to discover antibodies in the laboratory, the most well-known of which is a technology known as phage display. In this technology libraries are generated using molecular biology methods from human antibody producing cells. These libraries can be screened to detect molecules which bind to a target of interest, but the antibodies which can be isolated are immature and can't be directly developed as drugs. In contrast antibodies that have come from humanised mice are mature and they can be developed as drugs without further meddling.

Why were they not suitable?

Theoretically phage and yeast based antibody display systems can be used to discover antibodies, but in practice, these methods have severe limitations. The limitations are not well advertised but there are underlying issues with the technology. The antibodies in phage libraries are immature, which means they lack specificity to their target. Their binding affinities are very poor and their biophysical properties are highly problematic
These limitations are apparent from the very small number of licensed antibody drugs that have emerged from more than three decades of application of this technology by large teams in numerous pharmaceutical companies. Even the best known "phage antibody companies" have been using antibodies from mice. In contrast drugs from synthetic antibody platforms have frequently failed in late stage clinical development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals estimated to be used for this project are based on 30 years of experience in generating mice with altered genes. They are also consistent with the usage in the existing project license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

More than 70% of the animals used in this project are a consequence of breeding mice with complex combinations of alleles. Where possible we will try and breed homozygous mice with stable allele combinations, but as these strains are evolving it is hard to avoid extensive breeding.
The second most extensive use of mice is for immunisations, which are at the core of the scientific objectives. Many of these mice are used to assess vaccines. To gain statistical significance we need to immunize many mice to ascertain convergence of antibody responses. Investment in technologies to enable deeper mining of immune responses enables greater sensitivity and may in time allow fewer mice to be used per antigen.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

There are three measures we take to reduce mouse numbers:

1. Knockouts are made directly by zygote injection in mouse strains which carry all the other required alleles. This significantly reduces breeding and reduces timelines, although the variability of the method does mean that more alleles need to be carried forward in parallel.

2. We continue to isolate ES cell lines carrying combinations of alleles and use these as a background for targeted modifications thereby reducing allele complexity to n=1 and breeding time to 9 months or less.

3. We cryo-preserve mouse lines which are no longer in use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs

(harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice with human antibody loci

The mouse was selected for this project because genetic technologies have been developed in the mouse over the last 36 years to an extraordinary degree of sophistication and efficiency. The refinement of the experimental design and techniques for genetically manipulating mice mean that many fewer animals will be needed compared to reaching the same goals in another species.
The genetic alterations that we have introduced into the mice, although rather extensive are benign. The reason for this is the immune system of the mouse is similar to that of humans and we know that we are able to replace these mouse genes with their human counterparts. These mice are fully immune competent; thus they do not experience any immunological deficiency.

Mice with knockouts

In some cases we will make knockouts of target antigens in the genetic background of these humanized mice. This improves the immune response against the target, enabling us to get more and better antibodies from each immunized mouse. It should be noted that the drug targets selected must yield viable knockout mice as healthy mice are required to generate a good immune response. To minimize the impact of this genetic modification, we carefully check the literature and the IMPC database which provides an expectation on the phenotype of the knockout.
It should be noted that although IMPC is incomplete its coverage of the genome continues to expand. In cases where a phenotypic impact is expected, we will design alternative alleles with minimal consequence on the phenotype of the mice.

Immunization Methods

The immunization methods used are highly refined are widely used. Minimization of impact is achieved by using standard operating procedures and highly refined downstream methods to get the most out of every immunized mouse – thereby reducing mouse numbers.
In terms of the antigen, a significant amount of in vitro work is conducted before an immunisation starts to maximize the chance that the antigen is able to elicit an immune response. This includes ensuring that the antigen is properly folded into a native structure and presented along with relevant components – for instance by co-expression of co-receptors, removal of exogenous tags etc. By application of these principles, this ensures that the immune system is directed at an accessible part of the molecule. This may sound obvious, but a significant amount of animal use from repeat immunisations is avoided by rigorous application of these principles. Similarly, by focusing the immune system up front one can avoid going down the long pathway of drug development with a candidate that may eventually fail – with concomitant waste of animals during the testing phase.
Similarly, carefully preparing the antigen so that it is free of toxic or inflammatory agents avoids suffering and reduces animal numbers.

Refined down-stream antibody discovery methods

We have developed highly refined downstream methods for antigen receptor discovery. Some years ago, this would have been achieved by hybridoma methodology – which typically would have yielded a few useful clones from each mouse. By developing and applying single cell methods we are now able to recover 100-200 antigen specific B cells from each immunised mouse, which means the mouse numbers required for immunizations are much lower than they were previously.

Why can’t you use animals that are less sentient?

The immune systems require several months to develop a robust immune response against a target. The immune system is not mature at an earlier stage (immature life stage).
Lower organisms can’t be genetically engineered to the extent possible with mice, the mechanisms of an immune response are different and the structure of antibodies are also different, so other species can’t be used.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I don’t anticipate many refinements to the transgenic methods as these are already very standardised and efficient.
Advances in single cell sequencing technologies should lead to increases in the amount of data that we can obtain from a single mouse. For example, more complete information on the B cell responses to an antigen will enable us to use fewer mice and will also allow us refine immunisation methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I use the guidance on the NC3Rs web site https://www.nc3rs.org.uk and the IMPC website https://www.mousephenotype.org.
I also use documents prepared by the local establishment. Animal experimentation conducted under this project licence will comply with the guidelines in this document except where permission for a specific procedure or procedures vary from it.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I periodically check the NC3R's website which has many excellent SoPs and videos. I'm also a member of ISTT and its members are frequently communicating advances in the field and their experience implementing these.

Home Office

NON-TECHNICAL SUMMARY

120. Microbe and body rhythm influences on the development of type 1 diabetes

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Immunology, Autoimmune diabetes, Circadian rhythms, Metabolism, Infection

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to understand the effect of daily body rhythms on bacteria that are found in the gut, and how this influences cells of the immune system (CD8 T cells) to 1. attack their target cell in the pancreas (beta cells) in type 1 diabetes, at different times of day, and 2. alter how well immune cells deal with infection.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is currently no therapy available for preventing development of Type 1 diabetes, which is an autoimmune disease whereby the immune system of the body attacks insulin-producing beta cells of the pancreas. Insulin injections, required several times a day, are a life-saving/life-maintaining treatment, but many people find it very difficult to maintain good blood glucose control and may develop long-term complications. In this work, we aim to understand how body rhythms that regulate hormones and metabolism, as well as the immune system, work together with the bacteria that live within the gut. This will help us develop new knowledge about development of therapy based on regulating the immune system, and potentially, how best to give this therapy.

What outputs do you think you will see at the end of this project?

This work will generate new information about the way the daily rhythms of the body can influence the bacteria that live within us, the way the immune system works, and add to information about how both of these interact with the insulin-producing cells of the pancreas. The work will be published in scientific journals.

Who or what will benefit from these outputs, and how?

Other scientists will benefit in the short term, as it will add to information that should enable us to design better treatment, with a time scale of 5 years. Ultimately, as we understand the science better, and new treatments for type 1 diabetes are developed, this could benefit people who have type 1 diabetes, as well as those who may be protected from developing disease. The benefits could be seen in 5 to 10 years. In addition, understanding the way bacteria and the insulin-producing cells of the pancreas interact could also benefit people with type 2 diabetes, and provide basic information that may lead to further studies. Studies of the immune daily rhythms may help people with both type 1 and type 2 diabetes, as they have relevance for why people with diabetes may be more susceptible to infection.

How will you look to maximise the outputs of this work?

The outputs will be maximised by collaboration with other investigators, as well as people from allied fields of research who will find the principles that underlie the effects of the daily rhythm on the immune system, the hormonal system and the gut bacteria of importance to their work. We will disseminate the new knowledge to scientists at scientific meetings, the community of people who have type 1 diabetes, as well as the general public through public engagement activities. We will publish the work in scientific journals.

Species and numbers of animals expected to be used

- Mice: 15000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is the species of choice here because of the availability of strains and the immunological reagents, which allow investigation of development of immune T and B cells, together with the ability to track immune cells. They are also important in the study of responses that are similar to human immune responses.
Many of the mice used do not have any obvious abnormality that affects their day to day existence. Some mice are known to develop diabetes and we need to use these as the model of human type 1 diabetes, as our aims in this project are to study disease processes leading to diabetes. These will enable us to design treatment in the future.

We will study mice from neonates to aged mice. The neonates, and juvenile mice are studied because it is known from our work and those of others that influences early in life affect future development of diabetes. We study adult and aged mice, as they are nearer to development of diabetes, and it is important to study the disease processes, both early as well as later in life. Most mice will be studied before development of disease or within a short period after diagnosis. Some mice have a deficient immune system, and the use of these is necessary to allow us to study the cells recognising insulin and other self protein targets, without interference from other immune cells.

Typically, what will be done to an animal used in your project?

We have a number of different protocols in our project, and mice will have limited number of procedures as part of these protocols.

Initially, we will study mice that have one of either of the following conditions, prior to studying gut permeability and glucose tolerance:

1. Changes to light cycles
2. Changes to diet type
3. Changes to access to food (food restrictions)
4. Exposure to antibiotics.
5. Immunizations
6. Infection
7. Imaging

Investigation of insulin tolerance will only be conducted if the glucose tolerance results indicate a difference between groups.

Once we have conducted these initial studies, and they have been shown to be safe, we will then study combinations of conditions 1-7, the combinations of which will be determined by the data obtained. These combination studies will involve studies on mice receiving 2 conditions, the data from which will then generate avenues of exploration for a new set of mice to receive 3 conditions and so forth. This method will allow us to establish that the combined conditions are safe and provide important data to further focus the specific research question, minimizing unnecessary animal use.

What are the expected impacts and/or adverse effects for the animals during your project?

Up to 20% of the mice in the project as a whole may develop diabetes. They drink more and urinate more. The cages require more frequent changing. If they are not treated with insulin, they may start to lose weight. We would terminate the experiments within 2 weeks of developing diabetes, before the mice become unwell from diabetes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the mice will have mild severity. If they develop diabetes, this would be considered moderate.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will study aspects of development, where possible, in vitro. However, we cannot investigate interaction of the circadian rhythm, the gut bacteria and effects on the immune system to cause diabetes in people. We are unable to manipulate the conditions in humans, to fully dissect the importance of different components. We will use cells that arise under altered selection conditions in vivo, to test the influence on diabetes development. This has to be done in vivo as diabetes arises as a complex process that involves numerous cell interactions and the metabolic state, which cannot be recreated in vitro. Diabetes occurs because cells migrate to the pancreas, enter the pancreas and attack the insulin producing cells. The influences within the whole mouse that affect all these processes cannot be studied in tissue culture.

Which non-animal alternatives did you consider for use in this project?

Where possible we will study effects of changing conditions in tissue culture. We will also study these influences in humans. However, in people, we cannot investigate interaction of the circadian rhythm, the gut bacteria and effects on the immune system, which come together to cause diabetes .
Why were they not suitable?

We are unable to manipulate the different components leading to diabetes, with the appropriate controls, in humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers of animals is based on the known characteristics of the breeding of the animals, the need to carry out complex breeding, the number of experiments required in each protocol and the numbers estimated to be required for each set of experiments to give valid and meaningful results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the NC3R Experimental Design Assistant and have been guided by the use of power calculations, and the requirement to carry out pilot experiments, where there is no previous information about the expected outcomes of experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to assist our final experimental design where there is no previous information about the expected outcomes of experiments. We have developed protocols that reduces the number of donors required for experiments by optimizing the numbers of cells for experiments. We have consulted a statistician in planning our experiments to use the minimum number of mice to give us sufficient information based on statistical considerations. Where possible non-invasive imaging will be used to follow development of diabetes, rather than multiple animals. We will use the most efficient breeding protocols that we have designed based on many years of experience with the NOD mouse model.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is the species of choice here because of the availability of strains and the immunological reagents, which allow investigation of development of immune T and B cells, together with the ability to track immune cells. They are also important in the study of responses that are similar to human immune responses.

Many of the mice used do not have any obvious abnormality that affects their day to day existence. Some mice are known to develop diabetes and, apart from mice that will be treated with insulin, they will be studied before development of disease or within a short period after diagnosis. There are mice in which the immune system is deficient which are necessary to allow us to study the cells recognising insulin and other self-protein targets without interference from other immune cells. All mice will be housed in isolators, individually ventilated racks or filter framed cages to reduce the risk from infection.

Why can’t you use animals that are less sentient?

We cannot use animals at a different life stage, as we study diabetes in a model that has close resemblance to type 1 diabetes in humans. Species that are less sentient do not develop diabetes. Our experiments require day to day observation of complex physiology and immunology, and cannot be done on terminally anaesthetised

animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will monitor all mice for the development of diabetes. Many of the mice used do not have any obvious abnormality that affects their day to day existence. The mice that can develop diabetes will be studied before development of disease or within a short period after diagnosis (unless treated with insulin). There are mice in which the immune system is deficient which are necessary to allow us to study the cells recognising insulin and other self antigens without interference from other immune cells. All mice will be housed in isolators, individually ventilated racks or filter framed cages to reduce the risk from infection.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will use the PREPARE and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs website regularly, and at least monthly, to remain up to date on advances in the 3Rs. We will subscribe to the NC3Rs newsletter. We also remain aware of current literature that is published.

Home Office

NON-TECHNICAL SUMMARY

121. Modelling organ fibrosis and cancer in mice

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

fibrosis, cancer, therapy, inflammation, chronic disease

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this study is to advance our understanding of how organ fibrosis (scar formation in damaged tissue) and liver cancer develops as well as identify new drug targets and test new medicines for the treatment of these diseases.

A retrospective assessment of these aims will be due by 01 June 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is estimated that tissue fibrosis, which can affect any organ in the body, contributes to up to 45% of deaths in the developed world. The number of people diagnosed with organ fibrosis, particularly liver fibrosis, are increasing every year. Currently, only two drugs are licensed to treat fibrosis in a rare lung disease, however, there are no medicines approved to treat other lung disease or fibrosis in other organs.
Liver fibrosis is also a risk factor for developing liver cancer, and with Sorafenib, the only drug used to treat advanced liver cancer, only extends life expectancy by 3 months. Therefore, there is an urgent need to better understand the disease and develop improved liver cancer models for drug testing.

What outputs do you think you will see at the end of this project?

Work conducted under this project licence will generate data and new knowledge that will help advance our understanding of how organ fibrosis develops and what changes at the level of molecules and cells make the disease get worse. Our work will help advance knowledge the disease process and identify new drugs or drugable targets, which limit scar formation in damaged organs or prevent liver cancer.
We aim to identify biomarkers of disease (e.g. proteins or DNA in the blood that are released from the damaged liver) or imaging tools to help assess how advanced the scarring or cancer is or provide information if a drug is working.
Our work will be presented at scientific meetings and published in research papers to share knowledge gained with the wider scientific community and help advance knowledge in the field, ultimately for patient benefit.

Who or what will benefit from these outputs, and how?

In the short-term, scientists in both academia and industry will benefit from the discoveries generated under this program of work. This could be due to the development of new research tools, experimental approaches or identification of new pathways which when targeted yields therapeutic benefit.
Ultimately, the long term aims is to benefit patients either through development of new diagnostics (biomarkers or imaging tools) or new treatment strategies.

How will you look to maximise the outputs of this work?

By presenting our discoveries and national and international scientific meetings, publishing our research discoveries and through collaboration with academics or the pharmaceutical industry, we will be able to

maximise the impact of knowledge gained under this program of work.
Wherever possible we collaborate with others to share tissue samples, lines or provide training in methods through collaborative research or participation in workshops.

Species and numbers of animals expected to be used

- Mice: Up to 50,000 breeding and 39,100 experimental animals

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Tissue fibrosis and liver cancer develops over many weeks/years therefore adult mice are used.
To study disease biology and ask how a protein effects the disease process we need to use genetically modified mice which do not express that protein or express a modified (or mutant) form of the protein that is found in patients, identified in genetic studies as increasing the risk to develop that disease or a more aggressive form of the disease. Genetically modified mice are readily available therefore mice provide an optimal system to study the disease. Additionally the research tools/reagents needed to investigate disease mechanisms and test therapies are available and are able to be translated to higher mammals.

Typically, what will be done to an animal used in your project?

Chemical models of liver or lung fibrosis have been refined for many years and are very predictable models, therefore we know what the disease stage animals have reached at any given time point. We have lots of experience running drug studies in these models, therefore we know exactly when to give drugs and for how long to administer them. In the liver disease model mice receive bi-weekly injections of the chemical into their belly, whist in the lung model a chemical is inhaled into the lung. For some liver fibrosis models chemicals may be placed in the drinking water. We also use chemicals to induce liver cancer, where a mouse receives a single injection in the belly and cancer develops over many weeks.
Surgical models will be used to study liver disease, kidney disease, liver cancer or assess liver regrowth after partial removal of the organ. Pain relief is always given as needed. The liver disease models accurately mimic's a different type of liver fibrosis, where the bile duct is tied preventing flow or bile in to the intestine, bile spills into the liver and causes damage, this mimics a disease called cholestatic liver disease. To study liver growth, up to 70% of the liver is removed and then allowed to regrow over a period of 5 days (when normal mass is restored). Liver cancer cells are injected into the liver to study liver cancer and then test drugs. Cancers may develop over a few weeks. To induce kidney disease the ureter (a tube connecting the kidney to the bladder) is surgically tied to prevent urine flowing from the kidney to bladder, which causes kidney injury and fibrosis.
To model diet induced liver disease we will feed mice a modified diet (e.g. high fat) either with or without sugar water (comparable to coke). These animals gain weight and develop features of fat induced liver disease. Other dietary models include the methionine and choline deficient (MCD) diet model we expect mice to lose weight but develop fat induced liver disease.
Skin inflammation (redness and swelling caused by white blood cells) and scarring will be induced in the mice by either giving agents, which irritate the skin or chemicals that cause scarring. Punching two small holes in the skin and then watching them heal will be used to study how skin wounds heal. Pain relief is given as required.
Liver cell death will be promoted by giving mice chemicals or drugs at toxic doses (e.g. paracetamol) or inflammatory molecules, doses may be lethal or sub-lethal and mice will recover after a short period of feeling unwell.

Bone marrow chimera (a bone marrow transplant): normal or genetically modified (GM) mice will be irradiated to remove the white blood cells and then given new immune cells from a donor mouse of a different background e.g. normal in to GM.
All of our disease models are used to test therapies for that type of chronic disease or cancer.
In these models we may wish to perform non-invasive imaging whilst the animals are asleep, assess well-being using behavioural test or measure blood pressure. We may take blood samples to assess disease stage or drug metabolism. In disease models we might perform glucose tolerance tests.

What are the expected impacts and/or adverse effects for the animals during your project?

In our mouse models, mice may show signs of sickness e.g. hunched posture, diarrhoea, ruffled fur, look pale or feel cold. Supportive care and pain relief will be given and if the clinical condition does not improve within 24h mice will be humanely killed.
Surgical models: adverse effects due to surgical complications may include bleeding. Mice were the bile duct has been tied, occasionally become jaundice (skin becomes a yellow colour) or get swelling in the belly. Supportive care such as fluids, soaked diet and a warm environment will be provided. Pain relief is always given in surgical models and animals are carefully monitored by the surgeon and an assistant prior to and during the surgery to ensure that animals are sufficiently anaesthetised throughout the procedure.
In the dietary models most mice will gain weight, but not to a point where mobility is impaired, but in the methionine and choline deficient (MCD) diet model we expect the mice to lose weight.
Liver cancer model, mice will develop liver cancer over a period of up to 60 weeks but this will not result in liver failure.
Liver cell death caused by toxic chemicals or drugs will be either lethal where mice are humanely killed when very sick and the liver starts to fails or sub-lethal where mice will fully recover.
Lung fibrosis; mice will develop lung disease over a period of up 28 days and can lose weight during the first week of the models but regain weight after this time.
Skin fibrosis; the skin may become red (inflammation) and the skin will become thicker. Skin wound healing; the wounds created by “skin punching” are superficial and therefore do not bleed. These models last up to 28 days.
Kidney fibrosis; mice will develop kidney disease over a period of up 18 days and can lose weight during the first week of the models but regain weight after this time.
Heart fibrosis will be induced by increasing blood pressure, which stresses the heart by chemical infusion or by surgically restricting the aorta. Mice can lose weight during the first week of the models but regain weight after this time.

Bone marrow chimera: Mice will always receive replacement bone marrow after irradiation, however, they may be sick and lose weight due to the effects of the irradiation but will recover once the immune system has been replaced. Rarely the transplantation of the bone marrow may fail, if this occurs (animals fail to regain weight) then the animal will be humanely killed.
Imaging: mice may experience a small weight loss post imaging but this should recover within a few days.
Therapy, we do not anticipate therapies will cause significant adverse effects.
In all models Pain relief is given when needed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Only mice will be used in this program of work. We estimate that ~80% animals used will in procedures will be mild including breeding mice to maintain a colony, for experiments and to take tissue or perform mild models of disease such as acute liver injury or dietary models of disease. Cell isolation from liver tissue in non-recovery procedures comprise ~1% of experiments. Approximately 16% of animals will be of moderate severity, whilst up to 3% may fall into the severe category.
What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 01 June 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying complex diseases which develop and heal over many years.
Tissue fibrosis, a term which describes scar formation in an organ as a result of tissue damage is caused by many different cells in the organ changing their behaviour to try and heal the wound. If the damage is only small or limited to one insult, then the scar will dissolve. However, when the organ is repeatedly damaged over and over again, the scars persist and then reduce the ability of the organ to perform normal daily tasks. When disease is very advanced an organ can fail. Fibrosis occurs not only as a consequence of damage to the tissue but also through recruitment of white blood cells to the injured tissue, therefore signals from outside the affected organ are an important of the disease process.
Cancer, is also a complex disease, which involves many different cell types but is more likely to develop in a diseased or fibrotic organ e.g. liver disease.
This research will identify proteins which either cause or limit fibrosis or cancer. To prove that they do disease models may be performed in mice which are "genetically engineered" and lack the protein of interest.
Alternatively, we may wish to test drugs which we believe will limit tissue fibrosis or cancer growth.
For these reasons we need to perform some of our research and drug testing in animals.

Which non-animal alternatives did you consider for use in this project?

We routinely use human cells in culture (including cell lines) to understand and model the biological processes involved in causing tissue fibrosis and cancer or to perform drug testing.
We have started testing/developing 3D cell culture models as an alternative method for drug screening and understanding the biology of scar cells or cancer cells.
We have recently optimised a new technology to culture very thin slices of tissue from human liver, lung and kidney to model fibrotic disease and test scar-limiting drugs. We are now developing methods to model other fibrotic diseases. These technical advances will help minimise use.

Why were they not suitable?

Whilst these are useful tools, there are limitations of cell cultures systems, these include;

1. cells grown in petri-dishes sit on plastic, which is much stiffer than where they reside in the body. The increased stiffness can change their behaviour and they become "super activated" or fail to do the job they would in the body. These abnormal behaviours could lead to the identification of non-relevant pathways or fail to predict drugs which are likely to be ineffective in the disease.

2. Organ fibrosis development and resolution is regulated by many different types of cells communicating with each other within the damaged organ as well as through communication with white blood cells and receiving signals from other organs. Recreating all of these internal and external organ damage signals

is difficult to model in culture.
3. Using genetic engineered mice will help advance our understanding of the disease to help identify new targets for drug discovery.

Such systems are extremely useful for aiding our basic knowledge and for initial drug screening, and we use these systems to reduce animal use.
A retrospective assessment of replacement will be due by 01 June 2026

The PPL holder will be required to disclose:
- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Yes, we have used knowledge from previous studies to mathematically calculate the minimum number of animals needed in each group to generate data which allows us to answer our scientific questions. By doing this we can minimise use but be confident that the differences in a scientific measurement between two groups is meaningful and has not been obtained by chance.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken multiple approaches to ensure that we use the minimum number of animals for research purposes.
We have performed audits of our previous research studies and assessed research plans of current projects to predict use under this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Statistical analysis is performed to determine the minimum numbers of animals need to generate biologically meaningful data. If this is not possible then pilot studies are performed to reduce numbers and inform future studies going forward.
We employ efficient breeding strategies and where possible we use both male and female mice to minimise numbers of animals used.
Tissue is regularly shared between projects to maximise outputs from animal procedures and minimise numbers of animals used.
Wherever possible, we will use human tissue/cells or cell culture systems to replace animal models of organ

fibrosis and cancer. The group have accumulated archival tissue banks of frozen and formalin fixed tissues from our previous models and human normal and diseased tissues. These samples are used in multiple on-going projects to minimise the number of animal disease models used.

A retrospective assessment of reduction will be due by 01 June 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All of the disease models chosen are the lowest severity model that can be used to answer our research questions.
Accumulation of scar tissue in response to organ damage, namely fibrosis, can affect any organ in the body and is caused by many different types of injury. Scarred organs are also at a higher risk of developing cancer. Therefore to understand how this disease develops, determine if this process is common to all organs and test new therapies, we need to perform different models of tissue injury.

For example, chemical models of liver fibrosis or lung has been refined for many years and is a very predictable model, therefore we can predict the disease stage at any given time point. We have lots of experience running drug studies in these models, therefore we know exactly when to give drugs and for how long. In the liver disease model mice receive bi-weekly injections of the chemical into their belly, whist in the lung model a chemical is inhaled into the lung. We also use chemicals to induce liver cancer, where a mouse receives a single injection in the belly and cancer develops over many weeks.
Surgical models will be used to study liver disease, liver cancer, kidney disease or assess liver regrowth after partial removal of the organ. Pain relief is always given as needed. The liver disease models accurately mimics a different type of liver fibrosis and is used to test therapies for that type of liver disease. To study liver growth, up to 70% of the liver is removed and then allowed to re-grow over a period of 5 days (when normal mass is restored). Liver cancer cells are injected into the liver to model liver cancer. To induce kidney disease the ureter is surgically tied to prevent urine flowing from the kidney to bladder, which causes kidney injury and fibrosis.
To model diet induced liver disease we will feed mice a modified diet (e.g. high fat) either with or without sugar water (comparable to coke). These animals gain weight and develop features of fat induced liver disease.
The most refined model is always used.

Why can’t you use animals that are less sentient?

Organs contain lots of different types of cells and these cells all talk to each other to ensure that the organ does its job properly. When an organ is damaged, all of the different cell types are needed to help heal the injury. White blood cells also enter the organ at the site of injury to help clean up the damage and heal the wound. However, when organs are repeatedly damaged this healing process becomes abnormal and fibrosis occurs.

Fibrotic diseases in the liver, lung, skin, kidney, heart and liver are complex processes that develop many weeks/years. Fibrotic organs are also at a higher risk of developing cancer.
Because of the complex nature of the disease process it is not possible to recreate this using cells in culture dishes, therefore we need to study disease progression and test medicines in the whole animal.

Genetically modified mice, which lack a protein which is thought to be important in the development of tissue fibrosis are used to help understand the disease process better but also to help identify new drug targets to treat organ fibrosis and cancer.
Fibrosis is an inflammatory driven disease. Fish and insects (e.g. flies) lack the same broad range of immune cells found in humans, which means that there are differences between fish and mammals that could affect the disease biology. Some genes are not conserved between these species and mammals therefore some of the disease mechanisms may not be the same. Therefore drugs that target those cells or disease pathways may not work in these systems due to fundamental differences in the biology of the species compared to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals, regardless of disease model are checked regularly and supportive care is readily provided to minimise distress or suffering and improve animal welfare.
For surgical models we use good surgical techniques and operating theatres/equipment to minimise the risk of infection. The bile duct ligation model is a surgical model of liver fibrosis. In this model mice receive pain relief and a high level of post-operative care including soaked diet, a warm environment and fluids as required to minimize stress and suffering. By working with the vet team and animal behaviour/welfare scientists we have developed a clinical scoring system to help assess the animal's well-being and level of disease.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all models and optional procedures good practice guides will be used to help refine the model as described in the ARRIVE guidelines and Laboratory animals special article 2015, 49 (s1).
LASA Working Party guidelines on assessment and control of severity will be used throughout the project to determine if any animal is suffering distress.
Workman et al in 2010. British Journal of Cancer (2010) 102, 1555–1577 NCRI guidelines will be used to perform and monitor liver cancer studies.
Should distress occur immediate actions as described in the individual protocols would be taken to reduce an animals suffering.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

There are many sources in which provide information regarding 3Rs advances, these include; the NC3Rs website, NC3Rs seminars/events and emails, scientific publications and published guidelines as well as continued professional development e.g. local seminars, regular communication with the NACWO and veterinary team and academic collaboration with the welfare group.

As information on welfare or technical improvements, alternative less severe models or new non-animal model systems becomes available an appropriate strategy within the research group and veterinary teams will be implemented to ensure that animal use and suffering is minimised. This will include testing new models (animal or non-animal) and modifying procedures. **A retrospective assessment of refinement will be due by 01 June 2026**

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

122. Models to advance understanding and treatment of lethal children's brain tumours

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

paediatric, cancer, brain tumour, precision therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Brain tumours are the leading cause of cancer-related death in children, of which the most lethal type is commonly referred to as paediatric high-grade glioma (pHGG).The overall aim of this project is to advance understanding of the origins, underlying biology and treatment of pHGGs, for which currently there are no effective treatments that improve survival for patients. With greater understanding of how pHGGs develop and propagate, more precise therapies tailored to the unique biology of these tumours can be identified.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Paediatric high-grade gliomas (pHGGs) are incurable and a leading cause of cancer-related death in children, affecting approximately 70-100 children in the UK every year. At present there are no effective treatments for this universally fatal disease. Current standard treatments are broad-acting and invasive, involving debilitating chemotherapy, radiation and brain surgery, and ultimately do not improve survival. In fact, often there are also unintended effects on the still-maturing brain, which negatively impacts quality of life in the longer term for children receiving treatment. This dismal prognosis has remained unchanged for decades with less than 5% of patients surviving 5 years post-diagnosis.
Our aim is to improve the outlook for pHGGs by developing more precise therapies based on their unique biology. The accurate recapitulation of this disease using state-of-the-art animal modelling is crucial for this, to further our understanding of the biology of this disease and to develop newer, more effective precision therapies. With these models we hope to understand how these tumours form and propagate, discover what makes them different from normal brain cells, and find out how these differences play out in the tissue micro-environment of the brain; perhaps by recruiting other normal brain cells in support of tumour growth or enabling tumour cell evasion from immune surveillance. This information can only be gained using animal models of disease, and is important for developing the next generation of cancer treatments.
Specifically, this work guarantees new insights into how co-operating genetic mutations induce and maintain paediatric high-grade gliomas. The project also aims to reveal distinct therapeutic vulnerabilities in different glioma sub-types.

What outputs do you think you will see at the end of this project?

This research focuses on the mechanisms driving the development of children’s brain tumours. We expect to make advancements in our understanding of both fundamental and therapeutically relevant aspects of brain tumour biology. Therefore, the outputs will include new knowledge and publications as well as potentially, products such as novel diagnostic tools and/or therapies. These outputs will be of interest to academic researchers, clinician scientists, healthcare practitioners, drug development experts and pharmaceutical companies. However, the main impact of this research in the longer term will be on paediatric brain tumour patients and their families, as well as the NHS and social services.

Who or what will benefit from these outputs, and how?

Since current treatments for paediatric brain tumour patients produce debilitating and often life-long side-effects, the novel, potentially more effective treatments that this research aims to develop should be less damaging and produce fewer complications in patients. This should alleviate some of the costs associated with long-term care for the NHS, social services and families caring for patients.
In the short-to-medium term, scientists working on improving our understanding of paediatric brain tumours and others aiming to develop new treatment strategies for this cancer will benefit the most from the tools and data this proposal will generate. This is because the models and molecular dependencies this research will uncover

will be most relevant to their work. Academic researchers interested in brain development, stem cells and cancer will also benefit from the new modelling techniques we will develop. These can be used for manipulating neural stem cells in mice, to gain insights into brain development, stem cell function and cancer.
In the longer term, healthcare practitioners such as those designing clinical trials, drug developers in academia or industry and pharmaceutical companies can benefit from this research. They will be able to use these results to identify and refine patient populations they wish to target therapeutically or diagnostically, to improve the design of candidate therapies, or to evaluate the efficacy of new treatments.
Regarding the contribution of this research to the economic competitiveness of the UK, this work may identify candidate diagnostic markers and novel therapies with commercial potential. These commercial opportunities can add to the UK's already considerable competitiveness in the health and life sciences sector.

How will you look to maximise the outputs of this work?

Sharing data and communicating our progress to scientific, clinical, industry and lay audiences, and ensuring that this information is freely available, forms the basis for maximising the output of this work. The strategies outlined below will communicate our work to academic researchers, clinician scientists, healthcare practitioners, drug developers and pharmaceutical companies. This will ensure translation of novel diagnostic tools and experimental therapies to the clinic, so that patients' lives improve. The research outlined in this proposal will impact health and well-being, economic competitiveness, and alleviate strain on health and social services here in the UK.

Academia and Industry

1) Collaboration with Drug Development Teams – The research proposed in this application will identify drug targets for brain tumours, which will then be passed on to our collaborators for drug development and partnering with pharma. Eventually we hope to spearhead clinical trials and translate new drugs into the clinic.

2) Peer-reviewed Open Access Publications – All scientific results, including experimental diagnostic markers, therapeutic candidates and genetic dependencies specific to each tumour type will be published in peer-reviewed journals. All articles will be open access to ensure they can be widely disseminated. I will also prepare accurate press-releases publicising each publication.

3) Scientific Conferences – I will regularly present the results of this research at multiple national and international conferences. I will also share ongoing work "pre-publication" to receive vital feedback from the scientific and healthcare community and to guide and publicise my work. This will take the form of "work-in-progress" seminars and posting to preprint servers.

4) Data Sharing – The proposed project will generate a significant amount of data carried out on cells harvested from tumours in mice. These tumour cells will possess different combinations of mutations and will be screened with different drugs and gene editing technologies. To make this complex and rich source of information available to the widest possible audience, all sequencing and screening datasets generated will be deposited to publicly available online databases. Molecular biology reagents enabling the generation of tumour models in mice will be made available publicly as well, for dissemination to the wider brain tumour research community. Tumour cell lines generated during the course of this study will be deposited to publicly accessible cell repositories.

General Public

1) Public Engagement Seminars – I believe strongly in public engagement and science communication, and will participate in public seminars throughout the course of this project.

2) Scientific Media – I will actively engage with print and online media following publication of my work and will commission creative content to describe the results in general, visually arresting and moving ways. I believe this strategy will expand the impact of the work immeasurably, enabling people to see past the complexity of the disease mechanisms and appreciate the progress on cancer that the work will represent. I believe this strategy will help engender a scientifically literate and well-informed society.

3) Summer School – I will participate in an annual summer school event. The aim of this event will be to increase understanding of the specific challenges faced by brain tumour patients, to identify the pinch points in the clinical care of these patients, and reveal blind spots in the focus of biomedical researchers. Ultimately, the aim is to fast-track the development of new, more effective treatments to improve outcomes for this disease.

Species and numbers of animals expected to be used

- Mice: 7290

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Brain tumours cause the most deaths due to cancer in children. The prognosis for the most lethal type of children's brain tumour, called paediatric high-grade glioma (pHGG), is particularly dismal and has remained unchanged for decades. Currently in the clinic, pHGGs are treated exactly the same as adult brain tumours, even though children's tumours have completely different causes and underlying mechanisms. These conventional treatments also have a significant negative impact on quality of life, as children's brains are still growing and maturing when these harsh and inexact treatments must begin. To improve the outlook for pHGGs and develop new therapies that are kinder, more effective and more precise, we must understand more about their unique biology.
Mice are essential for the proposed research. Cells in a Petri dish cannot fully replicate the diversity and complex biology of the mammalian central nervous system. Moreover, invertebrate or nonmammalian models cannot reproduce many biological and physiological aspects of human brain tumours. Mice share a similar genetics, development and central nervous system anatomy with humans, and glioma models in mice display many similarities to human brain tumours. Of the commonly used model organisms, the biology of the brain, the brain regenerating cells (stem cells), the immune system and the response to chemoradiotherapy in mice are the most analogous to human. Therefore, to make clinically relevant discoveries and develop more effective therapies for pHGGs, experimental work using mice is essential.
Our previous work demonstrated that in order to model children's brain tumours such as pHGGs in mice, mutations have to be delivered into brain stem cells (also called neural stem cells or NSCs) either during gestation (i.e. embryonic development), or very soon after birth, in neonatal pups. When we delivered mutations later, in older animals, tumours failed to develop. The reason for this selectivity— why children's brain tumours only arise from mutations occurring at the earliest stages of life— is because children's brain tumours arise from mutations within NSCs that occur while the brain is being formed. Since the brain is formed during gestation and the first few years of life (after which the brain is relatively stable and there aren't many more cells being constantly added) these mutations in NSCs must enact their first cancer-causing effects in utero, before birth, or very soon after. This is in stark contrast to adult cancers that arise from mutations in adult stem cells. These mutations in adults require a lot longer to enact their cancer-causing effects and are also acquired later in life, in part due to lifestyle choices (smoking, obesity). In short, paediatric cancers are fundamentally different from adult cancers: arising in different stem cells and through different mutations. This causes paediatric cancer causing mutations to act much earlier in life (often before birth itself) to induce tumour development. This is the rationale for delivering mutations into embryonic and/or neonatal mice to model pHGGs in this project. We introduce the paediatric glioma mutations in mice at a similar life stage to when they occur in humans, i.e. during gestation. Then brain tumours develop in mice, just as they do in humans, thereby creating a mouse model that accurately represents the human disease. These models can then serve as a good system from which to infer knowledge about the human disease and to identify and test new therapies.
pHGGs are highly heterogeneous cancers – with many different co-occurring mutations and types of cells found

within them. Genetic sequencing has revealed that they comprise several distinct tumour subgroups or types: based on the different constellations of mutations they carry and the particular region of the brain in which they are found. However, the relevance of many of these extra mutations that are used to define these distinct tumour types is unknown. Furthermore, it remains unknown whether these extra mutations make some tumours more sensitive to certain drugs. In this proposal, I aim to understand precisely how different co-occurring mutations support tumour growth, with the goal of using this information to undo these tumours.
To do this, we will induce different types of pHGG tumours in mice, each type driven by a different combination of mutations. I propose using this approach to test the effects of these extra mutations, to find gene level changes that help drive these different types of tumours. In the process we will also discover what intrinsically makes these tumours distinct from one another. These results will then be confirmed in human tumour cells. In this way, research in mice will be used to find the proverbial needles in the haystack, and then the most promising candidates (aka gene level changes) will be validated in human cells.
Therefore, I hypothesise that co-occurring mutations used to group tumours into different types can be functionally evaluated using mouse models to reveal clinically tractable vulnerabilities.
In this project, we will:

1. Functionally evaluate co-occurring mutations and develop mouse models of highly aggressive children's brain tumours.

2. Identify the genes and gene level changes important for the growth of different types of tumours in mice.

3. Validate these genes and gene level changes in human tumour cells.

I also propose using this approach to test the effects of the different mutations in unprecedented detail, to find out how they alter the environment of the tumour. I anticipate that each of the mutations has a role in helping tumours grow, by influencing in turn the roles played by different types of cells in the tumour and how they interact with their neighbouring cells, immune cells and blood vessels. I will measure these mutation-driven changes in the tumour ecosystem by analysing precisely how the function, and relative amounts, of different types of cells is altered by different mutations. This will help us understand how co-occurring mutations change relationships between cells to allow tumours to grow, and how this differs between tumour types. This information will help us develop more precise, targeted therapies. This environment-centric approach is necessary to identify how genetic heterogeneity, i.e. the many different co-occurring mutations found in these tumours, helps support tumour growth.
The ultimate goal of this proposal is to aid in the development of a “precision” patient- and mutation matched approach to treating this devastating disease. Therapeutic opportunities that are revealed through the experiments proposed here, if validated in the clinic, will represent the most appropriate treatment for children with pHGGs carrying similar combinations of mutations.

Typically, what will be done to an animal used in your project?

For tumour induction, surgery will be performed on pregnant females to deliver DNA/virus/cells into the brains of embryos midway through gestation. Alternatively, DNA/virus/cell injections will be performed on pups no more than a day old, in which case surgery will not be required. Following surgery and/or injections, mice will develop normally while brain tumours develop. As soon as they begin to display symptoms of brain tumours, usually >4 months later, they will be humanely killed and their brain and tumour tissues will be harvested for our experiments.
Therefore, the outcome from the surgeries and injections are the mice that develop brain tumours over time. These tumours in mice will model lethal and incurable brain tumours occurring in children and young adults. Mice will be monitored using weekly imaging until onset of symptoms that necessitate humane killing. Tissue collected following killing will be used to establish cell cultures or for microscopy. The primary outcome of this work will be data describing increases or decreases in the time it takes for tumours to form and symptoms to develop, the appearance of the tumours and their aggressiveness in mice. The secondary outcomes will be the changes we can observe in Petri dishes, in terms of the ability of the harvested tumour cells to grow over time,

their ability to infiltrate and invade other areas, and other measures of tumour cell activity.
Optionally, tumour-bearing mice will be treated with labelling, imaging or chemotherapeutic agents, and may in addition be treated with focal, targeted radiotherapy. Labelling, imaging and chemotherapeutic agents may be delivered orally or by injection. Focal irradiation will be delivered in some cases together with chemotherapy. The use of focused radiation greatly reduces the adverse effects associated with whole-body or whole-cranial irradiation. These procedures will allow us to replicate in mice how brain tumour patients are treated in the clinic, and to test experimental therapies.
All mice will be housed, bred and subjected to listed procedures according to institutional, Animal Welfare and Ethical Review Body (AWERB) and UK Home Office guidelines. Every attempt will be made to follow the NC3Rs guidelines to reduce, refine and replace the number of mice. All work will be carried out with veterinary and animal husbandry staff oversight and under regulated procedures of mild to moderate severity. The utmost efforts will made to minimise pain, suffering and undue distress. The evaluation criteria for humane killing and tissue collection will be based on observation of neurological impact. Mice will be monitored daily for neurological symptoms, i.e. weight loss, lethargy, seizure prevalence, immobility and changes in gait, grooming or behaviour. As soon as neurological symptoms are observed, in collaboration with animal husbandry and veterinary staff, a decision will be made regarding humane killing, and tissue will be collected for research purposes.

What are the expected impacts and/or adverse effects for the animals during your project?

The appearance of any one of the following adverse effects will trigger humane killing of the animal to prevent undue suffering. The appearance of any one of these adverse effects will also mark the experimental endpoint, following which tissue will be harvested for experimental purposes. These effects are expected between 1 and 18 months following administration of the procedures listed in this project. These effects will arise due to the presence of brain tumours, and may include:
-Loss of appetite and weight, which is a common symptom of brain tumours and chemo/radiotherapy. This will be monitored and if weight loss is greater than 15%, or 20% for chemo/radiotherapy-treated animals, they will be killed to prevent undue suffering.
-The presence of brain tumours can cause problems with walking (gait problems, wobbling, or limb dragging) . If this occurs, animals will be killed to prevent undue suffering.
-The presence of brain tumours can sometimes cause the head to become tilted . If this occurs, animals will be killed to prevent undue suffering.
-The presence of brain tumours can sometimes cause seizures to occur. If this occurs, animals will be killed to prevent undue suffering.
-The presence of brain tumours can sometimes cause excessive lethargy. If this occurs, animals will be killed to prevent undue suffering.
-The presence of brain tumours can sometimes cause fluid to build up inside the brain (hydrocephalus). If this occurs, animals will be killed to prevent undue suffering.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity limit is: Moderate
70% of the animals will experience procedures of Moderate severity (animals on Protocols 2 and 3). The remainder, less than or equal to 30%, will experience procedures of Mild severity (animals on Protocol 1).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Modelling Paediatric Brain Tumours:

Although in vitro (Petri dish) studies can be used to test how cells become cancerous following gene mutations, this system cannot recapitulate the complex microenvironments existing in developing tissues such as the brain. Because our approach requires the use of specific cancer-susceptible cell types at specific points in brain development, this is currently only possible by using live animals that mirror the complexities and cell populations present in human development. Nevertheless, our judicious use of in vitro cell cultures and our targeted brain injection approach (as opposed to a completely animal-reliant strategy that is focused on producing a small fraction of mice of the correct genetic background from a large number of crossings), greatly reduces the number of mice required. In addition, testing new treatment approaches in the models we will develop has the capacity to highlight different tumour types for specific precision therapies. Together this will dramatically reduce the numbers of animals used for this work and markedly increase the efficiency with which we develop cancer models.

Treating Paediatric Brain Tumours:

Regulatory and research bodies require pre-clinical assessment of potential therapies in animals models prior to their translation into the clinic. Therefore, our translation of optimal new therapies to the children's cancer clinic requires the animal studies proposed here. Nonetheless we will continue to use in vitro drug sensitivity studies, including radiation/chemotherapy combination studies in vitro to optimise the selection of agents and thereby minimise the use of animal models in exploratory studies.

Which non-animal alternatives did you consider for use in this project?

We considered using other approaches such as "mini-brains" called organoids grown in culture dishes, fruit flies or nematode worms for the work proposed here.

Why were they not suitable?

Because "mini-brains", fruit flies and nematode worms lack immune cells, a functional blood brain barrier, the full complement of brain cellular diversity (arguably the most complex organ in our bodies), and the whole body context of a mammal, they cannot generate the data most crucial for our work: the impact of mutations and experimental treatments on how quickly and aggressively brain tumours form and recur.

Our approach requires the use of specific cancer-susceptible cell types at specific points in brain development. This is currently only possible by using live animals that fully recapitulate the complexities and cell populations present in development.

Regulatory and research bodies require preclinical assessment of potential therapies in animal models prior to their translation to the clinic. Therefore, our translation of optimal new therapies to the children's cancer clinic requires the animal studies proposed here. Nonetheless we will continue to use in vitro drug sensitivity studies, including radiation/chemotherapy combination studies in vitro to optimise the selection of agents and thereby minimise the use of animal models in exploratory studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken

to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals was determined with advice from a Senior Statistician at the Establishment to ensure that the work will yield reproducible and statistically sound information. Determining the numbers in this way guarantees that the work will not need to be needlessly duplicated in the future. Therefore, animal harm is kept at a minimum. Determining the numbers of animals needed using statistical principles also guarantees that the information and knowledge that is gathered is reliable, accurate and trustworthy. The reliability of this information is very important because it will be used for future, more innovative cancer research.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our use of intracerebral injections vs an approach relying purely on transgenic breeding to generate brain tumour models, and the use of in vitro cell culture approaches, greatly reduces the number of animals required. Furthermore, our in vivo mouse modelling experiments have been carefully designed with appropriate and stringent statistical rigour in mind, that is aimed at minimising the use of animals while ensuring robust and meaningful endpoints. These animal numbers are selected in collaboration with our highly qualified statistician colleagues and our considerable prior experience with brain tumour mouse models. In addition, we have optimised the use of material from each mouse, often harvesting fresh cells for culture, frozen tumour for genetic studies and fixed material for histology from the same animal. All samples and cells are stored in a frozen state when not in use. This minimises the number of animals required because there is no need to maintain a tumour-bearing colony of living animals at all times. Finally, for every experiment, as part of good practice and prior to any experiments, we will write an experimental protocol which includes clear objectives and methodology including statistical plan and endpoints.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our use of intracerebral injections vs an approach relying purely on transgenic breeding to generate brain tumour models, and the use of in vitro cell culture approaches, greatly reduces the number of animals required. Furthermore, each of our in vivo mouse model experiments has a careful statistical design that is aimed at minimising the use of animals while ensuring robust and meaningful statistical endpoints. These animal numbers are selected in collaboration with our statistical colleagues and our extensive experience with brain tumour mouse models. In addition, we have optimised the use of material from each mouse, often harvesting fresh cells for culture, frozen tumour for genetic studies and fixed material for histology from the same animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Methods : Brain injections of tumour-causing mutations

Mouse models of brain tumours, established using brain injections, will allow us to decipher how tumours form, how they respond to treatments and how the normal cells around them help them grow. Most importantly, mouse models of brain tumours can help us determine which new or experimental treatments show promise in eliminating tumour cells, and how these new treatments are tolerated by the body.

Models: Cross-referencing human tumour cells vs mouse tumour cells

In this project, we want to study how different mutations make brain tumours grow and evolve inside the body.

To do this, we will inject one type of mouse with mouse brain tumour cells and another type of mouse, with a less active immune system, with human brain tumour cells. Comparing human and mouse tumour cells will ultimately allow us to pinpoint exactly what allows these tumours to grow unabated and test treatments that prevents their growth.

Why these methods and models cause the least pain, suffering, distress, or lasting harm to the animals

These methods and models cause the least amount of suffering because the alternative approach to carry out this work would require crossing and maintaining many more genetically altered mice, only a subset of which would go on to develop tumours. In addition, our approach leads to tumour development following brain injections after many months. Prior to the rapid onset of symptoms (at which point mice are killed), the mice develop normally and show no signs of distress or suffering. This combination, the dramatically fewer mice needed to do this work, and the normal development of mice following brain injections, is why this approach causes the least suffering.

Why can’t you use animals that are less sentient?

Less sentient animals such as zebrafish, fruit flies and nematode worms cannot recapitulate the uniquely mammalian biology of the human brain. This is especially relevant to the development of new treatments for brain tumours, which have to be analysed for their effects on not only the tumour, but also on normal brain function and other critical organs in the body. These treatments also have to gain access to the brain through the blood brain barrier. These "extra challenges" facing brain tumour research cannot be studied in less sentient animals because they either do not occur in them or are much more challenging to address. However, they do occur in mice and more easily observed in them. Therefore mice are the most appropriate, least sentient animal models for studying and developing new treatments for brain tumours.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements will be made routinely over the course of the project and through constant liaison with veterinary and husbandry staff. If needed, amendments to the licence will be applied for, if new procedures are needed to improve animal welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Work in this protocol will be undertaken in accordance with the principles set out in the Guidelines for the welfare and use of animals in cancer research: British Journal of Cancer (2010) 102, 1555-1577.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through constant interaction and engagement with veterinary and animal husbandry staff at the facility including the NVS and the NACWO, annual attendance at NC3R conferences, and through receipt of electronic and printed media from NC3Rs on ongoing improvements to techniques and methodologies. If needed, amendments to the licence will be applied for, if new procedures are needed to improve animal welfare.

Home Office

NON-TECHNICAL SUMMARY

123. Modulating immune responses in the eye to restore tissue health and preserve function

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	pregnant, adult, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To advance understanding of the mechanisms responsible for immune-mediated damage to the eye and to evaluate new treatment to prevent these and restore eye sight.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

For most people, sight is their most important sense and its loss, be it partial or complete, inevitably has profound detrimental consequences. The eye is susceptible to a number of disease conditions that can seriously damage a persons vision. In almost all of these, the underlying cause involves a misdirected inflammatory response that can permanently damage the specialised cells at the back of the eye that are responsible for vision.
The three most important diseases of the eye in the developed world are: 1) Age-related Macular Degeneration (AMD), which cause irreversible blindness due to the progressive loss of specialized cells from the macular region of the retina. 2) Diabetic retinopathy (DR), in which blindness is caused by the abnormal growth of blood vessels, and accumulation of blood and fluid in the macular. 3) Uveitis or intraocular inflammation, is an autoimmune or autoinflammatory condition in which the immune system attacks the eye, leading to damage to the retina.

Collectively these diseases account for over 75% of cases of blindness registrations in the UK. In addition to the personal hardship incurred by sufferers, these diseases impose a heavy financial cost upon the state. The annual direct cost to the NHS of treating these conditions is estimated to exceed £3 billion and the cost to the welfare state of supporting those affected is estimated to be £6 billion/annum. In the UK the prevalence of these diseases is currently rising as a result of an increasingly aged population, the high incidence of obesity (AMD & DR), and the increasing incidence of altered immune responses (Uveitis).
Current treatments for these three diseases is at best only partially effective and relapses occur commonly. Whilst it is clear that in all three, the underlying cause is the infiltration and activation of immune cells into the tissues of the eye, as yet, the factors responsible for initiating the process remain unclear. Consequently there is an urgent need to advance understanding of the molecular signals that initiate these diseases and the cell types which promote the damage. In so doing the proposed study aims to identify biomarkers for these diseases that could be used to enable their early detection and to identify more effective treatment strategies with which to restore the health and function of the eye.
In addition, this study will highlight molecular pathways and cellular interactions that are responsible for inflammation associated with a wide range of diseases, including important autoimmune conditions like osteoarthritis, type 1 diabetes, and multiple sclerosis.
What outputs do you think you will see at the end of this project?

New knowledge: The outlined work aims to advance understanding of the molecular pathways and genetic causes of intraocular inflammation in AMD, Diabetic Retinopathy and Uveitis. As a result of the outlined research, we expect to identify novel targets for therapeutic interventions, the development of biomarkers to detect disease susceptibility as well as disease progression, and identify new approaches that could be used to prevent the development of the disease state.
Publication: The finding of these studies will be presented at national and international meetings including the annual meeting of the Association for Research in Vision and Ophthalmology (ARVO) and published in high-impact peer reviewed journals such as the Journal of Pathology, Nature Medicine, PNAS and Science & Translational Medicine. We are also active in outreach initiatives to patient groups and lay members of the public, where we present and discuss our research findings.

Who or what will benefit from these outputs, and how?

The short-term benefits of the work will be advancing knowledge and understanding of the disease mechanisms that contribute to intraocular inflammation. This will contribute to the scientific development of the different researcher's projects within my group.
In the medium-term (over 2-5 years): the work is expected to benefit researchers working in the fields of ocular disease and inflammation as a result of the dissemination of our research findings through publication. In addition our finding will also be shared with the general public and patients through outreach groups.
In the longer-term (greater than 5 years): The work is expected to benefit medical specialists, working in the field of ophthalmology and patients through the development of more effective treatments for uveitis, diabetic retinopathy and AMD using novel approaches based in part on the understanding of the disease processes developed during this project.

How will you look to maximise the outputs of this work?

Collaborations: The output of the work will be maximised through collaborations with scientists working in other disciplines (engineering, mathematics) who can use data produced in our investigations to develop novel approaches to mathematical modelling and image processing.
Dissemination of research findings: The finding of the studies will be presented at national and international meetings including the annual meeting of the Association for Research in Vision and Ophthalmology (ARVO), and published in high-impact peer reviewed journals. We are also actively engaged with patient groups and lay members of the public, where we present and discuss our research findings.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice will be used as the least sentient of the species for which established models of the ocular diseases exist to undertake the proposed studies. In addition, mice are amenable to the genetic alterations needed to undertake the study. Adult mice will be used as the imaging techniques used to monitor the disease are easier to perform at this stage of development.

Typically, what will be done to an animal used in your project?

The purpose of the studies is to determine the role that inflammation within the eye plays in determining the outcome of three important diseases of the eye; namely, uveitis, age related macular degeneration and diabetic retinopathy. In so doing, we aim to identify interventions and treatments that could be used to minimise the associated sight loss.
A significant proportion of the mice used in these studies will be genetically altered, however these alterations are not expected to have any harmful effects. Most of the studies involve the initiation of the disease by either

injecting substances into the eye or damaging the retina by exposing it to a bright light or laser. All of these procedures will be performed under general anesthesia, so the mice do not experience any pain or discomfort and upon recovery from anesthesia behave completely normally.
The ocular disease induced is very mild and is not painful, and whilst the animals may experience a degree of sight loss this does not result in any alterations to their normal behaviour. For a small number of experiments, eye disease associated with diabetes will be initiated by injecting the animals with an inducing agent. Although diabetic mice urinate more than usual, they otherwise continue to behave normally.
Following disease induction, the eyes of mice will be examined (usually twice weekly), under general anesthesia, to monitor the progression of the disease. In addition, small blood samples from the tail may be collected (up to once weekly) to monitor their immune response. Some of the animals will be given treatments aimed at preventing or minimising the disease process, usually involving giving a drug by injection, but in a small number of animals (<2%) by the surgical implantation under general anesthesia of a miniature drug delivery device. At the end of the study the mice will be killed using a humane method.

What are the expected impacts and/or adverse effects for the animals during your project?

The disease models used in these studies are mild and, whilst they may cause some sight loss, they do not evoke pain or result in the animals deviating from normal behaviour. Furthermore, in the mouse, vision is a much less important sense than smell, hearing and whiskering. Most of the procedures are conducted under general anesthesia, as a consequence the animals will experience several anesthetics during the course of the study. The administration of agents used during the study will not cause more than mild transient pain. Some of the mice rendered diabetic may experience mild (<10%) weight loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Half of animals will only be used for breeding and will only experience the mild severity category. The remaining animals will be in experimental protocols and are in a moderate severity category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is difficult to advance understanding of the role that inflammation plays in conditions such as AMD, DR, Uveitis and retinal degeneration because patients do not present themselves until the condition is well developed. Furthermore, it would not be practical or ethical to subject patients to the invasive procedures needed to collect ocular tissue and fluid samples required for analysis or to subject them to untested treatments. It is also not possible to replicate the complexity of the eye or the disease processes that affect it and their associated immune response using either ex vivo, in vitro or in silico models. Consequently, there is no alternative to the use of animals for these studies.

Which non-animal alternatives did you consider for use in this project?

To reduce animal use, an on-going emphasis of our research is directed at developing *in vitro* assays to elucidate *in vivo* observations and test hypotheses. The use of immortalized cell lines and primary cells will be used to facilitate initial investigation into how cellular phenotype and signalling pathways are modulated and to validate appropriate drug targets prior to their use in animal models.
To determine whether a therapeutic treatment is likely to translate into man, we will also perform *ex vivo* studies on surplus tissue left over from human transplants.

Why were they not suitable?

Current *in vitro* models are not able to replicate the complex anatomy of the eye or the pathological and inflammatory process that occur during disease. Nor are they suitable for studying how the disease develops through time, which is a crucial aspect of the chronic eye disease that are the focus of this research.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals needed to generate the genetically altered (GA) mice needed for the study is estimated at 500 animals per year. This figure is based on the number required to maintain the different transgenic lines and supply the GA required for experiments.
Experimental usage (across both disease protocols) is estimated at 500 per year. This number is based upon the scientific objectives of current grant funded projects, and equates to 10 experiments (each with 3 replicates). In estimating group sizes for the studies we have undertaken extensive analysis of data from previous experiments and performed power calculations using statistical packages.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Online tools were consulted but by and large they assume the use of parametric statistics, which are inappropriate for clinical assessment of the models of ocular inflammation and assessment by cell counting. We therefore used statistical packages that allowed us to estimate sample sizes. For models of AMD, we have and will continue to use the Experimental Design Assistant (EDA) from NC3R to design our experiments.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use efficient breeding and can allocate both males and females to specific disease models based on susceptibility to induction. Tissue sharing is encouraged where possible between group members, occurring on an ad hoc basis.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal models that replicate three important disease conditions of the eye (uveitis, age related macular degeneration and diabetic retinopathy) will be used. The study is reliant on the use of genetically altered animals, although the alterations used have no adverse effects on the animals. Care has been taken to select animal models that induce only mild disease and are none painful, and for which the associated loss of sight does not impair the animal's ability to perform its normal behaviour. The monitoring and assessment of the disease state will be undertaken using non-invasive imaging methods conducted under general anesthesia and consequently involves only minimal distress for the animal. The delivery of agents or collection of blood samples will be undertaken using well established techniques that causes no more than mild transient pain and no lasting harm.

Why can't you use animals that are less sentient?

Mice are the least sentient of the animal species that have eyes that are anatomically similar to humans and for which established disease models for the three diseases under investigation exist.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We continue to refine our methods for the induction and monitoring of ocular disease e.g. during the course of our previous studies we have advanced our anesthetic procedures to enable imaging to be conducted under gaseous anesthesia thereby avoiding the need to inject mice.
Within the research group, unsupervised algorithm and machine-learning based approaches are being actively explored to allow us to analyse and predict disease progression over time, develop more sensitive measures of treatment efficacy and correlate approaches to better quantify immune-mediated tissue changes.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We participate actively in 3Rs seminars, presenting our approaches and learning from others.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through continuing education including attending and contributing to 3Rs focused seminars and lectures.
Engagement with regional NC3Rs programme manager and Animal Services Unit.

Home Office

NON-TECHNICAL SUMMARY

124. Modulating Radiosensitivity in Tumour and Normal Tissues

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Tumour microenvironment, Radiosensitisers, Tumour hypoxia, DNA repair

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to improve the efficacy of radiotherapy given to cancer patients without exacerbating the side effects by using novel compounds that enhance the therapeutic response to radiation, named radiosensitisers.
Therefore, this project is mainly focused upon the interactions between radiation therapy and the tumour microenvironment, with an emphasis on the DNA damage response. We are asking whether manipulation of the tumour microenvironment can improve tumour response to radiation, whether alone or in combination with established chemotherapeutic and immunotherapeutic agents.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Although radiotherapy is frequently given to cancer patients with curative intent, there are many situations in which the outcomes remain very poor. For example, patients with locally advanced nonsmall cell lung cancer typically only have about a 15% chance of surviving 5 years despite receiving high dose radiotherapy with concurrent chemotherapy. In addition, radiotherapy can be associated with significant side-effects as a result of damage caused to adjacent healthy tissues which surround the tumour. Therefore, there is an unmet clinical need towards improving outcomes from radiotherapy. The aim of my research is to develop drug treatments which can enhance the effects of radiotherapy on tumour cells without increasing the side-effects of treatment. I anticipate that obtaining this increased understanding of the response of tumours to radiation will lead me being able to translate these pre-clinical findings into clinical studies with the ultimate aim that they will become established therapies for cancer patients.

What outputs do you think you will see at the end of this project?

We will identify the potential of several novel compounds to be clinically effective radiation sensitisers. We will have a greater understanding of the toxicity and efficacy of combining these treatments with radiotherapy. I have previously been able to translate my pre-clinical findings into clinical studies. Based on the *in vitro* data we have obtained with these compounds to date, I am optimistic that these drugs have clear potential to be effective radiation sensitisers.
We will also establish whether these drugs have exerted a synergistic anti-cancer effect, without damaging the surrounding normal tissue, when combined with other treatments such as chemotherapy and immunotherapy. If this work produces promising results, we would anticipate further clinical trials with these novel combinations. We will also aim to understand the mechanisms involved in the tumour response, to potentially open new therapeutic avenues.
The results of the proposed *in vivo* pre-clinical studies will be made available to the scientific community through presentations at National and International Conferences, and publications in peer reviewed journals. Where applicable, the results will also be made available through publicly accessible databases, and the outcomes of this project will be highlighted through the relevant funding bodies.

Who or what will benefit from these outputs, and how?

Although I hope that this work will broaden scientific understanding via conference presentations and publications in peer-reviewed journals, my ultimate aim is to develop effective therapies that are of clinical benefit to cancer patients. The tangible demonstration of this will be whether we can undertake clinical trials with

the most promising compounds that we are studying.

How will you look to maximise the outputs of this work?

We have collaborated with pharma companies as well as the Department of Chemistry in relation to development of the compounds that we will be testing. We have presented our data to scientific and clinical conferences and other meetings. We have also published our data in respected journals such as Nature Communications, Clinical Cancer Research and Science. We will continue to do so in the upcoming work under this licence.
The results of this work will initially be presented to the scientific community through National/International meetings, and appropriate funds have been requested to enable this. The meetings will be carefully selected and will include both smaller specialised conferences, as well as larger international meetings in order to reach both basic research and clinical research audiences. The data will subsequently be published in high-impact journals with relevant open access provision.
We will highlight our findings on relevant departmental websites and where appropriate, our research will be communicated in the form of a press release linked to publication of a journal article. We will utilise social media such as twitter to publicise our findings widely and encourage post-peer review comment on our work.

Species and numbers of animals expected to be used

- Mice: We expect to use up to 4,500 mice over 5 years

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse represents a feasible model to test our hypotheses, since multiple reagents, such as antibodies, are readily available, and since the current knowledge on cancer models and responses to therapies is also broadly available. Adult mice, in particular, will be used in this project licence.
With this project, we aim to gain understanding on the tumour response to different therapeutic strategies, including chemotherapy (established substances), radiotherapy, immunotherapy and novel compounds that will be tested under this licence; whether alone or in combination with one or more of the therapeutic strategies named above. The overall goal of the licence is to identify new therapeutic tools that will improve the tumour response to radiotherapy, namely radiosensitisers.
It is therefore, necessary to perform this work in a living organism, given the interplay of the different components that might be responsible for the tumour response, whether within the tumour or belonging to the tumour microenvironment.

Furthermore, we are interested in examining the response of the normal (non-tumoural) tissue to the given therapies, as this would be necessary to validate the suitability of the therapeutic strategy with the aim of bringing these advances to the clinical scenario.

Typically, what will be done to an animal used in your project?

In brief, we will induce tumours in our experimental animals and apply different therapeutic strategies to analyse the tumour response to the treatment. We will also analyse the impact of these therapies in healthy tissue, to validate the suitability of the candidate strategy in a clinical setting.

We will test novel compounds, never administered before to experimental mice. We will first test the safety of such compounds in a dose setting protocol, and determine an appropriate dosing regime in a pharmacokinetics and biodistribution protocol. Typically, experiments of tolerability will extend for a week (single dose, acute toxicity) or for a few weeks (repeated doses, chronic toxicity). A similar scenario is contemplated for experiments of pharmacokinetics.
Our tumour models will be optimised in a tumourigenicity protocol, where tumour cell types, numbers, use of Matrigel and experimental conditions for tumour implantation will be tested and determined based on the scientific needs. The particular involvement of certain genes in tumour formation and tumour response will also be tested under this protocol.
We will use superficial models of cancer, in which tumour cells are subcutaneously implanted in the experimental animal, usually on the flank or the back, under brief recovery anaesthesia. This is the least invasive method to generate tumours to study tumour response to radiation, since only the tumour will receive the radiation, with the rest of the body protected by appropriate shielding, therefore avoiding the involvement of adjacent normal tissue; and because the superficial tumours will not generally interfere with the correct function of internal organs. Tumours will be grown for the minimum time and volume that are needed to deliver the scientific outcome. Tumours will be measured regularly with callipers, a 3D scanner or more advanced imaging modalities (these to be performed under anaesthesia, and on occasions involving the injection of suitable contrast agents). Once the tumour reaches a certain size, different compounds will be administered to the experimental animals. The preferred route would be oral gavage, as considered more refined for the animal. Radiation, in any of the platforms routinely used in our facility will also be applied to the tumours, locally, to assess the tumour response in combination with other therapies.
A particular focus of attention in this licence is the role of the immune system in the tumour response to different therapies. Some experiments designed to fulfil this goal will include implantation of two subcutaneous tumours in the experimental animals. Only one tumour will be treated, with the second tumour being used to test the systemic effect of the treatment given, in particular effects on T-cell responses. This is named the abscopal effect. In another set of experiments to test the role of the immune system in the tumour response, we will aim to test that a successful therapy, manifested by tumour regression, is durable or specific to a cell line. With this aim, we will implant a second or third tumour (once the first tumour has fully regressed) and observe if the tumour growth is impaired. These are the experiments of tumour rechallenge. Finally, to test the role of a particular subset of immune cells, we will be obtaining these from donor mice and introducing them into recipient mice to analyse the tumour response to such intervention, whether in combination with other therapeutic strategies or not. These are the experiments of adoptive transfer. All these experiments represent very interesting scenarios for the clinical set-up and are described in more detail in the section of ‘Action Plan’.
These types of experiments, which are mostly focused on tumour response to the different treatments, are anticipated to extend for eight weeks, approximately. In some cases, experiments of tumour rechallenge upon tumour regression will be performed, and these will typically be completed within six months.
Experiments of normal tissue response are completed within 3-5 days, for irradiation of the abdomen, or within 4 months, for irradiation of the thorax.

What are the expected impacts and/or adverse effects for the animals during your project?

The main adverse effects that the experimental animals would experience under this licence are due to: -

Tumour growth (ulcerations, intramuscular growth, difficulty to eat, pain, body weight loss).

- Administration of substances, some of which might not have been previously tested *in vivo* (toxicity, whether acute or chronic: diarrhoea, dehydration, pain, body weight loss or behavioural changes, choking or cyanosis due to technical error in gavage administrations).

- Radiation, whether applied locally to superficial tumours (skin irritation, ulceration, body weight loss, behavioural changes, pain) or to the normal tissue (gastrointestinal and pulmonary toxicities: abdominal distension, hunched posture, diarrhoea, piloerection; increased or abnormal respiration rate).

- Modified diet (fat enriched): greasy coats, skin irritation due to scratching.

Some interventions will be performed under anaesthesia with the consequent risk of failure to recover. This is particularly relevant for the imaging techniques that some experimental animals will undergo, and which will typically last 45 minutes. Best practice for anaesthesia in small rodents will be applied, and therefore we expect all animals to make a rapid and unremarkable recovery from the anaesthetic.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is anticipated that approximately 20% of subject animals will experience moderate severity, with the balance experiencing severity no greater than mild.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Ultimately, we aim to develop radio sensitising treatments which can be combined with radiotherapy to increase the number of patients who can be cured of their cancer without exacerbating side-effects of therapy. For this, we need to gain understanding on the tumour response to different therapeutic strategies, including immuno-, chemo- and radiotherapy with our novel compounds alone or in combination. It is therefore necessary to perform this work in a living organism to understand the interplay between the different components that might be responsible for the tumour response for that particular treatment, whether within the tumour cells or their microenvironment.

Which non-animal alternatives did you consider for use in this project?

As a non-animal alternative, we extensively work with 2D monolayers and 3D spheroids cell cultures. With these models, we determine the most suitable candidate compounds to be further evaluated *in vivo*. Spheroid models recapitulate some features of solid tumours, like the gradients of oxygen and nutrients and, therefore, are a viable alternative to animal models in the context of, metabolism and hypoxia research, for example. In our lab, the use of these models enables us to select a narrower range of candidate compounds for *in vivo* evaluation and considerably reduce the number of experimental animals.

Why were they not suitable?

Any 2D or 3D cell culture models used to analyse the compounds or combination of compounds, have great potential for clinical translation. However, it is necessary to undertake some animal studies with these compounds in order to understand fundamental processes such as bioavailability, distribution, pharmacokinetics and metabolism that underpin cancer within living organisms and which cannot be satisfactorily undertaken *in vitro*. Moreover, we are interested in the role of the tumour microenvironment; such as hypoxia, vasculature or immune response, during cancer treatment, which can almost exclusively be studied in the whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our estimations are based on our previous knowledge on the variability of the outcomes of interest, for the specific animal models used in our lab.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use a variety of strategies to ensure that the minimum number of mice necessary to achieve the scientific objectives is used in each experiment. We have implemented the NC3Rs experimental design guidelines to design our experiments, for example by ensuring randomization and blinding to avoid bias and increase reproducibility. We use data from pilot experiments in power analysis and statistics-based guidance for future experiments. For example, we determined the effect size from our previous experiments using the mean time to reach a specified tumour size as endpoint. This effect size was then used to calculate the sample size required in our proposed experiment to allow robust comparison between groups. This gave us the overall number of animals included in this project licence.
In order to minimise variables and ensure reproducibility we apply a sturdy methodology in our lab, including the implementation of SOPs for numerous procedures, for example tumour cell culture, preparation and injection, preparation of compounds and vehicles, and their administration to experimental animals, tumour measurement or irradiation procedures, to cite some.

Robust methodology also includes the use of appropriate controls in each experiment, so that conclusions are sound. Each experimental group will differ in only one variable with respect to the correspondent control group, so any differences would be attributable to such variable.
Housing of experimental animals also plays an important role in experimental variability. With this in mind, housing and handling of animals will be to standards that minimise variability. Introduction of microorganisms that could potentially interfere with the results obtained in our experiments will be minimised by the use of individually ventilated cages, the use of appropriate PPE and the implementation of best standard practices for working with immunodeficient animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

New experimental variables to be introduced will generally first be tested in pilot experiments including a reduced number of experimental animals. For example, combination treatments of a novel compound and a well-known compound (such as a common chemotherapeutic agent) will be first tested in a pilot experiment. This will enable us to further investigate the tumour response and determine the schedule/dosing regimes for radiation, chemo- or immunotherapy of a given tumour model with a reduced number of animals. In turn, this will provide the data necessary for the power calculations, to determine the effect size and the minimum number of animals required to achieve a statistically significant result.

During pilot studies, we will obtain data such as tumour growth rate and kinetics, compound levels in blood and other physiological parameters. At the end of the procedure, various tissues and blood will be collected to investigate and optimise protocols for *ex vivo* studies such as immune profiling by FACS or immunofluorescence analyses by microscopy. All these findings will contribute to unveil some of the mechanisms of action of the candidate radiosensitisers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used, as they are the best characterised species for the types of experiments that we propose in this project licence. Furthermore, an array of reagents, including antibodies, are available for this species.
The basic method will be inducing a tumour by injection of tumour cells subcutaneously on the flank or back, as xenograft or allograft tumours. For xenograft studies, immunodeficient mouse strains will typically be used, with naturally occurring or genetically engineered mutations. For allograft models, immunocompetent mouse strains will typically be used in this project. This method of inducing tumours is considered to be more refined, as the animal welfare is not greatly compromised, since it spares normal organs, as compared with other methods (for example, orthotopic or spontaneous tumour models). In some cases, where there is more than one tumour inoculated, the total tumour volume limit for a single tumour will be applied for the combination of both tumours, to minimise suffering due to tumour burden on both sides. We will ensure that the tumour cells we use are optimised for the formation of tumours in the particular strain, for example, tumour cell number, use of Matrigel, tumour characteristics like vasculature or necrosis, with experiments performed under the protocol of tumourigenicity, which will employ a small number of animals.
Tumours will be regularly measured by callipers or a 3D scanner. The 3D scanner provides more accurate measurement and can be done faster by simply restraining the animals and presenting it to the scanner. This will also reduce the time of handling compared to the use of callipers. In some experiments, imaging procedures will be performed to gain more detailed information of tumour growth and physiology. These will be carried out under anaesthesia with appropriate contrast agent when necessary.
Radiation of a subcutaneous tumour is technically much easier in mice because irradiation can easily be delivered without the involvement of adjacent tissues by protecting the rest of the body with appropriate shielding. Radiation is performed under recovery anaesthesia.
To minimise the adverse effects of any novel compounds administered, these will be first tested under dose setting studies to identify the non-toxic doses and routes of administration. Once it’s proven safe, the pharmacokinetics and biodistribution properties will be assessed, and a multiple dosing regime will be tested again in the dose setting protocol. In this way the toxicities should be greatly reduced when these compounds are administered to the mice that we employ in tumour response studies or normal tissue response.

Why can’t you use animals that are less sentient?

Mice are the most commonly used species for the types of studies we are proposing in this project. Mouse models have been extensively used in the development of a wide range of chemotherapies and immunotherapies alone, and in combination with radiotherapy. They are classified as the lowest order species in which we can study tumour growth and adaptive immunity in a way relevant to humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For each step in the protocols we have introduced monitoring and controlling measures to minimise the harms for each animal used in this licence. Some of the most significant ones are specified below:
Tumour induction and growth: Tumour induction will be performed under brief recovery anaesthesia, which will facilitate precise positioning of the tumour to minimise the risk of tumour invading the underlying muscle. In the case where a mouse needs two tumour implantations, these will be performed under the same anaesthesia session. Tumour cells will first be tested under the protocol of tumourigenicity to optimise the conditions of tumour formation. Thus, only tumour models that are appropriate will be employed in subsequent experiments performed under other protocols. Tumours will be grown for the minimum volume scientifically needed. Some tumours may develop into an ulcer, which will be monitored for signs of healing for 48 hours and animals will be killed by a Schedule 1 if there is no improvement.
Administration of substances: Before we administer any novel compound that never been administered to experimental mice before, we will prove that the compounds are safe in the dose setting and that the pharmacokinetics and biodistribution properties are also satisfactory. We will use a small number of mice in these experiments. To minimise the adverse effects in experiments performed under the dose setting protocol, we will check the mice immediately after dosing and every 2 hours during the working day, and then daily throughout the treatment period. Mice will be killed by a Schedule 1 method if they lose 15% of body weight and or if any clinical sign would develop (such as changes in behaviour, laboured breathing, hyperactivity, abnormal gait, hunched posture, distended abdomen, diarrhoea). Only substances, administration routes and formulations that are shown not to

cause adverse effects will be used for tumour response experiments and for normal tissue response experiments. Oral gavage will be used whenever possible, as considered more refined than other, more invasive, routes involving injections. For some compounds, it is known that the bioavailability can be increased by increasing the fat content in the diet, which in turn would lower the number of doses of compound to be administered and the amount of compound given at each dose.
Radiation: Radiation will be applied locally to the superficial tumour, under anaesthesia. Damage to non-target tissues is minimised by the use of lead shielding or focussed radiation (including imaging) and precise positioning under anaesthesia. We will explore different irradiation platforms available within facility and apply the most refined whenever possible.
Irradiation of the thorax and abdomen to a maximum dose of 15Gy is not expected to cause any considerable adverse effects if the mice are killed within 4 months of the treatment for lung irradiation and 3-5 days for abdominal irradiation. Normal tissue response will be assessed by imaging and by post-mortem histology.

As a general measure, we will continuously revise our methodology and adapt it according to new policies, technologies and approaches aimed at minimising welfare costs. To achieve this, we will attend the seminars provided by the NC3Rs, keep up to date with NC3Rs recommendations via its website and communicate with local Regional Programme manager for advice to improve the 3Rs in our experiments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure that experiments are performed under in most refined conditions, we will follow guidelines of best practice based on:

- 'Guidelines for the welfare and use of animals in cancer research' (British Journal of Cancer, 102, 1555-1577, 2010);
- 'Preclinical formulations for discovery and toxicology: physicochemical challenges' (Expert Opin. Drug Metab. Toxicol. 2, 715-731, 2006) for administration of substances;
- 'The Design of Animal Experiments (Reducing the use of animals in research through better experimental design)', Edited by: Michael Festing - University of London, London, UK; Philip Overend - GlaxoSmithKline, UK; Mario Cortina Borja - University College London, UK; Manuel Berdoy - University of Oxford, UK;
- 'Handbook of Laboratory Animal Management and Welfare', Sarah Wolfensohn - BSc, MA, VetMB, Cert LAS, CBiol, FIBiol, Dip ECLAM, MRCVS, Head of Department, Veterinary Services, University of Oxford; and Maggie Lloyd - MA, VetMB, CertLAS, DipHE, MRCVS, Home Office and for guidance from NC3Rs and the University of Oxford 3R's Subcommittee, through their termly newsletters.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

To expand our knowledge on advances in the 3Rs, we will keep up to date with 3Rs newsletters. We will also attend the seminars provided by NC3Rs, keep up to date with NC3Rs recommendations via its website and seek advice to improve the 3Rs in our experiments.

Home Office

NON-TECHNICAL SUMMARY

125. Molecular analysis of key signalling pathways regulating inflammation and innate immunity

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

inflammation, innate immune response, inflammatory signalling pathway, autoimmune/inflammatory disease, infectious disease

Animal types	Life stages
Mice	adult, embryo, pregnant, juvenile, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to increase our understanding of the role of specific intracellular signalling pathways (i.e. biochemical interactions within cells) in controlling innate (inborn) immune responses to pathogen infection and their contribution to specific autoimmune/inflammatory diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work has the potential to identify novel drug targets for the therapy of specific autoimmune/inflammatory and bacterial diseases.

What outputs do you think you will see at the end of this project?

This programme will lead to publications in high impact peer-reviewed journals, of which my laboratory has a good track record. The research will provide important insights into the role of specific signalling pathways in the regulation of immune responses against infections and in pathological immune responses resulting in autoimmunity/chronic inflammation.

REGULATION OF PHAGOSOME MATURATION

Our research is likely to be of broad interest not only to those working on signalling in innate immunity, but also to academic scientists working on infectious diseases and clinical scientists interested in the transfer of basic research on chronic bacterial infections and inflammation to the clinic.

Information gained from our research will be of benefit to academic scientists working across the fields of cell signalling, immunology, cell biology and cancer. The proposed studies on the complex processes involved will also be of considerable interest to researchers working on infectious diseases. In the longer term, this research will inform new methods of targeting the complex in disease.

REGULATION OF PSORIASIS

Genetic studies link our signalling protein of interest to the development of psoriasis. The proposed work will increase our understanding of how this signalling protein induces psoriasis.

The protein is member of a family of related proteins which play important roles in activating other proteins involved in immune responses, autoimmunity and cancer. Some aspects of our work are likely to be of considerable interest to academic researchers investigating how signalling is controlled in immune responses and made dysfunctional in autoimmunity and cancer.

In the short-term, this research will lead to new collaborations with UK-based and international scientists investigating the role of substances involved in the body’s response to other diseases involving these proteins. In the longer term, the research may identify new potential ways of treating psoriasis and be of interest to pharmaceutical companies developing new treatment approaches.

Who or what will benefit from these outputs, and how?

REGULATION OF PHAGOSOME MATURATION

The Programme of Research in this application will determine the role of a specific immune signalling complex in regulating phagosome maturation and immune responses to pathogenic bacteria. This is likely to be of broad interest not only to those working on signalling in innate immunity, but also to academic scientists working on infectious diseases and clinical scientists interested in the transfer of basic research on chronic bacterial infections and inflammation to the clinic.
This research will provide important new information about the functions of the signalling complex in innate immunity and inflammation. This information will be of benefit to academic scientists working across the fields of cell signalling, immunology, cell biology and cancer. The proposed studies on this complex regulation of phagocytosis will also be of considerable interest to researchers working on infectious diseases. In the longer term, this research will inform novel applications of targeting the complex in disease.
REGULATION OF PSORIASIS

Genetic studies link our signalling protein of interest to the development of psoriasis, a chronic autoimmune disease affecting the skin which affects 2-3% of the population. This Project will use biochemical analyses of cultured keratinocytes to determine the molecular mechanism by which this psoriasis-associated protein induces gene expression to promote skin inflammation, identifying key regulators and effectors. The proposed work will increase our understanding of how the psoriasis associated signalling protein induces psoriasis.
The psoriasis-associated protein is member of family of related proteins play important roles in activating NF-κB transcription factors (proteins that switch on the nuclear expression of target genes) in immune responses, autoimmunity and cancer. It is likely that some of the novel regulators identified in this project will also control NF-κB activation by related proteins as well as the psoriasis-associated protein my laboratory researches. Consequently, this project is likely to be of considerable interest to academic researchers investigating how NF-κB signalling is controlled in immune responses and dysregulated in autoimmunity and cancer.
In the short-term, this research will lead to new collaborations with UK-based and international scientists to investigate the role of identified regulators and effectors in other diseases involving these proteins. In the longer term, the research may identify new potential therapeutic targets to modulate its signalling in psoriasis and be of interest to pharmaceutical companies developing new approaches to treat this serious autoimmune disease.

How will you look to maximise the outputs of this work?

Outcomes of our research will be communicated to the academic community by the established routes of peer reviewed publications and presentation at meetings. The principal investigator will present at other academic departments in the UK and abroad, and also attend national/international meetings.
Our work on psoriasis will be communicated to patients via the Psoriasis Association (UK) and the National Psoriasis Foundation (USA) as part of my laboratory's public engagement programme.
Publication of completed studies will be made in journals that adhere to the RC open access policy that ensures immediate access to the published study (Gold) or within no more than six months of publication by depositing in a freely accessible repository (Green).
Our biochemical studies may suggest new ways of controlling the innate immune responses to bacteria or to reduce inflammation in psoriasis.

Species and numbers of animals expected to be used

- Mice: 10,900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Justification of Species

Genetic manipulation in mice is well established and one of the most powerful means of testing functions and interactions of genes in a live organism. Mice have a relatively short generation time; its blood production system has been extensively studied and, in addition to the accumulated knowledge, there exists a vast array of reagents that facilitate the studies to a level unknown for many other organisms. No other species of lesser sentience can fulfil the requirements of this project to the same extent as the mouse.

Innate immune signalling in bacterial infection

My laboratory studies the function of two key signalling molecules that are physically associated with one another in a complex. We will use adult mice with fully developed immune systems containing knock-in mutations in which the signalling functions of these proteins are separately blocked by introduction of point mutations. These reagents will allow us to investigate the specific functions of these signalling proteins in innate immune responses to bacteria.

Inflammatory signalling in psoriasis

Recent biochemical and genetic experiments by my laboratory using a human skin cell line have identified a number of novel proteins that control the function of a key signalling protein that is mutated in rare families and induces psoriasis, a chronic autoinflammatory disease of the skin. To establish the physiological significance of these *in vitro* results, we have generated a genetically modified mouse strain which express the mouse equivalent of the psoriasis-associated signalling protein following injection with a specific compound called tamoxifen. Tamoxifen injection of these mice induces skin inflammation 4-5 days later, which has many similarities with psoriatic skin in humans. The functions of the novel regulatory proteins in controlling the signalling function of psoriasis-associated protein will be investigated using our novel mouse model of psoriasis.

Typically, what will be done to an animal used in your project?

Regulation of innate immune responses

My laboratory investigates the function of two signalling proteins that associate with one another in a complex and are critical in innate immune responses. Genetically-modified animals produced to investigate the roles of the signalling proteins we will study are not expected to show any pain, distress, suffering or lasting harm . As such modifications may alter the immune status, animals will be maintained in a barrier environment to minimise the likelihood of compromised health.

Animals bred for our research are not expected (<5%) to experience moderate harm. As it is not possible to fully predict the nature or severity of any potential defect, possible side effects will be closely monitored. We will monitor characteristics of normal mice and collate information on databases to ensure that any mice produced specifically for our work do not show any characteristics not seen in a normal mouse. Animals showing unexpected harmful types will be humanely killed, or in the case of individual animals of particular scientific interest, advice will be sought from the local Home Office Inspector. Where possible, methods will be modified to reduce suffering (e.g. administration of antibiotics after irradiation, and pain relief pre/post-surgical procedure). In disease modelling experiments, the severity of procedures will be limited by ensuring that animals are killed as soon as overt signs of disease are manifested, with rigorous monitoring for signs of suffering / distress at all times.

A small minority of mice will undergo up to four pre-treatment steps, although the majority will undergo either

none, one or two of these steps in addition to an ‘immunological challenge’. The challenge can consist of substances involved in the immune response, inactivated or live microorganisms or their components which are not expected to cause noticeable clinical symptoms. Substances, including infectious pathogens, may be administered by more than one route.
Monitoring of the immune response may involve withdrawal of blood from a superficial blood vessel, or introduction of substances which can be tracked in the body because they glow under special light.
Levels of stress can affect such assessments and everything will be done to reduce stress levels.

Bacterial infection experiments

Normal and genetically modified mice will be dosed with bacteria either through the mouth, nose, skin or blood system depending on the bacterial species and type of infection investigated. The duration of experiments will be kept to a minimum (maximum 14 days). Disease progression will be assessed by looking for changes relevant to each bacterial species. Mice will be humanely killed. In some instances, we will administer genetically-modified micro-organisms to mice to maximise data and to monitor the course of infection and potential spread to different organs.

Signalling in skin inflammation

Genetically modified mice will be injected with Tamoxifen which induces the production of a protein known to cause psoriasis in humans. Five days after injection, inflammation in ears is clearly visible by laboratory analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Immunological challenge

No adverse effects are expected from these treatments. In some cases administration of pathogen derived products may cause transient inflammation in a proportion (<5%) of genetically-altered animals. These will manifest as partial piloerection (raised fur), hunched posture and subdued behaviour.

Bacterial infection

Airway infection: Most lower airway infections will be short-term (1 week or less). Infection may, in some instances spread throughout the body. Gastrointestinal infection: Most GI infections are mild or with no symptoms and rarely spread in the body. Systemic infection: These infections can cause moderate symptoms quickly and experiments will rarely go beyond a few days in duration. Some animals will occasionally develop mild to moderate symptoms, consisting of reduced activity, piloerection, hunched posture and rapid breathing. During infection animals will be checked at least once a day. It will be rare to continue an experiment beyond 7 days. Endpoints: If animals display one of the signs agreed with the NACWOs and NVS prior to starting the study they will be monitored for 24 hours and advice sought from the NVS/NACWO. If there is no improvement in this time they will be humanely killed. Animals will be weighed at least twice a week if visible symptoms are not expected and weighed daily for infections showing symptoms. For any procedure with no prior data/information, animals will be weighed daily.

Induction of inflammation and/or autoimmunity

The majority of the mutant mouse strains under this programme do not spontaneously develop inflammation and/or autoimmunity. However, the probability of adverse effects is much higher (up to 50%) for mice in which inflammation and/or autoimmunity will be induced deliberately. All methods we use to explore control of the immune system are associated with the following risks and possible adverse effects:
Mice may develop autoimmune / inflammatory diseases (e.g. inflammatory bowel disease), wasting disease or other forms of inflammation (e.g. psoriasis). Humane end points will be taken into account for such conditions.
Wasting will initially be assessed by monitoring changes in growth rate followed by close monitoring of actual loss

of body weight and looking for clinical signs. As soon as 20% of body weight is lost, mice will be humanely killed.

Symptoms of chronic inflammatory bowel disease are diarrhoea, perianal ulceration, intestinal bleeding, occasional rectal prolapse and wasting. If wasting precedes the other symptoms, mice will be humanely killed as soon as 20% of body weight is lost. Alternatively, mice will be humanely killed if symptoms are seen.
Where we investigate the induction of skin inflammation, mice are expected to remain at the mild severity limit for the duration of the experiment. They are expected to display visible scaling of the trunk, ears and tail at day 10-15, by one month scaling is only detected in the ears.
Skin thickening will occur in some animals with only the ears remaining affected at the end of the study.
Mice will be monitored to ensure that any animal showing symptoms exceeding moderate severity for more than 24 hours will be humanely killed.
Whole body irradiation

All mice will be maintained in a barrier environment, to prevent adverse effects on the health of the animal as a result of treatment. The minimum radiation dose will be used. The gut lining may be damaged by radiation which may lead to weight loss and gut inflammation. Microorganisms may enter the circulation, which can result in blood poisoning. To avoid bacterial infections, mice will be given an antibiotic in their drinking water.
Irradiation is expected to result in no more than transient discomfort. However, some mice may develop colitis and such mice will be monitored for signs related to colitis. Mice will be humanely killed if they approach a loss of 20% of their initial bodyweight or have persistent (>24h) diarrhoea or bloating, or prolapsed rectum.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

80% of animals used are expected to exhibit mild clinical signs, with less than 20% displaying moderate severity symptoms.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Studies in cultured immune cells in the laboratory can provide significant information. However, understanding of the role of specific signalling pathways in the regulation of immune responses to pathogen infection and in autoimmune / inflammatory diseases requires the use of living animals.

Which non-animal alternatives did you consider for use in this project?

To investigate how signalling pathways regulate the function of immune cells, my laboratory has initially used

cultured cell lines and primary cells from wild type and mutant mouse strains. These experiments have enabled us to identify critical steps in specific signalling pathways and define mutations that disrupt the function of key component signalling proteins. These studies have allowed us to define a limited set of theories that merit testing in animal models.

Why were they not suitable?

In an immune response, multiple cell types interact with each other and with other cells of the body, and orchestrate a complex series of events culminating in the elimination of the pathogen. Similarly, abnormal activation of the immune system in autoimmune or allergic diseases involves a complex interplay between multiple different cell types. The complex interactions between components of the innate and adaptive immune system with surrounding tissues and organs require whole body model systems as cell culture systems cannot adequately mimic the complexity of tissue interactions that shape immune responses. The mouse is the most appropriate species for these studies because, as a mammal, its immune system is very similar to that of humans, and because of the extensive genetic modification technology that is available for the mouse, and the wealth of pre-existing data and methodology will maximise the net benefit from these studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animals have been estimated based on current planned experiments to address key questions. It is expected that each experimental type will need to be carried out three times with group sizes of 5-7 per condition to generate statistically significant data.
To maximise animal usage for one of our projects, male mice will be used as a source of cells for laboratory analyses and animal experiments will be carried out using female mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As much preliminary work as possible was carried out in the laboratory on established cell lines to reduce the number of theories that require testing in animals.
For most of the quantitative experiments, design will be based on ARRIVE guidelines and sample sizes may be set using statistical analysis. Otherwise we will use the minimum number of animals to provide an adequate description, generally on the basis of previous experience (our own or from the literature). Pilot experiments will use between 5-8 mice per group, which should be sufficient if a significant result is obtained. The experiment will be repeated to obtain further data if: (a) there are only small differences; in this case it may have to be repeated with larger numbers of mice and/or modifications; (b) does not work; in this case it would be repeated testing other candidate molecules/modulators.
Each experiment (including the pilot ones) will include a small group of animals that are susceptible to infection with the respective pathogen and develop a well-defined course of disease in response to a given dose of

pathogen. This group will serve as an internal control for the experiments involving infections, allowing comparison of results from different experiments (performed at different times, with different doses and/or batches of pathogens etc.). This group will also provide the quality assurance for the virulence of the inocula, which is necessary for comparison of results across experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mouse experiments will use inbred strains housed under identical conditions to minimise experimental variability. The basic principles of mouse breeding will be adhered to and gestation times, weaning age and litter sizes used to calculate the numbers of mice required to optimise the of the colony.
We will make optimal use of several tissues, fluids and cell types per individual mouse. The highly integrative approach will maximise the information obtained from minimal resources.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To achieve the objectives in this programme, we propose to use the laboratory mouse as the model organism. The mouse is the best characterised model for these studies, with many features applicable to human infection and autoimmune/inflammatory diseases. Their immune responses are well defined and the technology enabling sophisticated manipulations of the blood production and immune system is highly developed. Genetic techniques in mice are well established; mice have a relatively short generation time; its blood production system has been extensively studied and, in addition to the accumulated knowledge, there exists a vast array of reagents that facilitate the studies to a level unknown for many other organisms.
Animals produced under the breeding protocol are not expected (<5%) to exhibit a moderate outcome. However, we will employ careful monitoring for possible side effects.

Why can’t you use animals that are less sentient?

To our knowledge, no other species of lesser sentience can fulfil the requirements of this programme to the same extent as the laboratory mouse.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The severity of procedures will be limited by ensuring that animals are killed as soon as overt signs of the disease can be seen. Most of our procedures are of mild severity, with a minority of animals expected to reach moderate severity.
Where possible, methods will be modified to reduce suffering (e.g. administration of antibiotics after irradiation, and analgesia pre/postsurgical procedure).
Although the pathogens we propose to use in these studies have been studied in mice for a long time and are well understood, new strains of mice and immune modulation regimens will also be tested. This will be first carried out in pilot studies involving a small number of mice.
New strains or batches of pathogens will be tested in pilot studies on small groups of mice which will be carefully monitored for onset of clinical symptoms. This information will be used to adjust the inoculum to a standard level of virulence. It is usual that large batches of inocula are made, tested and frozen in small amounts ready for use at one time, with enough to last around 2-5 years in order that this procedure can be minimised.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

FELASA ‘Working Group on Pain and Distress’, EC ‘Endorsed Severity Assessment’ and NCRI guidelines will be followed and used to determine the earliest endpoint possible on an experiment by experiment basis to allow a valid scientific outcome.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will constantly review our protocols and experimental design to reduce, refine and replace the use of animals.
Frequent meetings are held at our institution on the advances in the 3Rs and their implementation. All staff working under this licence will attend these meetings and frequent advice regarding the well-being of animals under this license will be sought from the vet and animal care staff.
We will follow external sources, including National Centre for Replacement Refinement and Reduction of Animals in Research resources (website https://www.nc3rs.org.uk/) and NCRI guidelines.

NON-TECHNICAL SUMMARY

126. Molecular Imaging in Cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, imaging, therapy, models

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The goal of our work is to create new lung cancer imaging tools for visualising and characterising metabolism in live tumours. By investigating the metabolic profile of these tumours, we aim to determine if new imaging tools

can identify tumours sensitive to new treatments (or combination treatments). We can then subsequently use these tools to guide therapy in individual cancer patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

There has been an encouraging increase in the number of cancer therapies over recent years but this has left a challenge. How do we get the right patients on the right drugs quickly? There are several strategies to address this problem but non-invasive imaging is the only technology that can look at the whole tumour as it changes during the course of treatment. Conventional imaging techniques measure the size and location of suspicious lesions and allow doctors to make decisions about patient management but they fail to look at how the tumour is functioning. There is an emerging range of molecular imaging techniques that try to address the problem of assessing tumour function. The most widely applied of these functional assessments is radionuclide imaging, of which the most promising is a technique called positron emission tomography or PET. PET visualises labelled molecules that are injected into the body, these molecules specifically 'home in' to the tumour and give a visual readout of tumour characteristics. Doctors can then use this information to guide treatment decisions, which might include giving a patient a particular therapy or crucially taking them off a therapy that is not working (and may be causing side effects) onto drugs that are most likely to have clinical benefit. This is important in order to get the best outcome for the patient but is also a cost-effective way to administer new cancer drugs. There is not enough data on current imaging technologies to allow them yet to be used to personalise treatment, therefore this project aims to generate that data and take it forward for clinical evaluation. We need better imaging agents that target relevant cancer biology so we also aim to develop these imaging agents and evaluate them as part of this project.

What outputs do you think you will see at the end of this project?

We expect this project to generate data and protocols suitable for publication in peer-reviewed journals which will inform of the clinical application of imaging technologies and an understanding of cancer biology and drug response. Specifically we expect to produce one or two imaging agents that could be taken forward for clinical evaluation by our clinical collaborators.

Who or what will benefit from these outputs, and how?

The purpose of this project is developing better imaging of human cancer and, while this project is not involving humans, we expect that in the short term (1-3 years) we will generate data and products that can be used in clinical trials. We have built extensive relationships with the Respiratory Physicians, Lung Oncologists, Nuclear Medicine Physicians and Radiologists who very keen to further develop the most promising imaging agents developed in this project licence into clinical imaging trials. These trials will aim to provide evidence that specific imaging approaches can be used to guide treatment in clinical trials, predicting whether patients will respond to a particular line of drug treatment or radiotherapy regime.

How will you look to maximise the outputs of this work?

Prior to formal publications the results of this project work will be widely disseminated through conferences, seminars, colloquia and workshops at local, national and international events. We will also share results with collaborators across our various networks and colleague and make resources available to other researchers. Work will also be published in peer-reviewed journals, which are open access.

Species and numbers of animals expected to be used

- Mice: 7500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

To develop tools which are ultimately designed for use in diagnosing human cancer we must use models which most faithfully represent the human condition

Typically, what will be done to an animal used in your project?

Typically mice will be bred in-house to contain specific silenced cancer causing genes. Cancer will be initiated by using of viruses which contain elements that can switch on these silenced cancer genes. These viruses are placed into the respiratory tract of an animal whilst it is anaesthetised to prevent any discomfort and for immobilisation. Lung tumours will then form in the relevant locations in the animal over a period of several months. Tumour growth will be monitored using non-invasive imaging techniques similar to those used in the clinic. At which time we may also use developmental imaging techniques to understand the type of information that these signals represent. Imaging will also be conducted under anaesthesia to reduce movement during scanning which would invalidate the procedure. To maximise the information gained from each animal this imaging may be up to 5 hours in length. We may also repeat this imaging to understand how our imaging signals change during tumour development and to understand the earliest changes which is relevant to early detection of cancer. We may also then provide treatment in the form of drugs or radiotherapy to determine if imaging signal changed after treatment particularly to see if imaging can be used to predict early response to treatment.

Imaging may be repeated during the course of treatment similar to what would be expected in a clinical trial. At the end of the study mice are humanly killed and tissues taken for extensive molecular analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Lung tumour bearing mice can have altered breathing rates as the lung capacity is reduced - this does not typically result in any signs of discomfort. Changes in breathing rate can occur from 2 months onwards and we would normally expect that mice would not be used for longer than 2 months beyond this stage. At the latter stages of disease mice can lose weight and breathing can become more laboured - at this stage mice are typically used for less than 2 weeks. Anaesthesia used in imaging (including when used for imaging mice with lung tumours) can have some short term effects on behaviour including loss of locomotion but these tend to resolve completely within 24-48 hours. Tail vein cannulations cause some damage to the vessels which typically does not cause discomfort and resolves within a period of days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In most cases we would expect the severity to be mild (70%), moderate (30%) **What will**

happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancers are complex and their behaviour is the result of an interplay of several factors including different cells types, poor blood flow and a variable supply of nutrients. Mouse models are the only system that can model this complexity. To evaluate new imaging tools, anticancer agents and radiotherapy we must use these complex model systems to determine their clinical potential.

Which non-animal alternatives did you consider for use in this project?

We considered and are continuing to investigate cells grown in a dish either directly from mouse or human tumours. We also looked at models which contain tumours cells in a way that simulates a living tumour. We investigated the use of computer models which simulate tumour behaviour.

Why were they not suitable?

Experiments on cell grown in a dish can give an important indication of whether an imaging agent will work in a living animal or person but they do not guarantee that it will work. This is because these cell systems cannot reproduce the influence that the circulatory system and other tumour cells have on the delivery of the imaging agent to the tumour and its subsequent clearance. Cell systems also do not reliability predict clinical drug or radiotherapy responses. These are crucial factors that will determine the likely success of any new imaging agents in the clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on experience from the laboratory over the previous 24 months, we also will expand our work due to the start of two new PhD students so this figure has had a 50% increase to account for these personnel.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal use will be minimised by using the smallest possible experimental groups in preliminary studies to determine whether a statistically significant effect is obtained with a new imaging agent or intervention (typically six animals in each group; control and test groups). A power analysis may then be used to determine how many

more animals are needed to reach significance. However, if the effect produced by the imaging agent, or imaging protocol, is small then it is likely that the agent will be abandoned at this stage since it is unlikely to be translatable to the clinic. If the effect of an intervention (treatment or radiotherapy) is small (<20%) we are unlikely to be able to measure imaging changes accurately and a new treatment protocol (or new agents) will be considered. Animal use is also minimised by the use of non-invasive imaging techniques in which each animal can act as its own control, for example, before and after treatment. I have also received formal training in experimental design and statistics and include those principles in our experimental planning. In addition, we take advice from our in-house statisticians and use the NC3Rs Experimental Design Assistant or other statistical websites to inform us of our effect size to guarantee our studies are meaningful.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Animal use will also be minimised by inducing tumours through direct tissue injection of agents that result in genetic changes activating cancer causing genes. Such an approach avoids the large breeding programmes and animal use required to produce such genetic changes through animal breeding.

We will also reduce animal use by reducing the experimental unit in our imaging studies down to individual tumours rather than an average of the whole animal. We have demonstrated in previous work that these tumours arise independently in the lung. Individual tumours identified on imaging will be matched to their removed tumour tissue thereby increasing the information that can be gathered for each individual lesion and increasing the power of the study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Genetically engineered mouse tumour models are becoming increasingly important as systems in which to test new drugs and in which to develop new methods for detecting and predicting the responses of tumours to these treatments. This includes new non-invasive imaging methods, such as those that will be developed in this project. The growth in the use of these models relates to our rapidly growing understanding of the genetic basis of cancer, our ability to genetically manipulate the mouse to produce accurate models of the human disease. The imaging techniques are minimally invasive and thus are not expected to have any significant adverse effects. We will use non-recovery anaesthesia wherever possible but as imaging allow repeated measures in the same mice we also aim to get as much information from each mouse as possible.

Why can’t you use animals that are less sentient?

The development of cancer is a time-dependent process and so tumours do not form in immature mice. Mice are the least sentient species that can be genetically manipulated and provide an accurate model of human cancer development.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are also refining our methodology to have the least impact on welfare such as improved animal monitoring including temperature and respiration monitoring on multiple mice throughout the imaging procedure. We have

introduced heating during inductions to maintain body temperatures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We adhere to the “Guidelines for the welfare and use of animals in cancer research” Workman et al. (2010) British Journal of Cancer volume 102, pages 1555–1577

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continually review our imaging procedures. Advances in imaging technology are available through international meetings and are published widely in journal and pre-prints. We will engage with these imaging advances as soon as they are sufficiently validated with demonstrated improvement to existing methods. We will take advice from the Named Veterinary Surgeons, Named Training and Competency Officer, Home Office Inspectors and the NC3Rs website. Our technical staff are very proactive in adopting 3Rs advancements such as non-aversion handling and single-use needles and contribute/attend in-house events such as 'culture of care AWERB' and 3Rs workshops.

NON-TECHNICAL SUMMARY

127. Molecular mechanisms in eye diseases with vascular complications

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

retina, vision, blood vessels, eye disease, macula

Animal types	Life stages
Mice	juvenile, adult, embryo, neonate, pregnant
Gerbils	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The molecular mechanisms that drive pathology in human eye disease with vascular complications are so far only minimally understood. In this project we aim to gain a better understanding of the mechanisms that might be responsible for these diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The retina critically depends on healthy blood vessels delivering oxygen and nutrients, and removing waste products. This is crucial for normal vision, and complications caused by abnormal blood vessel behaviour in the retina are the main cause of blindness in the Western world. Vision is affected when vessels become leaky or start to proliferate (forming new vessels). This happens in diabetic retinopathy (DR), retinopathy of prematurity (ROP), age related macular degeneration (AMD) and macular telangiectasia type 2 (MacTel). In other instances vessels may become blocked and degenerate, as in diabetic macular ischemia (DMI) or retinal vascular occlusions. In order to develop therapies for these blinding diseases it is imperative to properly understand the cellular and molecular mechanisms that control retinal blood vessel behaviour in health and disease.

What outputs do you think you will see at the end of this project?

The most important insights we anticipate to gain from our work are the elucidation of molecular mechanisms that drive pathology in human eye diseases with vascular complications, which will result in publications and the development of therapeutic approaches to treat those diseases.

Who or what will benefit from these outputs, and how?

Pathology of blood vessels in the retina is the major cause of blindness in the developed world. Because humans so heavily depend on visual function, any visual impairment has major consequences for life quality of the affected individual but also is a significant burden on society. Our efforts to understand the cellular and molecular mechanism that control retinal vascular behaviour in health and in eye diseases, and our aim to develop and test novel therapeutic approaches for such diseases are therefore of major importance, not only for the individual, but also for society as a whole. The groups who will directly or indirectly benefit from this research are diverse. They are patients with blinding eye diseases who need improved therapies, ophthalmologists who need a better understanding of the diseases they are treating and industry who need novel targets to treat those diseases.

How will you look to maximise the outputs of this work?

We are working within the context of a highly collaborative consortium, with very close links to clinical partners and international research groups. Therefore, any progress will be rapidly applied to the benefit of patients. Furthermore, publication of our work will not depend on whether our research hypothesis is confirmed or not, as both outcomes will provide novel insights into the biology of human eye diseases with vascular complications.

Species and numbers of animals expected to be used

- Mice: 1000
- Gerbils: 150

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mouse pups because their retinal vasculature has a similar stage of development and susceptibility for disease as the retinal vasculature in premature human babies.

Adult gerbils will be used because their retina contains a specialised region for high acuity day light vision as in humans (but not mice). This specialised region in the retina is anatomically and biochemically different from the peripheral retina and shows very different disease susceptibility in humans. We will therefore use gerbils to study macular telangiectasia (MacTel), which in humans only affects the high acuity area of the retina.

Typically, what will be done to an animal used in your project?

Newborn mouse pups will typically be exposed to different oxygen concentrations for up to 10 days. Most of them will also have received one or two injections by the time they are killed humanely when they are around 2-3 weeks old.

The gerbils will typically experience a normal life as our main experimental approach is via the diet modifications, mimicking unhealthy Western diet, which have minimal impact on animal welfare. Most of them will be killed and analysed after 3-24 months of diet exposure.

What are the expected impacts and/or adverse effects for the animals during your project?

In this project notable adverse effects caused by the planned experiments are not anticipated. Gerbils may experience mild distress or pain from injections but otherwise changes to the metabolism and the retina will not be detectable by the animals. Similarly, mice may experience mild distress or pain from injections or sampling, but otherwise changes to oxygen levels and the retina will not be detectable by the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice: 30% sub-threshold, 65% mild, 5% moderate (intraocular injections done under general anaesthesia)

Gerbils: 31% sub-threshold, 62% mild, 7% moderate (intraocular injections done under general anaesthesia)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Blood vessels are normally perfused with blood and interact with surrounding tissue. These conditions can so far not be recreated in vitro. Therefore it is not possible to study all aspects of vascular behaviour in cell culture experiments.

Which non-animal alternatives did you consider for use in this project?

It is possible to study molecular mechanisms of biological processes in vitro using cultured cells or organoids.
Why were they not suitable?

However, the eye diseases we are studying are complex and the result of interactions between multiple cell types and tissues. Since the details of these interactions are not known yet it is not yet possible to model them in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Much of this project will use qualitative readouts (that require minimal animal numbers) in multiple iterations in order to optimise and characterise our model systems. It is not possible to predict the success and speed of this approach accurately. Therefore, the animal numbers are based on estimates on how many experimental iterations and hypothesis tests can feasible be achieved within the project duration.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In this project we aim to study phenotypes with large and specific effects that can be measured clearly. This reduces the statistical need for large cohorts of experimental animals. Furthermore, we will use an iterative approach (based on small cohorts) to optimise our model systems. Once this is achieved, power calculations will be used to design proof of principle experiments aimed at therapeutic interventions.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Experiments will be run staggered so that the outcomes of one experiment can be used to optimise the design of the next experiment. Furthermore, we also plan to use global analysis approaches (such as global metabolomics, single cell gene profiling and mass spectrometry imaging) as readouts, which will provide a maximum amount of data per animal and reduce the need for large cohorts (because measuring different genes or metabolites individually needs more sample material and larger cohorts). Lastly, postmortem samples (serum and organs) will be shared with collaborating groups to maximise the insights gained from each animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Many of our experimental manipulations target the systemic metabolism in a way that is similar to the challenges seen in humans with unhealthy lifestyles, i.e. they will not cause immediate pain or suffering. In instances where the retina needs to be directly manipulated (e.g. via intraocular injections) or imaged in vivo, no major surgical interventions are required, minimising distress. Furthermore, the majority of experimental readouts will be done under non-recovery anaesthesia and/or postmortem.

Why can't you use animals that are less sentient?

The mouse retina strongly resembles the human peripheral retina, but the human central retina (the macula) is not well modelled in mice because they do not possess a macula. In fact, the only animals that possess a macula are primates and it is often argued that non-human primates are the best animal model to study the human macula. However, we have found evidence that gerbils (but not mice) possess a region in their retina that genetically resembles the human macula and propose here that gerbils are the least sentient animals to model the human macula. Zebrafish, which are less sentient than rodents, may also be used to study retinal biology. However, zebrafish do not have a retinal vasculature and the design and the cellular composition of the fish retina contains crucial differences compared to rodents and humans, making fish unsuitable to address our current research questions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Recent developments in genetic engineering allow the manipulation of specific genes in a time dependent manner in specific cell populations. This means the systemic effects on the animals by such manipulations can be minimised. We will explore the use of such approaches during this project.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the NC3Rs ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines) and make use of the NC3Rs Experimental Design Assistant (https://www.nc3rs.org.uk/experimental-designassistant-eda).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly check the NC3Rs website (https://www.nc3rs.org.uk/arrive-guidelines) and guides for alternatives such as EURL ECVAM (https://ec.europa.eu/jrc/en/eurl/ecvam), Animal Welfare Information Centre (https://www.nal.usda.gov/awic/alternatives-literature-searching) and
Duke University (https://guides.mclibrary.duke.edu/animalalternatives/databases).

NON-TECHNICAL SUMMARY

128.Mouse models of pancreatic cancer and therapy

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Pancreatic Cancer, Tumour Microenvironment, Fibrosis, Metastasis

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Pancreatic Ductal Adenocarcinoma (PDA) is a dismal disease with late detection, rapid progression and limited treatment options.
The overarching aim of this project is to improve the mechanistic understanding of PDA development. Specifically, we aim to identify mechanisms of PDA pathogenesis with an emphasis on the abundant microenvironment and its role in tumour development, metastasis and therapeutic response in vitro and in vivo.
Specific Objective 1: To define and characterise how the stroma regulates tumour progression, metastasis and resistance to therapy
Specific Objective 2: To identify novel approaches to target the tumour microenvironment
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pancreatic Ductal Adenocarcinoma (PDA) is the 11th most common cancer (with ~9000 new cases/year in the UK), but is the fourth leading cause of cancer related deaths. The 5-year survival rate is ~9%, which has largely remained unchanged for the last 40 years. PDA is detected late where only 10-15% of all patients have operable disease; however, this is still associated with a 5-year survival rate below 20%. Patients with non-operable disease (~80%) are only offered standard of care chemotherapy, which only marginally increases survival. Although Abraxane and FOLFIRINOX recently have been approved as chemotherapy treatment regimens for PDA, the increased survival is months, not years. PDA is projected to be the 2nd most common cause of cancer-related deaths within a decade and has been denoted as a cancer of unmet need by CRUK.

What outputs do you think you will see at the end of this project?

The primary output of this project is data and novel models – information that advances our mechanistic knowledge of how tumour cells conscribe host stromal cells and how these in turn promote tumour development. Our findings will be made available to the broader public and other scientists through publication in peer-reviewed journals, presentations at scientific conferences and meetings and outreach.
The expected benefits of the work can be summarised as follows:

1) Knowledge of tumour restrictive and promoting signals of the tumour microenvironment

2) Knowledge of the role of individual mutations and associated changes in the tumour microenvironment

3) Knowledge of the role of inflammation and fibrosis in pancreatic cancer

4) Development of more representative models of pancreatic cancer

5) In integrating the knowledge gained from the above, identification of key therapeutic targets for future hypothesis driven therapeutic intervention

6) Test of novel therapeutic agents currently investigated in clinical trials and their potential mechanism of resistance

7) Publication in peer-reviewed journals and presentation at conferences to share the work with the wider scientific community

Who or what will benefit from these outputs, and how?

The main beneficiaries of these outputs will be other scientists, health professionals as well as pharmaceutical companies working on pancreatic cancer. We anticipate that patients won't be able to benefit from this work within the time frame of this project licence, but might benefit in the next 10 years. This might be via better classifying pancreatic cancer and understanding better which patients are likely to respond to current treatments as well as by developing new compounds.

How will you look to maximise the outputs of this work?

Our findings will be made available to other scientists through collaborations, publication in peer reviewed journals and presentations at scientific conferences and meetings. The Establishment has a policy of ensuring that all publications from scientists are available on free access to all.

Species and numbers of animals expected to be used

- Mice: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are more comparable to humans than less sentient model systems (fish, invertebrates) in their pathophysiology and show higher levels of conservation in nucleotide and amino acid sequences. This is important as we intend to use reagents such as small molecule inhibitors and antibodies that have been developed with the aim to treat human pancreatic cancer.
Adult mice are to be used and the development of the disease and pathophysiology closely resemble the human condition.
The pancreas of non-protected species and less sentient species does not sufficiently resemble the human pancreas, so we would be unable to use them for animal models of pancreatic cancer. Embryonic stages would not provide us with a sufficient window to follow tumour development and besides it is not feasible to perform the desired interventions in embryos.

Typically, what will be done to an animal used in your project?

Some mice (bred under other Project Licences) harbour genetic modifications similar to the human disease, which pre-dispose them to the development of pancreatic cancers when exposed to an appropriate agent such as Cre recombinase. In other mice, which are bred specifically to tolerate human tissue, tumours will be implanted under the skin of the mouse for ease of monitoring, or into the pancreas or the bloodstream to study cancer spread (metastasis). Mouse cancer cell lines can be transplanted into mice sharing the same genetic background (so called syngeneic mice) without rejection, which enables the study of the immune system in disease development. Pancreatitis, which is a frequent human disposition, may be induced to accelerate the disease development. Tumour growth is not associated with pain during the period in which we conduct our observations. Tumour growth will be monitored regularly by either use of callipers for superficial tumours, or by imaging methods such as ultrasound for internal tumours. For some procedures that involve surgery under

general anaesthesia, such as implanting human tumour fragments or removing a primary tumour for secondary tumour to grow, we will administer pain killers and monitor the mice closely during recovery.
Some mice may receive either potential novel therapeutic agents, existing clinical agents or placebo administered by a variety of routes, but usually either by mouth, or by injection either under the skin or into the abdomen to study the effects on tumour growth and / or tumour composition. The mice will also have blood samples taken either from the tail vein or by sampling from a heart chamber under anaesthesia (in which case the animal does not regain consciousness before humane termination). Occasionally mice may be administered washing solution and disaggregating enzymes whilst under non-recovery anaesthesia to allow us to undertake analysis of single cells from selected organs.
Mice may be studied for up to 200 days after a period of therapeutic agent treatment for tumour growth. Fast growing tumours will be monitored daily.
Mice will be group housed in ventilated cages which have their environment enhanced with items such as tunnels, houses, nesting material and gnawing blocks.
At the end of any protocol mice will be humanely killed.

What are the expected impacts and/or adverse effects for the animals during your project?

The impact of the gene modifications are not expected to cause any adverse effects per se other than, in the case of the tumorigenic mutations, promoting the propensity to produce tumours. It is possible that the tumour growth might affect normal physiological functions (such as eating, locomotion or breathing) however, mice will be observed daily and any side effect that cannot be managed satisfactorily will be killed humanely.
Injections would only cause very transient pain. Pancreatitis in mice is anticipated to be sub-clinical but will be monitored carefully for signs of pain and discomfort.
After surgical procedures we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of mice are only expected to experience the mildest clinical symptoms due to tumour growth before they are humanely killed Some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery with a specialist tube. We will aim to utilise the least stressful route of administration wherever possible.
Mice that undergo surgery will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing this is not painful.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will only use animals where there is no suitable alternative. Pancreatic cancer is a very complex disease that involves a number of different cell types e.g. epithelial cells, fibroblasts, immune cells, blood vessels, and as yet

no *in vitro* cell culture system exists that faithfully phenocopies this microenvironment. In addition, pancreatic cancer is characterised by a particularly dense extracellular matrix (ECM). The infiltrating cells and ECM deposition, collectively known as the tumour microenvironment, plays a major role in tumour initiation, progression and metastasis. Moreover, drug efficacy is decreased due to low penetrance and an abundance of anti-apoptotic signals.

Which non-animal alternatives did you consider for use in this project?

My laboratory is committed to establish better *in vitro* models that reflect the complex *in vivo* environment. For example, we have made progress in developing models that recapitulate essential features of the tumour mictoenvirnment. We conduct a great deal of research in these systems already and use these to inform our *in vivo* experiments such that the number of animals used can be limited. Moreover, we are continuously evaluating whether *ex vivo* model systems compliment the *in vitro* co-culture models. We will continue to test and develop these *in vitro* and *ex vivo* systems over the next few years to address how well they model human tumours.

Why were they not suitable?

Whilst enormous progress has been made in the field of cancer research using *in vitro* models, there are several questions that can only be addressed using animal models of disease. For example: investigation of therapeutic response and resistance and interactions with the immune system is most faithfully addressed using pre-clinical *in vivo* models. For these reasons, studies on *in vivo* tumour models need to be performed, in which the benefits are weighted against the likely adverse effects, and humane endpoints utilised.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used is estimated as follows:

- I currently have 3 projects which directly interrogate the interactions between tumour cells and the microenvironment in vivo and one project which aims to optimise and refine models of metastasis. In addition, several projects in my laboratory relies on in vivo models to test specific hypotheses generated from in vitro studies.

- A few studies are anticipated to start and develop under the next 5 years which will require extensive analysis of tumour/stromal cell interdependencies and effect of therapeutic intervention.

- The experience from last 5 years and recent increase in the number of animal models that have been used

in the lab.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments are designed using the principles outlined in the experimental design tool on https://eda.nc3rs.org.uk/ and reported following the ARRIVE guidelines as well as the PREPARE guidance on https://norecopa.no/prepare/prepare-checklist
Power analyses will be performed to ensure that we use the minimum number of mice to generate significant results. In cases where power calculations are not feasible, group size will be estimated using the resource equation. Moreover, we involve those with statistical expertise to ensure that we are using optimum groups sizes, and hence minimum number of mice, in our experiments, we use optimal procedures to reduce the number of mice. For each implantation experiment with a new tumour cell line, a small number of animals may be used to determine their tumorigenic potential and the required number of cells necessary to establish tumours so that the smallest number of animals can be used for the experiment itself. Similarly, for implantation experiments involving a new stromal cell line or subsets, a small number of animals may be used to determine their biological impact on tumour growth and the required number of cells necessary to establish an effect so that the smallest number of animals can be used for the experiment itself.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot experiments (2-4 animals) may be conducted to estimate the biological effect of an intervention (such as a drug) when not available.
We use optimal breeding strategies to reduce the number of genetically engineered animals.
We take care to ensure that each experiment is appropriately analysed and that the maximum amount of information is gathered thus reducing the need for experiments to be repeated. For example, at the end of each experiment, data is compared to previous studies by appropriate statistical methods (e.g. Kaplan Meier plots of age at endpoint, Mann Whitney analyses using a one tailed distribution to reduce mouse numbers). Where cell transplantation models are no longer needed, cells and/or tissue will be frozen to avoid unnecessary propagation of the model. Finally, in vivo experiments are preceded by relevant in vitro experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals expressing the Pdx1-cre transgene together with oncogenic Kras frequently develop papillomas, however, animals with considerable papilloma burden seem to live quite normally without evidence of distress or discomfort. Animals subjected to pancreas-specific delivery of recombinases (eg Flp or Cre) by virus are not anticipated to experience these issues.
We interact frequently with colleagues that have a vast amount of experience with spontaneous mouse models of pancreatic cancer and have learned to recognize symptoms before animals exhibit any signs of pain (such as: reluctance to move, abnormal posture, vocalization or aggression). We are instating standard operating

procedures for animal care and monitoring where animals will be humanely killed, by Schedule 1 method, if displaying signs of loss of body condition or suffering. Social, environmental and behavioural enrichment will be provided.
None of our protocols exceeds a moderate severity level. Despite the occurrence of metastatic disease, the extent is limited, and animals succumb to primary tumour burden. Moreover, we do not see signs that suggest the animals suffer such that a severe classification would be required. In all cases, signs are monitored very carefully so suffering can be kept within or below moderate limits.

Why can't you use animals that are less sentient?

Less sentient animals do not exhibit a similar stromal reaction and histopathological features as human PDA. Mouse is far more similar to humans than other animals and this is critical both for using reagents like drugs developed for human disease and for translating findings to the clinic. Cancers develop over many weeks to months, so use of terminally anaesthetised animals or immature animals is not practicable.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal suffering will be minimised by making every effort to keep the tumour models employed at the subclinical levels. Wherever possible, this will be achieved by using non-invasive imaging modalities to monitor tumour growth and the development of metastatic disease. In addition, as detailed in the individual protocols, steps will be taken to minimise the severity of the procedures. As such, while cerulean-induced pancreatitis typically is sub-clinical, repeated injections are needed, which will be alleviated by application of analgesia. Finally, we will ensure that all animals receive the highest standard of care, and preventative medicine (including anaesthesia and analgesia where required) will be used.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).
We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)] administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.
Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23]
Aging mice will be monitored and managed according to Wilkinson et al (2020) Laboratory Animals: 54(3): 225 – 238.
We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our NACWO, NVS and HO inspector.

NON-TECHNICAL SUMMARY

129. Mouse models of prostate cancer initiation & progression.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

prostate progenitors, castration-resistance, immune system, genetic drivers, cancer

Animal types	Life stages
Mice	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Our aim is to improve the understanding of prostate cancer initiation, progression and disease spread (metastasis), in particular the contribution of genetic alterations occurring in diverse cells of origin. Ultimately, by the use of our mouse models, we aim to develop new treatment strategies which can be translated into the clinic.

A retrospective assessment of these aims will be due by 15 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Prostate cancer (PCa) has become the first leading cause of cancer-related mortality in men in the UK, accounting for 15% of all male cancer deaths. PCa patients exhibit highly variable clinical behaviour; some have indolent disease whilst in others it is lethal.
Localized treatments, which include radical prostatectomy, and radiotherapy, are highly effective for prostate cancer patients. However, 20-30% cases relapse. A main challenge for treating prostate cancer patients is a lack of sufficient patient stratification, which result in standardise treatments to a highly heterogeneous, often multifocal disease. Moreover, currently available immunotherapies have limited effects in PCa patients, highlighting the need to study in depth the prostate local environment for development of adequate therapies. The use of mouse model systems, with a complete immune system will allow us to address those questions and pursue novel therapeutic interventions.

What outputs do you think you will see at the end of this project?

The expected outputs of this project would include:
(i) New knowledge regarding the prostate tumour initiating cells, with particular focus on cell types sustaining more aggressive tumours, leading to the lethal stage. The research will contribute to the prediction of PCa subtypes by cell origin, their associated disease outcome and defined their specific molecular network to be targeted to abrogate tumour progression.

(ii) New knowledge regarding the requirement for several genes or cellular pathways for the function of normal or malignant prostate cells (e.g. inflammatory, stress response pathways), with a particular focus on those selectively required for tumour maintenance, metastasis and therapy resistance. The research findings will be published in academic journals and will be of interest to scientists in the field.

(iii) Identification of specific candidate therapeutic targets in PCa, which would be of particular interest to identify new biomarkers and to develop novel therapies to translate into personalized medicine.

Who or what will benefit from these outputs, and how?

We anticipate that a large part of benefits stated above would be seen within the 5-year duration of the project. The main beneficiaries of these will be other scientists, health professionals as well as pharmaceutical companies working on prostate cancer. We anticipate that patients won't be able to benefit from this work within the time frame of this project licence, but might benefit in the next 10 years. Patient benefit might be via better classifying prostate cancer and understanding better which patients are likely to respond to current treatments, as well as novel immunodulatory combinatorial strategies.

How will you look to maximise the outputs of this work?

Our findings will be made available to other scientists through collaborations, publication in high quality journals and presentations at scientific conferences and meetings. Our Institution has a policy of ensuring that all publications generated are available on free access to all.

Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cancer development is dependent not only on the changes occurring within the transformed cells, but also on the interactions of the cells with their microenvironment. Mice are more comparable to humans than less sentient model systems (fish, invertebrates) in pathophysiology and show higher levels of conservation in nucleotide and amino acid sequences. This is important as we intend to use reagents such as small molecule inhibitors and antibodies that have been developed to target human proteins.
While this has elucidated many changes in cancer cells, it provides little information about the local environmental factors influencing early-stage cancer development in life. Also certain hallmarks of cancer, such as spread of cancer and blood vessel formation, are impossible to study in vitro (cell culture). Therefore, mouse models are important for studying the in life aspects of human prostate cancer development. Mouse models have been engineered to develop tissue-specific cancers, which accurately mimic their human counterparts, and have potential applications to test the effectiveness of novel cancer therapeutics. Moreover, non-protected species and less sentient species do not have prostate, so we would be unable to use them for animal models of prostate cancer involving the injection of prostate cancer cells in the organ where they are found in man. Embryonic stages would not provide us with a sufficient window to follow tumour development and besides it is not feasible to perform the desired interventions in embryos (such as tamoxifen injection in pregnant females). Therefore, adult mice are to be used.

Typically, what will be done to an animal used in your project?

Normal and genetically altered mice will be used to investigate the role of certain specific molecular pathways in the induction, progression and metastatic potential of prostate cancer cells.
The animals will have tumours grown in them initiated through either use of cancer prone genetically modified mice; by the use of inducing agents or by the implantation / injection of existing tumour cells / tumour pieces. For one of the protocols to investigate the spread of cancer we will inject cancer cells into the heart chamber with the aim of delivery to bone sites. However, we do not know the eventual locations until we complete the first study. It is possible that there could be multiple site tumours, but we will monitor the mice very closely to measure the total tumour burden and limit to that which is necessary to achieve the scientific target. To mimic some of the testosterone driven prostate tumour processes, some of the mice will, on occasions be castrated, under general anaesthesia and given post operative pain killers (analgesia). Other surgical procedures requiring general anaesthesia and analgesia are tumour implantation (into specific organs of interest), tumour biopsy (a gold standard method used clinically) and the implantation of small drug delivery systems under the skin.

To monitor the tumour growth, a combination of methods will be used: the use of callipers (for subcutaneous

implanted tumours) and imaging under light general anaesthesia will be performed on a number of occasions to monitor tumour growth. On occasions it will also be necessary to inject, by one of several possible different routes, chemical agents that will allow better imaging of the internal tumours. The majority of animals are not expected to show signs of adverse effects that impact on their general well-being. Very rarely the severity of these signs may be such that the humane end points may be reached (i.e. 20% loss in bodyweight) and the mice culled humanely. The majority of the procedures will result in no more than transient discomfort and no lasting harm.
In order to evaluate the contribution of immune cells in the progression of prostate cancer and associated metastasis, some mice will also have endogenous immune cells destroyed by radiation therapy. These same mice will also be injected with replacement immune cells. Some mice will also have current and potential new therapeutic agents administered to help understand both mechanisms involved in the cancer development but also as a means of assessing the usefulness of new potential treatments for prostate cancer and the subsequent spread. Some mice will have a second challenge of tumour administration to determine the duration of therapy efficacy.
As prostate cancer is a disease of old age, and we will also want to investigate how the cancer spreads and develops in other organs, it will be necessary to continue to follow these mice for up to 28 months.
All the mice will be humanely culled at the end of the experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

The impact of tumourigenic mutations are not expected to cause any adverse effects per se as these in most cases only manifest following administration of inducing agents. Following inhalation of inducing agents mice carrying tumourigenic mutations are expected to have prostate tumours. It is possible that the tumour growth might affect normal physiological functions (such as eating, locomotion or breathing). However, mice will be observed daily and any side effect that cannot be managed satisfactorily will result in humane culling of the animal.

Injections would only cause very transient pain.

After surgical procedures we will monitor mice for signs of pain and administer effective pain relief for as long as it is required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of mice are only expected to experience the mildest clinical symptoms due to tumour growth before they are humanely sacrificed. It is possible that there could be, for a small proportion of the total mice used, multiple site tumours following injection of tumour cells into the heart chamber. Additionally, some mice will experience the discomfort of repeated (daily) injections of therapeutic agents or oral delivery with a specialist tube. We will aim to utilise the least stressful route of administration wherever possible.

A minority of mice will undergo surgery and these will be anaesthetised for the operation and receive pain killer post-operatively until pain subsides. Some mice will also have repeated anaesthesia for the purposes of imaging the internal tumours. Whilst loss of consciousness may be distressing this is not painful.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 15 March 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While valuable studies of human cancer are performed using tumour material and cell lines derived from both mice and human samples, the mechanistic understanding of cancer pathogenesis and its dynamics from tumour initiation to metastasis requires use of living animals (in vivo). In particular, cancer development and spread involves a plethora of interactions between cancer cells and their surrounding host and their behaviour is governed by multiple signals originating from both their immediate neighbours and from distant tissues. Genetically engineered mouse models (GEMM) have been designed to develop cancers, which accurately mimic their human counterparts, and have potential applications to test the effectiveness of novel cancer therapeutics. This cannot be replaced by in vitro studies or indeed even in different in-vivo models such as zebrafish or insects which remain far less complex than their murine counterparts. . Additionally, inducible mice and tissue-specific Cre recombinases are used to restrict mutations to the biologically appropriate tissue.

Which non-animal alternatives did you consider for use in this project?

Use of animals will be minimised by making use of computer modelling (e.g. prostate cancer patients' data) and in vitro model systems. In particular, we will use a variety of in vitro approaches to investigate how manipulation of nucleic acid based targets alter cell behaviour in cultured cancer cells (prostate) prior to undertaking in vivo studies.
Methods to be utilized include cell biology techniques to measure organoid-growing capacity, cell proliferation, survival, migration, invasion, etc., biochemical and molecular biology techniques such as western blotting, enzymatic assays, proteomics, RT-PCR, etc. to study protein function. In addition, we will use molecular pathology (e.g. immunohistochemistry) to substantiate findings from our in vitro models in human tumour samples.

Why were they not suitable?

The study of cells in culture (in vitro) provides us with clues on the mechanisms of cellular processes in a simple and valuable context, which allows the establishment of hypotheses regarding the function of cells in a living animal. However, these systems do not recapitulate the complex cellular interactions described above.
A retrospective assessment of replacement will be due by 15 March 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

The overall aim will be to generate models whereby a measurable effect e.g. reduction in tumour volume or tumour incidence following manipulation of a gene of interest or treatment with a drug can be determined using the minimal number of animals.
Data available from the literature or from pilot studies are used to perform power analysis to determine an appropriate sample size for the definitive experiment. In general, we will use a sample size capable of detecting a 40% practical difference with 80% power and 95% confidence.
Based on past experience, group sizes of between 10 and 30 animals (dependent on the readout, fewer for transplanted tumours compared to spontaneous tumours in GEMM mice) per experimental group suffice. However, for an experiment to be well controlled and meaningful, we may include more than one experimental group. For instance, in implantation experiments where we deplete a gene in a cell line or prostate subpopulation using shRNA, we will use two independent shRNAs targeting the gene as well as a control shRNA. Moreover, we would typically examine more than one model cell subpopulation/line. Likewise, we may use several doses of a drug, or several different drugs or treatment combinations to test a hypothesis.
Considering power, the number of experimental groups, and the number of genes and drug targets we are interested in, we have then estimated the total number of mice to be used over the licence lifetime.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Use of animals will be minimised by (i) making use of in vitro model systems wherever scientifically justified, (ii) use of in vivo bioimaging to follow disease development and response in real time (rather than culling cohorts of mice at defined time points), (iii) inducing tumour initiation by injecting virus in vivo (iv) the use of pilot experiments to test for the extent of an expected phenotype prior to a full scale confirmatory experiment (thus avoiding full scale experiments that may lack sufficient statistical power), and (v) the cryopreservation in multiple aliquots of prostate cancer samples (which eliminates a requirement for continuous production of cohorts of mice with experimentally initiated prostate cancer).
For our engineered models an efficient breeding strategy will minimise the number of mice used to obtain the desired genotype.
Experiments will be appropriately controlled and mice of the same age, genetic background and source used to reduce the variability of results and to produce highly consistent data. Wherever possible and appropriate, a single group of animals will serve as a control for duplicate experimental group. The proposed experimental designs and methods of analysis of the results will follow statistical guidelines and involve discussion with our bioinformatician scientist to provide sufficiently powered studies, minimizing the number of animals used in each experiment. The design of individual experiments will generally involve factorial designs, which maximise the information obtained from the minimum resource.
We will be conducting and recording our experiments to be able to publish our results following the ARRIVE guidelines [https://www.nc3rs.org.uk/arrive-guidelines] and will use randomisation, blinding etc. where

appropriate so as to minimise biases. Furthermore, additional resources may be used to aid experimental design such as the NC3Rs experimental design assistant tool (https://www.nc3rs.org.uk/experimental-design-assistant-eda).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be performed if applicable and, after analysis of the results, group sizes for subsequent experiments will be determined based upon these data. As far as possible, multiple parameters will be evaluated in a single mouse. Live imaging of the same animal at multiple time points also greatly reduces the numbers required.
A retrospective assessment of reduction will be due by 15 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice have been chosen for the study because they represent the least sentient species from which meaningful experimental data can be generated, while exhibiting considerable genetic and biological similarities to humans. Other less sentient non-mammalian species, such as Danio rerio or Xenopus, which lack an urogenital system that is comparable in complexity and anatomy to that of Homo sapiens have been considered and rejected as models.

The conditions under which the experimental animals are kept and used for the proposed procedures are designed for the least possible disruption of natural behaviour and quality of life. We constantly work to improve husbandry and procedures to minimize actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare in situations where the use of animals is unavoidable. As detailed in each protocol, there is provision for the appropriate anaesthetic and analgesic regimes as well as appropriate culling methods following guidelines on administration of substances to mice by Morton et al (2000) and working with cancer models (Workman et al 2010).

Why can’t you use animals that are less sentient?

Only a mammalian prostate cancer model system has the potential to accurately mimic both the anatomy and

complex cell biology, including microenvironmental interactions, of human normal and tumoural prostate. Furthermore, there is considerable experience in the wider scientific community regarding the use of mice as a model system for human malignancies and many reagents exist for the phenotypic characterisation of mouse cells.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The conditions under which the experimental animals are kept and used for the proposed procedures are designed for the least possible disruption of natural behaviour and quality of life. We constantly work to improve husbandry and procedures to minimize actual or potential pain, suffering, distress or lasting harm and/or improve animal welfare in situations where the use of animals is unavoidable. As detailed in each protocol, there is provision for the appropriate anaesthetic and analgesic regimes as well as appropriate culling methods.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Relevant published literature will be used as template for experimental design and decision making (Workman et al., 2010. Guidelines for the welfare and use of animals in cancer research. BJC, 102, 1555-1577).
We will follow guidelines of good practice [Morton et al., Lab Animals, 35(1): 1-41 (2001); Workman P, el al. British Journal of Cancer, 102:1555-77 (2010)] administration of substances will be undertaken using a combination of volumes, routes and frequencies that themselves will result in no more than transient discomfort and no lasting harm.
Guidelines for Body condition score. [Ullman-Cullere, Lab Anim Sci. 1999 Jun;49(3):319-23]

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By reading 3Rs literature and participating in 3Rs workshops locally and nationally. Through discussing refinements with our NACWO, NVS and HO inspector. I am also a member of the AWERB and I am a regular attendee of our Retrospective Review meeting and the 3Rs Poster session, both of which take place annually.
A retrospective assessment of refinement will be due by 15 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

130. Mouse Models to Investigate Neurological Dysfunction

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterise highly refined preclinical mouse models to help us understand specific intellectual disability and neurodegenerative disorders in humans.
A retrospective assessment of these aims will be due by 10 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The most common cause of death in England and Wales is neurodegeneration (roughly equal first with ischaemic heart disease in Scotland and slightly less impactful in Northern Ireland but still a major killer). Neurodegenerative diseases include Alzheimer's disease, Parkinson's disease, motor neuron disease including amyotrophic lateral sclerosis, spinal muscular atrophies.

Neurodegenerative disease also makes up aspects of syndromes and a prime example is the occurrence of Alzheimer's disease in Down syndrome: having the neurodevelopmental disorder Down syndrome (the most common known genetic form of intellectual disability) is the single biggest risk factor known for early-onset Alzheimer's disease.

We have almost no treatments for neurodevelopmental cognitive deficits (such as Down syndrome) or for neurodegenerative disorders in humans, let alone cures, although they massively impact our lives. Nor do we understand how a neurodevelopmental disorder like Down syndrome results in a neurodegenerative disorder later in life. We require many different types of models, including cells, human tissues, ex-vivo preparations and animals, to be able to understand these human conditions. We will use mice to show us why and how disorders develop from the early embryo to old age, investigating the interactions between different cell types, in order to ultimately understand disease (for example, Down syndrome, intellectual dysfunction and neurodegeneration) and find treatments.

What outputs do you think you will see at the end of this project?

At the end of our project we aim to have new information about the causes of dysfunction in the central and peripheral nervous system that arise from specific genetic mutations affecting cognition and locomotion, and leading to neurodegeneration. We aim to shed light on the earliest processes, some of which may be suitable targets for therapeutics, or for developing much needed biomarkers of specific diseases.

We will also have new, highly refined, animal models, for therapeutics testing including by genetic manipulation such as the use of new gene-therapy based medicines, or gene editing, for example.
Examples of benefits that we expect from current studies from include:

a) Being able to continue to map specific deficits in memory to a small region of synteny to human chromosome 21 in mouse Down syndrome models. In previous studies we have identified five candidate genes for a specific memory deficit in a mouse Down syndrome model; we expect to be able to start assessing the role of such genes during the course of this licence and thereby deliver potential future therapeutic targets, thus in the long-term, outside of the scope of this licence, helping to ameliorate memory deficits in this disorder.

b) In addition, we are aiming ultimately to identify other genes (possibly up to 3-5) that modulate Alzheimer's disease in Down syndrome. We have yet to identify these genes, but current work is giving important new information which confirms there are genetic targets that can be modulated in Down syndrome-Alzheimer disease, and potentially in Alzheimer disease in the euploid population.

c) Using a combination of mouse models and human immortalised pluripotent stem cells we have been able to determine novel gene transcripts in motor neurone disease. During this project we aim to determine the functional significance of these variants on motor neurone disease pathology.

All studies are aimed at eventually taking us to therapeutics for the disorders modelled, and in all cases we work closely with clinicians and other functional/clinical experts to ensure that knowledge is disseminated and opportunities for therapeutic developments are exploited.
All of this research takes place with regular and frequent interaction with a range of specialists including clinicians who are experts in the disorders we study, and basic scientists including behaviouralists, neuroimagers, cell biologists, molecular biologists and other experts, to help ensure we fully capitalise on the information from our mouse models and relate this back to the human condition.

All of this research will be published and disseminated to non-scientists through the charities that fund our work, and the patient/carer groups, and to scientists/clinicians through publications and presenting work at specialised scientific meetings including both academic and industrial audiences, and lay meetings.

Who or what will benefit from these outputs, and how?

Our research has impact over the short-term and in the long-term, after completion of the project.
In the short-term, the biomedical research community will be the main beneficiaries of our work, in that we will create new resources (mouse models) and disseminate new data on our specific disorders of interest and their underlying mechanisms. The mouse models will help in refining models to address specific questions on the pathology of our diseases of interest. The information on affected cell types, aberrant molecular pathways, aberrant changes detected by neuroimaging, aberrant behaviours, interactions between neurons and other cell types will inform biomedical researchers about early stage disease changes.
In the long-term, the resources and data we produce (both of which will be freely available, long-term, either in biorepositories (mice) or in the literature (data)) will be used by us and by others to help provide the basis for producing therapies for the diseases of interest, and possibly also biomarkers for diagnosis and understanding disease progression.

How will you look to maximise the outputs of this work?

Our ethos is that all individual mouse models should be studied by the widest group of experts possible, so that we maximise our understanding of phenotype. We work on neurological disorders, but to fully understand these disorders, we need experts in heart, skin, etc., to assess our mice holistically. Therefore, we have a wide-ranging set of long-term collaborators from different fields to whom we send samples for analysis, and if we find novel phenotypes we will always go to the experts in that area to ask them to follow up our findings.
All new knowledge is disseminated via publication, meetings, talks, academic and lay. Unsuccessful approaches are equally important and we also publish these in our papers and where possible as individual papers.

As well as conventional scientific press we also have an active social media presence and regular communication with other media (newspapers, radio).

Species and numbers of animals expected to be used

- Mice: 42400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of

the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We work with mice because we can relatively easily manipulate the mouse genome to create animals that exactly mimic the genetics of people who have the disorders we work on. Also, until recently it was very difficult to manipulate the genome of many species, other than mouse, and so there is a wealth of mouse strains that are helpful for biology and which are compatible with the novel mice we make.
We study all life stages, from embryos through to old age, because we are interested in the functioning of the nervous system in different disorders, relevant to neurodevelopment and to later neurodegeneration -- noting that generally we do not know when neurodegeneration starts.
Typically, what will be done to an animal used in your project?

Typically, mice will be used for breeding, to keep our mouse colonies going.
There is no 'typical' regime for all our mouse models, the experiments depend on where we are with understanding the features of the mice we are working with.
For example, we have different protocols to assess the whole, awake animals for locomotion, memory, behaviour:
To assess locomotion in our mouse models, typically we may look at how mice walk, and how far they walk, by giving them free access to a running wheel and then timing how long they are on the wheel, and how far this adds up to running over a particular time period. We might also assess truncal strength by putting a mouse onto a wire hanging above a cage, and timing how long it takes for the mouse to haul itself onto the wire and run along it to the cage edges.
To assess memory, typically we may place a mouse into a box shaped like a capital T - the mouse is placed at the bottom of the T and will explore along the stem up to the T-junction and then turn right or left. We will then take the mouse out of the box, and put it back at the bottom of the T. Because mice are foraging animals, a normal mouse will again run up the stem of the T but then turn in the opposite direction, because it wants to explore. Mice with memory deficits may have forgotten which direction they first went in, and go in the same direction. Thus, we can detect if mutations cause memory deficits.

What are the expected impacts and/or adverse effects for the animals during your project?

Depending on the model of neurodysfunction, we expect to see different features in the mice, most of which will be progressive, most of which are mild or moderate.
For our Down syndrome models, these animals have relatively mild learning and memory deficits, but live to old age - effects are mild but throughout life.

For the motor neuron disease models, these have loss of locomotion which in most cases is mild and throughout life, with our physiological models. Some transgenic models may develop severe symptoms by age four months, but we rarely work with such mice, and then only for a few specific experiments such as to determine the effect of introducing a gene knockout (by crossing in such a locus), as a test for possible therapeutics.
Similarly, for the Alzhiemer's disease models, some are known to have seizures in up to 20% of mice by 6 months of age, but again, these are transgenic models and so overexpress the gene of interest which may lead to the seizures. We have no plans for working with such mice.
For the movement disorders, the phenotypes are also related to locomotion.
We do not have reason to believe that pain is part of any of the phenotypes we study. There may be some weight loss depending on the mutation, but generally this is insufficient to be a welfare issue.
In a small number of strains, locomotion and weight loss will be severely affected and mice may reach humane endpoints within a few months.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

25000 mice on the mild breeding protocol are not expected to suffer any adverse effects and the majority will not have any obvious features that are different from other mice.
We primarily work with models that express the normal or a mutant gene at the same level as occurs naturally – this is unlike transgenic mice for example, in which the gene level is usually many times above normal. These mice are 'physiological models'. Therefore, most the features of our mice are mild and slowly progressing.
The majority of our mice with disease causing GAs are physiologically expressing models with mild features in the heterozygous state (i.e. with one copy of the mutant gene, not two) and therefore most will be bred under the mild protocol. When breeding new GA mice, or generating new crosses (e.g. generating mice with two copies of the gene of interest), mice will be bred on the moderate protocol in the first instance. Up to 25% of the 10000 mice may be show 'moderate' features.
In a minority of cases, GAs may lead to severe phenotypes during breeding ages, due to for example, neurodevelopmental abnormalities; up to 50% of the 1000 mice may exhibit these features under this protocol.
Up to 400 mice undergoing a protocol involving surgery will be non-recovery after terminal anaesthesia.
Protocols for characterising the animals, without surgery, involve up to 6000 mice, where up to 90% of animals may experience 'moderate' features.
Severe characterisation protocols will only involve up to 1000 mice, with less than 50% expected to experience severe features.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 10 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are studying diseases of the nervous system. For one set of disorders that involve cognition, many cell types are involved, and we can neither model behaviour other than with the whole animal, nor do we yet know about all the cell interactions and the effect of development so we have to work with animals.
For another set of mainly neurodegenerative disorders, scientist cannot yet grow the mature neurons that we work on, in dishes, nor can they grow the multiple different cell types together that represent the older human brain, in the body with environmental, hormonal, metabolic and other important influences, including ageing. Therefore, although the mouse lifespan is much shorter than that of humans, nevertheless mice go through an ageing process that mirrors our own, and we can study neurodegenerative disease in mice.

Which non-animal alternatives did you consider for use in this project?

Lower vertebrates and invertebrates are used in the field to understand the interplay between genetics and conserved molecular pathways. However, our goal is to understand disease from a systemic viewpoint within the complexities of the mammalian nervous system. Critically, our most refined humanised models involve large genomic replacements – to understand human mutations in the most physiological way possible – that are not currently possible to engineer in other model organisms with available technology.

Why were they not suitable?

Scientists do not know how to grow the adult neurons we need to investigate, cells in dishes cannot recapitulate the complexity of developing and ageing in a body, and the effects such as hormones and metabolism, and we cannot study behaviour on cells.
A retrospective assessment of replacement will be due by 10 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on a combination of previous throughput and power calculations for individual upcoming experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the minimum number of animals to give us a statistically meaningful outcome, based on a prior statistical tests such as power calculations. We are careful to use control groups that are age-, sex-, genetic background matched, in order to reduce cohort sizes.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We design breeding plans to work with the minimum number of mice that will give us all the experimental and control genotypes that we need. We undertake small scale pilot studies to determine effect sizes for power calculations. We aim that as much tissue as possible is frozen/fixed and banked within our laboratory for use to use for future studies, and to share with collaborators, and this reduces the need to breed and age mice.
A retrospective assessment of reduction will be due by 10 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse is currently the only mammalian species that we can use to examine the full complement of parameters that are measurable in behavioural and physiological changes, cellular and molecular changes arising from neurodysfunctional disorders, in concert with our ability to tailor the genome of these animals to maximise the information gained from each mouse. We also try hard to develop protocols that detect early changes, such as behavioural changes, prior to major deterioration; such detection can only improve with time and as we learn more about mechanisms including from the very earliest stages. Note that we tend to work with physiological mouse models that have mild phenotypes.
Refinement within our experiments includes processing primary cell lines (e.g. fibroblasts from ear clippings) (and these are immortilised and no further biopsies need to be taken), for multiple future use to ask questions at the cellular level. We also work with human cell lines, such as fibroblasts and induced pluripotent stem cells, to complement, our mouse studies, to validate our findings with the human condition.

Why can't you use animals that are less sentient?

We are studying neurodysfunction in the mammalian nervous system, and while mice are different from humans at all levels, we are sufficiently close in evolution that basic mechanisms are almost always conserved, as are genes -- which is not the case in non-mammals. Therefore mice are the model of choice to study mammalian neurodysfunction, also given the number of different mouse models available to the research community that informs our research.
Other vertebrates may be used to understand some of the biology of the disorders we study, but are not the best at recapitulating pathology such as, for example, behaviour. Similarly, while many aspects of the central nervous system are conserved from humans to invertebrates and may help us understand disruption to these tissues, lower organisms such as fish or flies do not harbour the complexity and intricacies present in mammals, and mammalian models better recapitulate complex pathological changes in disease. For example, invertebrate models often carry far fewer genes than mammals and do not have the paralogues or even orthologues found in the mammalian genome, making modelling of some disorders impossible. Genetic systems in fish may be relevant for some disorders but the manipulation of the fish genome is nowhere near as sophisticated as that for mouse, and cannot currently give us the refined models we work with for human disease, and again, fish may not have the specific genes we wish to investigate. For complex genetic disorders such as Down syndrome (a chromosomal disorder) the technology simply does not exist to model such features in any system other than mouse.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For all tests it is important that mice have no additional stress, therefore mice are handled by experienced operatives only, calmly, and are habituated to testing rooms as well as arenas if possible.
For all handling at all three sites of availability, tunnel handling or cupping are used for all mice, for the benefit of

all animals.

For all tests mice are only housed in modified cages or arenas for the minimum time needed to gather meaningful data.
Mice undergoing phenotyping tests have increased monitoring and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests.
Through experience, we have refined methods for handling and caring for a minority of GA mice strains that demonstrate aversion to handling and disturbances. In such strains, we limit phenotyping procedures (do not perform phenotyping tests that elicit an adverse reaction), take extra care when changing cages and performing welfare checks (moving more slowly and quietly), and only change cages when absolutely necessary to reduce disturbances.
Mice that have been given anaesthetics are continuously monitored -- in the case of sedation until they are fully recovered. These mice then have regular extra checks when they are taken back to their home rooms. When general anaesthetics are necessary, the combinations with least adverse effects will be used.

Pipelines are designed with thought given to the overall experience of the mouse and the number of type of tests any one animal will go through.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from LASA guidelines.
All sites of availability conform to the highest level of quality control on all fronts including husbandry, phenotyping and administrative processes.
Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at REDACTED guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We receive regular information and updates on the 3Rs from all three sites of availability where we work. We also attend 3Rs events. When we develop 3Rs advances ourselves, we present these at 3Rs events.
A retrospective assessment of refinement will be due by 10 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

131. Neural basis of spatial learning and memory

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Hippocampus, Memory, Navigation

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged
Rats	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The hippocampus is a brain structure that supports spatial memory and navigation, in all mammalian species. We aim to understand how hippocampal neurons create a 'map' of space, and how this neural map supports navigation during behaviour. Our specific goals are to understand how hippocampal neurons transform basic sensory information to create a representation of space and how dysfunction of these networks underlies the cognitive changes during aging and neurodegeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our work will deepen our understanding of how the brain represents space (places, directions and distances) and how animals learn to localise themselves in space during development. The study of how hippocampal processing is affected by neurodegenerative diseases may identify early pathological markers that could be used for both diagnostic and therapeutic goals.

What outputs do you think you will see at the end of this project?

The project comprises basic scientific research that will increase our understanding of how the brain supports spatial cognition. The outputs of this project will be new scientific findings, describing how neural activity in the hippocampus (and connected brain regions) supports navigation and spatial memory. The outputs will primarily take the form of publications in peer-reviewed journals, but will also be disseminated at academic conferences and to the lay public via popular science initiatives. Materials, data and methods may, where appropriate, be disseminated via internet download.

Who or what will benefit from these outputs, and how?

In the short timescale, the primary beneficiaries will be other scientists working in the field of learning and memory research. Our research will inform our fundamental understanding of how neural networks for spatial memory and navigation work in healthy adults, during post-natal development, and during aging and neurodegeneration.

In the medium term, the basic science knowledge gained will likely inform broader fields of scientific enquiry, some of which have the potential for clinical translation. For example, understanding how memory networks malfunction during neurodegeneration may inform strategies for developing new pharmaceutical interventions, and understanding how memory networks emerge in development may increase understanding of the clinical symptoms of developmental amnesia patients, and inform the search for therapeutic interventions.

In the long-term, a detailed understanding of the neural-network level mechanisms for learning and memory will be an invaluable aid to designing interventions for memory dysfunction of all types (developmental amnesia, normal aging or neurodegeneration).

How will you look to maximise the outputs of this work?

We will disseminate our research by publishing results in peer reviewed journals. We aim to publish all results,

including those that do not confirm our hypotheses.
We will also present our work to academic peers at scientific conferences (national and international), and engage with the popular science media in order to disseminate our results to the general public.
Raw data and analysis methods will be shared with the scientific community (following peer-reviewed publication), to allow other groups to gain insights from our experiments and reduce replication of work.
In order to broaden the academic reach of our work, we will also engage in collaborations beyond our immediate field. For example, we will collaborate with theoretical neuroscientists, to allow better *in silico* models of how the brain works. We will also engage with clinicians and neuropsychologists working with dementia patients, in order to find how understanding neural networks for memory in rodents can translate into aids for diagnosis or therapy in this clinical population.

Species and numbers of animals expected to be used

- Mice: 1500
- Rats: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project will use rodents, in particular rats and mice. Rodents are good at navigating in familiar environments and remembering what has happened to them there. We already know a lot about the anatomy and physiology of their brains, and in particular of the parts of the brain to be studied in this project. This means that we are well-placed to fill in substantial missing section of our knowledge: how patterns of neural activity create memories (spatial memories in particular), and how the recall of those spatial memories can influence behaviour.
Rats have the specific advantage of being docile and displaying high levels of spatial memory and navigational abilities. Mice, on the other hand, offer unmatched access to genetic tools, allowing us to induce specific gene mutations relevant to diseases such as Alzheimer's disease, as well as using genetic techniques to record from and manipulate functionally/genetically/anatomically defined ensembles of cells.

Typically, what will be done to an animal used in your project?

In the most typical experiment, rodents will undergo a surgical procedure under general anaesthesia, to carry out chronic (long-term) attachment of devices for monitoring neural activity to the skull of the animal. Analgesia will be provided during the surgery and during recovery. Following recovery, the attached devices do not, in themselves, cause any pain or distress to the animal.
Animals will then undergo experiments in which neural activity is monitored simultaneously with behavioural memory testing. The connection of attached devices to systems for amplification and recording of neural signals causes no more than momentary discomfort. Animals will typically be motivated to learn using appetitive (desirable) rewards such as sweet foods, and mild levels of food restriction. Low levels of food are not stressful for the animals, and may also be healthier than a diet based on free availability of food.
Neural recording and behavioural testing experiments typically continue for weeks, or even possibly months.
At the end of the experiment, animals will be humanly euthanized, using an overdose of an anaesthetic agent.

What are the expected impacts and/or adverse effects for the animals during your project?

Some animals may feel pain or discomfort during the recovery from surgery (2-3 days). Post-operative analgesia

will be provided to alleviate this.
Some animals may experience excessive weight loss following food or water restriction. In these cases, animals will immediately be removed from the experiment and provided with freely-accessible food and/or water.

In some experiments, specific brain regions may be lesioned (destroyed), in order to test what role these regions have in learning and memory. In rare cases, lesions may be followed by seizures. In the first instance, these will be controlled by administration of benzodiazepines (following veterinary advice). If seizures cannot be successfully controlled using this method, the animal will be humanely killed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

30% of animals will experience the severity category 'Mild'.
70% of animals will experience the severity category 'Moderate'.
What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The core aim of this project is to understand how patterns of activity in neural networks create representations of the world (for example, maps of an environment, and an animal's place within it), and how these neural representations then drive behaviour. In order to achieve this, we must study the activity of networks of neurons in animals, as the animals are engaged in the behaviours that we are researching (the expression of spatial memory).

Which non-animal alternatives did you consider for use in this project?

Computational modelling, *in vitro* studies of neuronal activity, research in humans, research in less sentient animals (e.g. insects).

Why were they not suitable?

Computational modelling: we have collaborated (and will continue to do so) with colleagues who devise computational models of hippocampal function and we have used these to design experiments and predict their outcomes, but all existing models are extraordinarily simple in comparison to the complexity of the brain, and cannot substitute for experiments themselves.
In vitro studies: whilst *in vitro* studies can (and have) give information about single neurons or small isolated networks, the only suitable method for studying the normal function of neural circuits underlying complex behaviour is by studying neurons in the intact, behaving animal.
Less sentient species: no homologous structure to the hippocampus has been described in less sentient (non-vertebrate) species.
Humans: implantation of chronic indwelling electrodes in humans is only permissible in a very small number of clinical situations and thus is impractical for most research purposes. There is no noninvasive method of

monitoring the firing patterns of groups of individual neurons in humans. Human neuroimaging techniques (fMRI, PET, MEG) lack either fine temporal resolution (PET and fMRI) or fine spatial resolution (MEG), and anyway deal with comparatively large sections of cortex. They cannot provide information about individual neurons.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of experimental animals have been estimated using a) power analyses, b) experience from previous published studies of effect sizes, and group sizes necessary to test effects, c) group sizes necessary to test effects in our own previously published research.
A pure power analysis approach is not always appropriate for *in vivo* neural recording experiments, as the number of animals required will depend on the success rate of neural recording (numbers of neurons per animal). It is therefore necessary also use estimates based on previous experience of similar experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will seek advice from the University's applied statistics advisors.
We will follow the ARRIVE and PREPARE guidelines and use the NC3Rs Experimental Design Assistant.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies, allowing us to explore whether hypothesized experimental effects may be present, before committing larger number of animals.
Technical developments which enable us to monitor the activities of larger numbers of brain cells in each animal.
Use of computational models that enable us to make highly specific testable predictions about the role of hippocampus and other structures in spatial memory, minimizing the number of experiments required to reach a conclusion.
Most procedures involve long-term experimentation with the same animals, allowing for within animal comparisons, which significantly reduces the number of animals needed to reach statistically significant conclusions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The model animal used will be rodents (rats and mice).

The major methods used will be:

- Behavioural training. This is necessary to assess cognitive learning and memory capabilities in animals. The large majority of these tests will use only appetitive (rewarding) stimuli, hence the only harm is mild food or water deprivation.

- *In vivo* neural recording. This is necessary in order to be able to draw direct functional links between neural activity and behaviour. Neural recording implants do not cause suffering and distress in themselves, hence the potential for pain and suffering is confined to the post-surgical period (in which analgesia will be provided, see below for details).

Why can't you use animals that are less sentient?

The rodent is the most appropriate animal for the study of the spatial functions of the hippocampus. Laboratory rats display high levels of spatial memory and navigational abilities, and their spatial and non-spatial memory has been tested extensively for over 100 years.
In order to investigate which neural circuits support learning and memory, it is necessary to assess neural function in awake and behaving animals, such that direct inferences can be drawn regarding how neural activity patterns influence behaviour.
Less sentient species, for example invertebrates, do not have brain structures homologous to the hippocampus, and thus are not an appropriate model for learning and memory in mammals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Almost all of our behavioural tests will use appetitive (rewarding) stimuli, the only aversive tests used will involve, for example, bright lights/loud noises or mild air puffs. Animals will be motivated to seek reward using mild food or water deprivation, we will only use the minimum levels of deprivation, for the minimum duration, necessary to achieve uniform consistent behavioural results. Water deprivation will only be used in experiments where food deprivation proves inadequate. On the basis of previous experience, food deprivation will be sufficient in the clear majority of cases (estimated 80-90% of animals used).

Animals are given extensive post-operative care including antibiotics and analgesics where they will be deemed to be necessary. Analgesics are always administered pre-operatively.
Animals are closely monitored throughout the experiments and any signs of problems with implants or other aspects of surgery are immediately dealt with, or, if this is not possible, the animal humanely killed. Similarly, animals are closely observed and monitored during the recording experiments and during interactions with other animals.
Housing cages will be spacious and enriched with rodent toys, chewable materials such as wood, running wheels and a shelter, unless these interfere with the experimental design.
We will use wireless recording systems where possible, in order to eliminate any distress caused to the animal by the recording tether.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Resources hosted on the NC3Rs website, in particular:

- ARRIVE guidelines on experimental design and reporting results.

- 'Procedures with Care': 'Aseptic Technique in Rodent Surgery'.

- Rodent housing and husbandry
- Rat and Mouse Grimace scales

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will use the resources published on the NC3Rs website to ensure that the group undergoes continuous training and professional development with respect to the 3Rs.
We will follow technological advances in the published scientific literature, allowing more efficient recording techniques (yielding more neuronal data per animal), miniaturising recording equipment (leading to a refined animal experience) or allowing recording in more naturalistic settings (for example, wireless recording).

Home Office

NON-TECHNICAL SUMMARY

132. Neural circuit dynamics underlying cognition in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The overall aim of this project is to understand how brain cells communicate and how that supports cognition, the mental operations to obtain knowledge, thought, experience, senses, and complex behaviours. In addition, we will investigate how these functions go wrong in diseases, such as dementia and intellectual disabilities with the aim to find new drug targets or treatment windows for these conditions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A central question of studying the central nervous system is how complex mental operations in the brain emerge from the constant interactions among nerve cells representing sensory stimuli, motor processes and emotional conditions across various brain regions. Presently the level of knowledge that neuroscientists possess about the underlying biological events that give rise to perception, memories, thoughts, and decisions is very limited. Accordingly, we are still essentially lacking detailed knowledge of root causes for many neurological disorders, including dementia and intellectual disabilities. One possible angle which attracts intense interest is that it might be possible to understand complex mental operations and their defects in disease at the level of a neural circuit, a population of interconnected nerve cells that are collectively activated for a common task.

What outputs do you think you will see at the end of this project?

Our project aims to identify ‘responsible connections’ among nerve cells, whose connection strength is adaptable to mental processes such as learning, memory and decision making in the brain. With such knowledge, scientists will be able to selectively target these connections to enhance their performance in dementia and intellectual disabilities as treatment. Furthermore, nerve pulses among these connections will be detected by medical devices, so that an abnormal pattern of such nerve signals can be used as a ‘marker’ for early diagnosis well before obvious symptoms appear in patients, such as Alzheimer’s disease. In addition, our results may identify a ‘critical time window’ when preventive measures targeting these nerve cell connections can still be effective before they degenerate. These new discoveries will lead to publications, available to the general public.

Who or what will benefit from these outputs, and how?

Our new knowledge towards a detailed understanding of the neural basis of mental processes that generate memories, thoughts and decisions will be valuable for other researchers in basic neuroscience research and raise awareness and curiosity in the general public as to how our brain works.

The new knowledge regarding why, when and how these mental operations collapse in disease will be indispensable for translational scientists, clinicians, and drug companies. In the long run, it will be invaluable for novel strategies and applications in battling against dementia and intellectual disabilities, including AD.

How will you look to maximise the outputs of this work?

We will collaborate or foster potential collaboration with colleagues who share a common interest with us in the physiology of cognition and its dysfunction inside and outside the institution, potentially including industrial partners as well.

For example, we will disseminate all new knowledge internally within the research institute, the university, and

nationally.
We will present our results to British Neuroscience Association meetings and UK DRI Connectome Meetings as well as other informal seminars and symposiums. We will then present our results in international conferences in Europe and the USA to further disseminate research findings internationally. This will include e.g. FENS meetings and SfN meetings.
Finally, we will strive to publish our results in respected journals in the field, such as Neuron, Nature Neuroscience, Nature Medicine, Journal of Neuroscience and eLife.
In these ways, our scientific results and experimental 'know-how' will be shared as early and wide as possible.

Species and numbers of animals expected to be used

- Mice: 6960

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mice in our project. This is because many cognitive processes happening in humans can be observed or replicated in mice. Furthermore, mouse models of dementia and intellectual disabilities such as Alzheimer's disease are essential for the understanding of the progressive changes in neural circuits responsible for cognitive decline. We will predominantly use adult mice as they are mature and capable of adapting to behavioural training and experimental procedures more effectively.

Typically, what will be done to an animal used in your project?

Some electrophysiological recording and/or optical imaging experiments will be performed in animals under terminal anaesthesia.
In other experiments, animals will first undergo a surgical procedure under general anaesthesia to allow the placement of a head-ring or cannula and then recover before further behavioural training if necessary.
After recovery, behavioural training will be performed If it is required for relevant scientific questions. After behavioural training, animals will be subject to electrophysiological recording (maximal 10 days, once a day) and/or optical imaging sessions (maximal 10 days, twice a day) under fully awake conditions.
Upon the completion of planned experiments mice will be killed by a non-schedule 1 method which is licensed for the purpose of tissue collection, or by a schedule 1 method.

What are the expected impacts and/or adverse effects for the animals during your project?

The maximal level of severity expected in this study is moderate.
For the maintenance of genetically modified mouse lines, we do not generally anticipate adverse effects. If disease mouse models are to be used. Symptomatic animals with negative phenotypes will be maintained only to the humane end-points defined in this licence.
Some of the experiments will be performed on anaesthetised mice. In those the depth of anaesthesia will be carefully monitored. In addition to general anaesthesia, animals will receive local anaesthesia in the surgical sites and analgesia to reduce distress and pain.
In some experiments, animals will first undergo a surgical process under general anaesthesia to allow for example the placement of a head-ring or cannula, and then recover before further behavioural training.
Complications during surgery and recovery are rare, but animals will be closely monitored for any sign of

discomfort, pain or ill health. If complication occurs, they will be dealt with swiftly using standard veterinary procedures.
Some animals will be water or food-restricted in their home cages to motivate them to perform cognitive behavioural tasks for water or food rewards. In such case, animal's weight will be strictly monitored and controlled to a maximal threshold that is approved by the licence, without affecting the animal's general wellbeing.
Specific checkpoints related to specific adverse effects have been detailed in each protocol.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Moderate.
All animals used in this project, except for the maintenance of general genetically modified mice protocol 1 (mild).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The primary objectives of this project are:
1. To understand how real-time neural circuits operate underpinning cognitive demand, such as network oscillations, memory, and decision making.

2. To understand what happens when these mechanisms break down, causing neurological disease such as dementia.

Firstly, it is not possible to manipulate specific neural cell types, the molecular and cellular pathways in healthy humans and those who have diseases e.g. dementia. Therefore we need another method to investigate how these processes impact cognition and its deterioration.
Secondly, cognitive processes cannot be fully recapitulated in vitro, such as cell culture, 2D or 3D organoid and invertebrate model systems. Using an in silico model, such as computational simulation of cognitive processes, it cannot be fully assured without using valid animal models paired with well characterised behavioural tasks.

Finally, transgenic mouse models are powerful tools to render targeted manipulation of cell types, pathways and circuits in vivo. In addition, mouse models of dementia and intellectual disabilities such as Alzheimer’s disease are essential for the understanding of the progressive changes in neural circuits responsible for cognitive decline.
Therefore, using mice in the current research plan is still needed.

Which non-animal alternatives did you consider for use in this project?

We will shift a considerable amount of experimental data generation, such as basic physiological and pharmacological studies to in vitro neural culture, 3D organoid and brain slice preparations.

We will also employ computer-based neural network modelling/analysis.

Why were they not suitable?

Data generated using non-animal alternatives mentioned above are not sufficient to answer the core objectives of this project.
In vitro neural culture, 3D organoid and brain slice preparations can be used to generate hypothesis and to determine cellular and molecular causes or changes in neural circuits associated biology and pathophysiology. But these results can't be directly linked to real-time brain computation processes which are the core question of this project, because these in vitro systems do not generate complex behavioural and (ab)normal memory or executive function.
Silicon computational simulation will provide conceptual predictions of how neural circuits perform in realistic models. But these theoretical leads must be proved or disproved by data generated from a real brain.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Apart from the breeding and maintenance protocols (Protocol 1&2), the numbers of animals to be used are estimated based on the average of estimated sample size (n=15, please see next section for further discussion):
Protocol 1 & 2: We estimate that we need up to 10 breeding cages for each of the 6 transgenic mouse lines, considering changing mating pairs about every half-year over a period of five years. After genotyping, mice with desired genotype and their wildtype littermates will be used in corresponding protocols. Their numbers have been estimated in protocols 3 and 4 (see following). Offspring of mating pairs which are not going to be used in protocols 3 and 4 will be culled.
2 mice X 10 cages X 6 lines X 10 times of changing mating pairs in 5 years = 1200 mice
Additionally, the required number of mating pairs for each line will be monitored 'on-line' and flexible according to our scientific progress. If scientific evidence shows that the active mating for the line is not required, we will reduce the number of mating pairs accordingly.
Protocol 3 & 4: We take the single-cell recording to estimate the likely maximal number of animals we may need because other recording or imaging procedures may be paired with it when using the same mouse. In such a way, we will reduce the total number of animals.
We aim to have N=16 for 6 (an initial estimated number) different recording parameters (such as intrinsic properties, LTP, LTD, spike phase locking, etc) Each parameter requires one recorded cell. (We aim to obtain more parameters from one recorded cell, but this can't be guaranteed.) We will use 1 cell from 1 animal for 2 genotypes for 6 transgenic mouse lines over two different ages. In addition, we may follow 2 different protocols. To be cautious, we also estimate the possibility that one quarter of these experiments (e.g. key findings) may have to be repeated for reproducibility.
16 mice X 6 parameters X 1 cell X 1 mouse X 2 genotypes X 6 lines X 2 ages X 2 protocols X 1.25 repeat = 5760 mice
To sum up, the estimated maximal number of mice for the 5-years period will be:
1200 + 5760 = 6960 mice
About 1100-1400 mice are likely to be used annually according to our protocols to achieve our objectives.

What steps did you take during the experimental design phase to reduce the number of animals being

used in this project?

We are taking the following considerations in the experimental design phase:

1. **Unbiased and randomisation.** First, we will make sure all mice are housed in identical environments with similar husbandry. Second, we will randomly select mice for treatments/measurements in our protocols. Finally, the experimenter will be blinded during experiments as possible as he/she can unless apparent phenotypes prevent such blind design.

2. **Pilot experiments.** For each set of parameter comparison in this project, we will always start with a 'pilot cohort' with a small sample size, such as 6 animals per group. We will be able to improve the quality and efficiency of our overall design with the information obtained from these pilot data.

3. **Power analysis:** After data obtained from pilot experiments, statistics are then used to test whether sufficient animals have been used per group. The same experiment may then be repeated, or not, to test whether our initial design provides sufficient power (e.g. 0.8 or 0.9). Power calculation (https://powerandsamplesize.com/Calculators/) will be used to further test our initial estimation. Besides, the PPL applicant has access to a local full-time bioinformatician/biostatistician for consultation.

4. **Sample size estimation**: In addition to power analysis, the estimated sample size is likely between 10 to 20 to obtain statistically significant results. This estimation is based on previously published work of the PPL applicant, as well as recently published work in well-respected journals by immediate peers in the field (cellular/systems neuroscience).

For instance, in a comparison of 2 means with 2-sided equality, assuming group 'control' mean is 100 and group 'treatment' mean is 70 (expecting a 30% difference), standard deviation as 30, power as 0.8 and α as 0.05, the calculated required sample size is 16.
(http://powerandsamplesize.com/Calculators/Compare-2-Means/2-Sample-Equality)

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

First, lead experiments have been performed by the applicant during his previous scientific training to confirm the technical feasibility of demanding electrophysiological recording (such as in vivo patchclamp recording) as well as quantitative behavioural designs. Besides, the reproductivity for the animals being successful in learning the proposed behavioural tasks within the proposed time window has also been verified.
Second, researchers will receive extensive training for the procedures in the proposed protocols where technical expertise significantly influences the success rate. Therefore, the number of animals to be used will be significantly reduced as experimental 'error testing' using animals will be minimised.
Third, we will maximise the data acquisition from a single animal whenever appropriate during the project. For example, the single-cell recording could be paired with population recording, local field recording or imaging.
Finally, computational simulation and in vitro preparation, such as cell culture, slice culture, acute slices will be used in classical physiology/pharmacology experiments related to the core objectives of this project. This will reduce the overall number of animals to be used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and

methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using mice because their central nervous system is sufficiently similar to that of humans, which is essential for investigating mechanisms of cognition such as network oscillations (brain waves), memory and decision making We will use wildtype mice and a few transgenic mouse lines, including mouse models of dementia, e.g. Alzheimer's disease and frontotemporal dementia.
We will predominantly perform in vivo single-cell and population electrophysiology recordings and Ca^{2+} imaging in this project. Some experiments will involve training animals to perform cognitively demanding tasks. During behavioural training, we will always keep fine-tuning our protocols and apparatus to minimise stress and increase comfort for the animals.
These methods to our knowledge, are most up-to-date, necessary scientific tools to address objectives set in this project.

Stereotaxic injection

Stereotaxic injection is used to directly introduce pharmacological agents, viral vectors, dyes etc., to targeted regions and/or cell types in the brain. This is more defined than other ways to delivery agents to the brain, such as intravenous or intraperitoneal injection. It is a short procedure performed under general anaesthesia with quick recovery.

In vivo electrophysiology recording

In vivo electrophysiology such as patch-clamp recording or high-density silicon probe recording will be used to record electrical activities (the commutation between nerve cells) in real-time from targeted regions in a computing brain at single-cell or population levels with high spatial (as good as subcellular specificity) and temporal resolution (as good as sub-millisecond specificity). The obtained data are far more informative and precise than traditional sharp electrode or EEG recordings in vivo. To our knowledge, they are the most refined methods in the field to date and will be performed under general anesthetised or awake conditions that animals have been well habituated and trained to minimise stress and discomfort.

In vivo Ca^{2+} imaging

Single or two-photon imaging methods are used to visualise in real-time cellular or neural network activities in targeted brain circuits in a living brain. They can simultaneously provide morphological and activity data with unprecedented detail in vivo. Therefore, they are more refined than other methods to visualise brain activities with high spatial and temporal resolution. These methods will be performed under general anaesthesia or awake conditions that animals have been well habituated and trained to minimise stress and discomfort.

Behavioural training in virtual reality

Virtual reality is used to train head-restrained mice to perform simple cognitive tasks such as spatial navigation and decision making. Virtual reality system provides simulated environments, which can be well controlled with minimised human (experimenter) interference, allowing consistent training/measuring conditions, opportunities to use a wider variety of experimental parameters and more precise control/ measurements of perceptual stimuli/responses of the tested animal. Therefore, behavioural training in virtual reality is more refined than many other traditional behavioural paradigms, and the most appropriate in our project setting.

Why can't you use animals that are less sentient?

The scientific focus of this project is cognition.
Invertebrate models such as fly or zebrafish can be used to study simple responses of neurons to external stimuli and molecular, cellular pathways that cause certain neurological diseases. However, they do not have complex behavioural, memory and cognitive biology and thus it is not possible to study the neural circuitry dynamics that render high-order brain function/dysfunction.

Like humans, mice can integrate sensory and non-sensory information from the outside world as well as their own to command complex behaviours that are vital for their survival, such as foraging, escaping from predators and mating. In addition, mouse models for dementia and intellectual disabilities such as Alzheimer's' disease share many pre-clinical and clinical symptoms including cognitive impairment that

are well characterised in human patients. Furthermore, mice can be readily manipulated genetically allowing target-specific testing of the anatomy and function of neural circuits with high spatial and temporal precision.

Finally, we have planned a significant amount of experiments using mice that will be terminally anaesthetised (see protocol 3) precisely for this consideration.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will use well-established methods and agents for anaesthesia and analgesia in any potentially painful procedures such as surgery. Extra-monitoring/care will be provided to these animals for at least 24 hours after the procedure.
We have made refinement considerations in the following aspects of the project:

1. **Animal husbandry**. Mice will be housed in an enriched environment in their home cages. Small toy items for running, tubes, gnawing sticks for social interaction and safe nesting material will be provided. The disturbance will be kept minimal.

2. **Surgery**. We will carefully select the combination of anaesthetics as well as analgesia. We will calculate the dose for each animal (e.g. via i.p.). Whenever possible, we opt to use the respiratory route, which allows precise control of the depth of anaesthesia and rapid recovery. We also set a post-surgery husbandry scheme (please see details in relevant protocols) to monitor animal's condition to minimise pain and discomfort.

3. **Behavioural training**. Detailed refinement schemes have been provided in the relevant protocols. Briefly, mice will be first made familiar with the experimenter over short daily handling sessions before daily habituation sessions with the apparatus start. We will use a tube to move mice from cage to experimental equipment. Mice will only start to learn tasks when they show no sign of distress.

4. **Behavioural design/equipment**. We will be kept informed with novel designs and new apparatus in the field that can significantly reduce animals' discomfort but provide robust scientifically relevant behavioural readouts. For instance, we are aware of and maybe soon testing the 'Mobile Home Cage' design (https://www.neurotar.com/product/mobile-homecage-mhc-v5/), which may allow mice to navigate more naturally in comparison with virtual reality.

5. **Recoding/imaging sessions**. We have set the maximal number of allowed recording/imaging sessions from a single animal and the maximal length of a single session (Please see details in relevant protocols). Whenever possible, we will reduce the number of repeated sessions and shorten the length of each session.

All these considerations above are aiming for minimising pain, suffering, distress, or lasting harm to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

First, routes and volumes for the administration of substances are taken from the Laboratory Animal Science Association good practice administration of substances guidelines 1998 (http://www.procedureswithcare.org.uk/lasa_administration.pdf).
Second, we will consult the following guideline specifically for in vivo electrophysiology experiments: Recommendations for the Design and Analysis of In Vivo Electrophysiology Studies *The Journal of Neuroscience*, June 27, 2018 • 38(26):5837–5839

Additionally, we will follow established institutional guidelines for in vivo imaging experiments.

Third, we will follow published local institutional 'Guidelines and Policies for Good Practice' in all procedures involving animals.
Finally, we will comply fully with the following guidelines published by the UK government:
Home Office Guidance:
1. Animal research: technical advice:

Technical advice and guidance for licence holders.
2. Guidance on the Operation of the Animals (Scientific Procedures) Act 1986

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep efficiently up to date with any new paradigms, protocols, technologies that are aiming to refine experimental procedures but at the same time able to maintain feasibility to test our scientific questions.
We will collaborate with colleagues, attend seminars and conferences nationally and internationally to be consistently updated regarding any new procedures which promote animal's welfare in our ongoing project.
At each stage of the project alternative ways to investigate our questions will be considered such as computational models.

Home Office

NON-TECHNICAL SUMMARY

133. Neural mechanisms regulating cardiovascular homeostasis in health, disease and ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Ageing, Neurohumoral regulation, Hypothalamus, Hypertension, Autonomic nervous system

Animal types	Life stages
Rats	adult, aged, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We will expand on the hypothesis that during ageing, the development and/or maintenance of disorders of the cardiovascular system are associated with changes in the expression of a network of genes in the nervous and endocrine systems that form functional networks and that are influenced by lifestyle and nutritional choices, environmental stimuli, age and sex. We will continue to identify key genes and modes of gene regulation in these networks and determine their contribution to the biological system as a whole.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Despite the inevitability of old age, little is known about pathophysiological processes that result in the accompanying homeostatic deterioration. Focusing on two linked aspects of the ageing process, namely osmoregulatory and cardiovascular dysfunction, we will ask how nutritional choices, based around high-salt intake or water deprivation, can act at a genetic level to result in homeostatic imbalance. In order to address the gaps in knowledge revealed by this unmet medical need, we will study the involvement of the nervous system as a master regulator of these functions. In the short-term, the proposed studies will generate important basic knowledge about the way that the nervous system modulates cardiovascular and osmotic homeostasis, and how imbalances lead to disease states. In the
long term, we anticipate that these studies will provide essential information necessary for the development of innovative therapeutic approaches (drugs and gene therapy) for the homeostatic deterioration that accompanies old age.

What outputs do you think you will see at the end of this project?

In the short-term, the proposed studies will generate important basic knowledge about the way that the brain controls the cardiovascular and osmoregulatory systems, and how these mechanisms can go wrong in old age. In the long term, we anticipate that these studies will provide essential information necessary for the development of innovative therapeutic approaches (drugs and gene therapy) for cardiovascular diseases (particularly hypertension). As is our habit, new data in the form of research results will be published in a timely fashion in high-impact, peer-reviewed international journals. By publishing in open access journals, and dissemination at national and international conferences, all data will be freely accessible to the research community. We will share our experiences at 3Rs conferences. All genomic datasets will be deposited in public databases. All novel clones, vectors, animal models, tools and reagents etc. will be offered to the research community upon publication of the primary results subject to costs and availability constraints. Novel viral vectors will greatly benefit the research community. We will modify and update our existing website to enable it to be a forum for communication and dissemination of information about this project.

Who or what will benefit from these outputs, and how?

The proposed research is essentially multidisciplinary in nature and will be of interest to many different research communities, including neuroscientists and physiologists. As we may uncover novel drug targets, the research will also be targeted at pharmacologists. Further, one of the fundamental questions in modern biology is the link between a cell's dynamically modulated transcriptome and its functional phenotype(s). Thus, our exploration of this question in a physiological context will also interest molecular geneticists and anyone engaged in the broad theme of functional genomics. In the medical setting, clinical scientists studying and treating hypertension, cardiovascular and metabolic diseases will find worth in our results. Likewise, our data may influence pharmaceutical companies especially in the medicinal chemistry field. We anticipate that our development of technologies, such as cell-specific viral gene manipulation tools, will be of interest to many scientists as they

seek to refine their work.

How will you look to maximise the outputs of this work?

ACADEMIC
*Project Specific Objective – publication.
We will disseminate our results in relevant high-impact, open-access journals, including opinion pieces where relevant.
Deliverables - a minimum of 10 publications in the most appropriate journals to reach specialists in the field and those with a broader interest
*Project Specific Objective - conferences and seminars.
We will present our work at local and international conferences and at invited seminars.
Deliverables – major local (British Society for Neuroendocrinology (BSN) annual meeting; Society for Endocrinology annual meeting, 3Rs conferences) and international (Experimental Biology, USA) impact.
*Project Specific Objective - collaboration.
I have considerable experience initiating and managing major international collaborations. I have also initiated collaborations with mathematicians with a view to the better exploitation of big transcriptome datasets. We work with leaders in the field to carry out state-of-the-art-work on predictive mathematics, algorithm development, and bioinformatics.

Deliverables – active development of project specific bioinformatics tools and sharing of experience and dissemination with local Bioinformatics Users Group.
*Project Specific Objective - training.
There remains a dearth of scientists with the combination of skills that enables integration of bioinformatics, genomics and molecular genetics with whole animal in vivo physiology, but there is an increasing demand for such approaches within academia and industry. This is being driven by the postgenomic era and the need to determine the functional meaning of genomic data at the whole animal systems level. This project will contribute to the training of young scientists in these areas of high demand.
Deliverables – Intensive bioinformatics training, and continual training and professional development for all participants.
PUBLIC SECTOR
*Project Specific Objective – policy development
We envisage a contribution towards evidence based policy making and influencing public policies and legislation at a local, regional, national and international level. As such we also expect an impact with nutritionists, dieticians and occupational therapists, as well as care-of-the-elderly and geriatrics specialists. It is particularly important that we raise awareness of the importance of proper hydration in the elderly. With the support of the Institutional Policy team, we will develop a focused, targeted and timely engagement strategy that delivers the key messages and policy implications of the findings to the relevant stakeholders. Outputs may include a workshop with relevant policymakers/an interactive tool/case study to demonstrate implications of the research for policy, as well as accessible, targeted policy briefings.
Deliverable – cultivation of links with NHS and public health colleagues.
COMMERCIAL PRIVATE SECTOR
*Project Specific Objective – commercial exploitation
In the event that our results reveal commercial possibilities, these will be eagerly pursued where in the best interests of the research and impact.
Deliverables – regular discussions with our commercialisation team with a view to exploring the possibility of exploiting our findings commercially.
THIRD SECTOR AND THE GENERAL PUBLIC
*Project Specific Objective – public engagement
We view engagement with the public about scientific research an important component of being a scientist.
Deliverable – as the results are rolled out, we will work with the Institution Public Relations team with a view to obtaining press/TV coverage of our work.

Species and numbers of animals expected to be used

- Rats: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In order to understand mammalian cardiovascular homeostasis and its pathologies, it is necessary to study the adult animal, in this case rats, the most tractable model for physiological studies. In some cases, juvenile animals will be examined (before they have developed hypertension). In other cases we will examine the cardiovascular and osmoregulatory morbidities that are prevalent in older rats, as indeed they are in elderly humans.

Typically, what will be done to an animal used in your project?

We want to understand the functions of novel nervous system genes in the control of the cardiovascular system, and how these genes are involved in the development of cardiovascular diseases, particularly hypertension. To do this, we alter the activity of genes or cells in the rat, then monitor the physiological consequences using non-invasive methods where possible. To achieve these ends, surgery is required in order to introduce drugs or genetic tools, or to implant devices into the animal that monitor physiological parameters. Surgery typically lasts for no more than three hours, and recovery is rapid over the following 3 days. We will change the diet of some animals (e.g. high salt) in order to induce high blood pressure and osmotic changes. Experiments can last as little as 48 hours, and usually last for no more than a month. However, as cardiovascular diseases in humans are chronic, it is sometimes necessary to monitor an animal for up to 6 months.

What are the expected impacts and/or adverse effects for the animals during your project?

As a result of surgical procedures, animals will experience short term moderate pain. This will be alleviated as much as possible using analgesic drugs. Some animals will develop high blood pressure. This does not result in obvious effects on activity, health or behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About half of the animals will undergo moderate (surgical) procedures. The rest will experience mild (non-surgical) conditions.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are necessary because we propose to investigate the workings of the whole animal, specifically how the nervous system controls the cardiovascular system, and how this goes wrong in high blood pressure. These mechanisms can only be understood within the physiological integrity of the whole organism.

Which non-animal alternatives did you consider for use in this project?

We have considered cultured cell lines. Indeed, for many experiments on basic signalling pathways and transcriptional regulation mechanisms, we use cell lines to establish principles that are then tested *in vivo*.
In addition, the efficacy of all our viral constructs is first thoroughly evaluated in vitro prior to use in vivo. **Why**

were they not suitable?

Cell lines corresponding to adult neurons do not exist and currently available in vitro techniques for the study of the brain, and its interactions with the body, are deficient and are of dubious physiological relevance. Further, these techniques often require the use of use cells and tissues taken from juvenile animals, thus demanding the sacrifice of large numbers of rats.
That said, we are currently exploring the use of organotypic and explant methodologies with encouraging preliminary results.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We estimate that we will study 10 genes in 5 nervous system regions. For each gene we will carry out 3 experiments. Each experiment will involve 20 animals. 10x5x3x20=3000.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs' Experimental Design Assistant in order to ensure that our plans are critiqued and finely tuned. In all cases, the experimental unit is a single animal. In the past, we pooled animals to give individual experimental units, but thanks to improvements in the sensitivity of techniques, single animals can now be used. Note that technical improvements also enable us reduce animal use by simultaneously extracting DNA, RNA and protein from the same tissue sample.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We comprehensively and non-invasively physiologically assess each animal. These data are compared to molecular data in order to obtain as much useful information as possible. In addition, where possible and valid, we share animal tissue with other collaborating groups in order the maximise data harvesting.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use animal models that enable us to study how the nervous system controls the cardiovascular system, and how these mechanisms go wrong in high blood pressure. The following models are employed:

1. We use a genetic model of hypertension. In the Spontaneously Hypertensive Rat (SHR), high blood pressure develops with age without any surgical or nutritional intervention.

2. We use nutritional models. We alter the availability or content of diet to mimic human conditions that result in cardiovascular changes such as dehydration and high salt consumption. These models are not stressful to the animal.

In these models, we will alter the activity of target genes. In some cases, we will use well-characterised drugs, but in most cases we will use highly specific genetic methods. We use viral vectors to deliver genetic tools to specific brain regions. These genetic tools allow specific genes to be up- or downregulated. We can then monitor the physiological consequences.
We use the most up-to-date non-invasive methods to monitor the physiological consequences of gene manipulation. We use telemetry, which involve implanting a device into the animal. This device either records or transmits real-time data that can then be analysed. At the time of recording, the data acquisition is completely non-invasive in conscious and freely moving animals. This is a great advance over previous methods that used indwelling cannulas.

Why can’t you use animals that are less sentient?

In order to understand mammalian cardiovascular homeostasis and its pathologies, it is necessary to study the adult animal, in this case rats, the most tractable model for physiological studies. We use terminal anaesthesia to harvest tissues, but unfortunately anaesthesia has severe effects on the nervous system that confound and preclude its use in cardiovascular studies. These include changes in gene expression that would affect our transcriptomic and physiological experiments. Indeed, it has recently been demonstrated that anaesthetics uniquely activate hypothalamic neurones (Jiang-Xie LF, Yin L, Zhao S, Prevosto V, Han BX, Dzirasa K, Wang F., 2019, A Common Neuroendocrine Substrate for Diverse General Anesthetics and Sleep. Neuron 102:1053-1065).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are fully aware of the requirement to constantly refine our procedures in order to minimise harm. For example, we monitor animals as often as practical in addition to standard post-operative requirements. We will ensure that pain management procedures are the most effective and up-to-date. We have recently implemented a repeated handling protocol to reduce the stress of subsequent procedures.
In this application, we have changed practise we refine our procedures. Examples are as follows:

1. Previously, we used 72 hours of dehydration and 5 days of salt loading. This has been standard practise in the field. However, in this application, we have reduced dehydration to 48 hours and salt loading to 5 days. Our experience over the duration of our previous licence has informed us that the data obtained will be robust and significant without the need for more animals.

2. Instead of subjecting animals to dehydration or salt loading, we are exploring the use of the use of genetic tools. Using viruses, we can target excitatory DREADDS to vasopressin neurones. hence these neurones can be activated by the drug CNO.

3. In the past we have monitored fluid intake and urine output by placing animals in metabolic cages. We will not do this anymore. Instead, we will sample urine from hydroscopic sand.

4. Animals will be group housed after surgery when intake measures are not necessary.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We monitor the comprehensive and invaluable NC3Rs website (https://www.nc3rs.org.uk).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We keep up to date with advances in the 3Rs by attendance at annual meetings of NC3Rs, where we present data and interact and collaborate with fellow participants. We are kept informed of advances by regular communication from the Institutional animal services Unit, and by our local representative on the Animal Affairs Group. We monitor the NC3Rs website to keep abreast of updates (https://www.nc3rs.org.uk).
My Postdocs are members of early career researcher 3Rs group. The purpose of this group is to provide a forum for raising in-house 3Rs-related issues and discuss potential solutions. They will also act as a hub for sharing existing 3Rs approaches from external sources and consider local implementation.

Home Office

NON-TECHNICAL SUMMARY

134. Neuronal mechanisms underlying Rett syndrome

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Rett syndrome, Sleep, Neurons, Learning, Synapses

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to understand how loss of MeCP2, a DNA-binding protein, affects neuronal activity and causes the symptoms of Rett syndrome.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Rett syndrome is the second most common form of intellectual disability in females affecting 1 in 10,000 females. Furthermore, mutations in MeCP2 are found in approximately 1.5% of males with intellectual disability. This number is expected to increase as genome sequencing becomes more widespread. No treatments currently exist for these disorders. Understanding how loss of MeCP2 affects neuronal function may help us identify new therapeutic targets for this disease.

What outputs do you think you will see at the end of this project?

This project will provide us with new information about how loss of MeCP2 leads to Rett syndrome.

Who or what will benefit from these outputs, and how?

The scientific findings from this project will benefit scientists working on MeCP2, Rett syndrome and memory research. In the longer term, beneficiaries may include human patients suffering from Rett syndrome, their families, and the clinicians responsible for their treatment. Thus, this work should have an impact on health and well-being. Improved treatments for MeCP2-related disorders and intellectual disability would be of considerable economic benefit to society in terms of decreased care costs and hours lost to work for families.

How will you look to maximise the outputs of this work?

We will publish our findings in open access scientific journals and present our findings at scientific and family conferences.

Species and numbers of animals expected to be used

- Mice: 1200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The proposed experiments will use adult mice that contain mutations in the MeCP2 protein, which exhibit symptoms that resemble those observed in patients carrying these mutations in MeCP2.

Typically, what will be done to an animal used in your project?

The majority of animals will be used to isolate brain slices for recording neuronal activity. A small number of

animals will have a device implanted in their brain to record neuronal activity during sleep and in the awake state.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of animals will experience no adverse effects. For the small number of animals undergoing surgery, we expect a quick recovery. However, some discomfort may occur pain after surgery. To minimise this discomfort, animals will receive pain relief before and after surgery. To ensure that no significant distress occurs, animals will be monitored daily and a scoring system will be employed, including the Grimace scale, apetite, and behaviour.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals (95%) will experience no adverse effects. The remaining 5% may experience some discomfort after surgery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Mouse models of Rett syndrome exist disorders exist and these mice exhibit symptoms that resemble those observed in patients. Importantly, mice have neuronal network activity that resembles that seen in humans, and therefore serve as important targets for drug discovery. It is only possible to carry out this project in whole animals.

Which non-animal alternatives did you consider for use in this project?

We considered the use of cells derived from human patients.

Why were they not suitable?

It is not yet possible to study neuronal activity and see how it correlates with changes with behaviour using human cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Our experiments require comparison between mice that lack MeCP2 and normal mice. Due to variation between animals, experiments typically require a minimum of n = 10 mice per experiment. These numbers have been derived from statistical calculations and over ten years of experience performing these experiments.

Much of the data to be gathered in this programme of work will be collected using brain slices. Most of the brain regions that we will study can yield up to six viable slices per animal (three slices containing left and right side of the brain). Therefore, we aim to use slices from one animal on multiple projects simultaneously – thus reducing the number of animals used to provide tissue.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used the proposed techniques for over a decade and generate robust, reproducible data with the minimal number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have spent considerable effort designing and performing mathematical models to study neuronal activity before experiments are designed. It is only when we have a firm, achievable hypothesis worked out from computational models, that we perform experiments using animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The project will use mice that do not express MeCP2 protein and which exhibit characteristics that resemble those observed in patients with Rett syndrome.

The proposed experiments will examine how loss of MeCP2 changes neuronal activity. Most of the data will be gathered using brain slices prepared from adult mice under terminal anaesthesia. However, the nature of the method implies a great deal of abstraction from the ‘real’ situation in the whole animal. Therefore, it is necessary to validate the results in living mice. We will perform these experiments, wherever possible, under terminal anaesthesia. However, there are times when we will use animals that are anaesthetised. Examples of this include when recording neuronal activity that occurs during sleep.

Why can’t you use animals that are less sentient?

The aims of the proposed work involve examining patterns of neuronal activity that are not present in less sentient species such as drosophila, worms etc. We cannot use mice at a more immature life stage because the neuronal activity in these animals is very different.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Most of the experiments will be performed in terminal anaesthesia and as such mice do not experience any adverse effects of the procedures. Some animals will have electrodes implanted in the brain under general anaesthesia in the animal facility. We will minimise suffering by ensuring the best animal husbandry protocols, daily monitoring of the animal, administration of pre- and post-operative analgesics, and veterinary support is available if required.

The animal units uses a rolling environmental enrichment program ensuring all animals are housed in a varied and stimulating environment. This minimizes stress of the animal and reduces boredom.
Scientists also use the nc3r's initiated tunnel/cupping of animals technique as opposed to tail handling, this reduces stress to the animal and ensures the 3R's are being met.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All members of the laboratory are well trained in the proposed experiments and have personal licenses ensuring that best practises are followed. Lab members continually monitor the literature on these issues are refer to the websites such as nc3rs.org.uk.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Members of the lab routinely attend training forums conducted by experts in the 3Rs. These events involve passing on information on recent advances in the 3Rs and often include presentations by experts in animal welfare include members of the NC3Rs and veterinary surgeons. Attendance at these events has led to changes in our experiments. For example, we stopped picking up mice by tail and instead using tunnels when transferring animals between cages or into equipment. We also routinely monitor developments in the field using websites such as nc3rs.org.uk.

Home Office

NON-TECHNICAL SUMMARY

135.Reward Processing in the brain

Project duration

3 years 2 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

brain, reward, learning, decisions

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main reason for our work is to advance knowledge about how humans process reward information in the brain. Our work aims to improve our understanding of how rewards are valued based on key characteristics and how this information is used by the brain when making decisions about which reward is best. To do this, we need to know how the brain processes economic (reward) choices that are the most fundamental processes for survival.
We define the word ‘rewards’ scientifically as stimuli, objects, events, situations or activities that are crucial to our individual survival and that of our species. We are interested in how reward mediates learning, approach behaviour (getting closer to an object or stimulus because an animal or human likes it and/or wants it), economic decision making (the process underlying the choice between rewards) and emotions.
The basic way reward and economic decisions are processed in the brain appears to be very similar between humans and non-human primates. This means the non-human primate (NHP) work we do can be used to understand the fundamental brain processes in the healthy and the diseased human brain.
As a result, our work will contribute to our understanding of the processes that drive drug addiction in humans,

A retrospective assessment of these aims will be due by 30 March 2024

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

By understanding the brain signals underlying the reward and economic decision processes will enable us to understand the basic building blocks of reward directed behaviour and explain why such decisions may go right or wrong.
It is now thought that cells called neurones (nerve cells) in the brain detect rewards but not how such 'reward signals' detected by these neurones lead to the choices we make. There are good learning and decision theories available, and we will use them to formulate and answer our questions. For example, how does the brain detect fatty and sugary food and liquid rewards that lead to obesity that is so harmful to so many people? Other examples of our research will look at how uncertain rewards are processed and how this may lead to irrational choices that are harmful to humans.
Knowledge of normal processes is fundamental if we are to understand what goes wrong in reward disorders such as obesity, risk taking and drug addiction. Any, even minor, advances are likely to help the search for treatments that could save thousands of lives.
In addition, because in our daily life we receive many different rewards, we also need to understand how the brain interprets the rewards other humans are getting and how this affects the way we behave. To understand why we misjudge rewards in friendly and unfriendly situations may help us understand how to reduce social conflicts. The knowledge gained from these experiments should help us to understand the abnormal processes in reward addiction, obesity, gambling, attention deficit disorder and other disorders, and provide further steps to improve human health and welfare.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Non-Human Primate, 7-9 animals (transferred from current licence).

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Our NHPs live in rooms that house 2 to 4 animals. This is considered an appropriate number to ensure their welfare. Unfortunately, some animals will fight as they get older and try to establish hierarchies. This can result in injuries and the need to separately house animals for their safety. A separately housed animal will always be able to see, hear and communicate with the other animals living in the same room. If socially compatible, separately housed NHPs will have periods of time during which they are allowed to have direct contact with other NHPs; these contacts will enable them to groom each other and to conduct other social activities; however, these contacts this will be closely supervised.
It takes us several months to train our animals to enter the laboratory from their living area and to perform specific tasks. These tasks include making choices by moving a joystick in front of a computer monitor to obtain a fruit juice reward. It is not unusual for NHPs to remain focused and busy on these tasks for several hours on a given day. During these periods, the animals sit in a custom designed 'primate chair' (a Perspex box) in a natural position.
When performing brain recordings, we restrain the animal's head movements by connecting an implanted head holder to the primate chair. For experiments where this is required we slowly and carefully train each animal. This can take several months.
Once trained the NHPs are visibly relaxed and will fully engage in their tasks. Indeed, the animal's comfort, cooperation and engagement are essential if we are to obtain useful scientific results. An animal that is not comfortable, or ill, will not perform their task properly; thus, it is in our interest as researchers to make sure our animals are comfortable. If a researcher detects lack of comfort in an animal sitting in the primate chair in the experimental room, we stop and give it a break. We then search for and eliminate the reason for their discomfort. If the situation cannot be remedied during that day's session, we stop the procedure for the day, give the animal any remaining liquid, and return the animal to its holding cage. We do not test the animal in the experimental room before the reason for the discomfort has been eliminated.
During our experiments we control each animal's access to food and fluid. However, when we test the behaviour or record from and/or stimulate the brains of our animals, we ensure that each animal always receives its daily fluid and food requirements, and we make sure particularly attractive foods, such as fruits are provided. Basic, nutrient, dry food (NHP chow, dried fruits, nuts) is available at all times in the home cage. We carefully monitor each animal's weight so we can adjust the feeding regime if necessary. We provide free food and water access at least one day every week, and we give our animals week(s)-long breaks every few months.
In order for us to be able to record the activity of neurones in the brain we have to undertake several surgical procedures on our NHPs. These surgeries normally take about 5 to 9 hours during which our animals are fully anaesthetised (asleep and unable to feel pain). Just like humans undergoing surgery in a hospital, our surgery is performed under fully sterile conditions, and with subsequent pain relief provided as advised by the veterinarian. Brain recordings require each animal to undergo surgery during which metal implants are attached onto the skull. The first surgery is often a metal restrained post. Months later a small chamber may be implanted onto the skull. In a small number of cases, an additional surgery or two may be required to repair an implant. Following surgery, we often locate brain areas we intend to study deep in the brain by using one or more x-ray sessions during which the animals are under sedation anaesthesia. During these sessions we record the activity of neurones, which enables us to specifically identify the brain centres that respond when we touch different parts of the body (which otherwise would disturb an awake animal). We also sedate our animals every few months in order to thoroughly clean their implants. This means each animal will undergo full general anaesthesia for a surgical procedure up to a maximum of four times in its lifetime, plus several periods of sedation anaesthesia for the shorter procedures such as implant cleaning.
We record the activity of individual nerve cells in fully conscious (awake) animals. This is done by inserting

microelectrodes (extremely fine needles, less than one fifth of a millimetre) through a small skull opening within the implant chamber into a specific brain area. The stability of these recordings requires head restraint. These sessions normally last up to 4 hours, exceptionally up to 5 hours, after which the head restraint is removed and the animal returned to its home cage. The head restraint schedule will continue for up to 30 months, and in rare exceptions 48 months. These recording with head restraint are performed up to 5 days each week for several months, after which the animal is given a one- or two-week break before returning to testing.
Electrode insertion does not cause the animal pain, because the dura, which is the tissue covering the brain, has lost its ability to detect pain, and because there are no pain receptors inside the brain. Each animal is likely to experience occasional mild discomfort when sitting for extended periods and after having experienced fluid restriction in the hours before testing starts. However, the occasional discomfort is mild and not sufficient to stop the animal from making sophisticated decisions when offered different choices in order to obtain a reward. The way the rewards are presented is carefully designed to enable the researcher to detect the lack of comfort during the experiment and in the recorded data (for example the NHP will make poor choices or no choices at all). With more intense discomfort that agitates the animal or affects its voluntary choices, we search for the reason and remedy it immediately, or return the animal to its holding cage as described above.
We also inject very small volumes (microlitres) of solutions containing molecules that will label the nerve cells we are interested in the specific parts of the brain. The use of these labels helps us identify the exact neurones for recordings or stimulation using small optical fibres (less than one fifth of a millimetre). Such injections may be done under sedation, in which case this will add to the total number of sedations an animal receives.
Surgery or inserting electrodes is not without risk. Animals can develop brain infection or oedema (swelling), surgical stitches may open, paralysis or mild muscle weakness on one side of the body may occur, or mild and almost undetectable seizures have been seen in rare cases. We treat these conditions with antibiotics, anticonvulsants, pain medication, and other medication as advised by a veterinary surgeon. If affected animals do not show signs of improvement within 12 hours, they are humanely killed. In addition, if the animal has not recovered within 12 hours in cases of pain or complete limb paralysis, 24 hours in cases of brain oedema, or 48 hours in cases of systemic infection and wound healing, the animal is humanely killed. Any animal that develops more than mild, localised and transient seizures that require medication using antiepileptic drugs for more than 24 hours will be humanely killed. Complete paralysis has never been observed and is unlikely to occur and would result in immediately humanely killing the animal.
In summary, each animal will undergo behavioural training for about 1 year after which it will undergo neuronal recordings for up to 30 months, and in rare exceptions 48 months. At the end of this time, each animal is killed humanely.
A retrospective assessment of these predicted harms will be due by 30 March 2024

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

To understand higher brain function and provide crucial information for improving the treatment of human disorders, we need to investigate biological signals in the intact working brain. Understanding individual cells is the key for understanding higher brain function because individual cells are the basic units of the brain that process information. Only by doing this in NHPs can we understand how individual nerves function in relation to behaviour at a level found in humans.
Computer simulations, tissue studies and human brain imaging do not permit researchers to study the activity of individual brain cells.
Other animals such as insects or rodents do not have the complex human like behaviour, the highly developed brain structures of interest (e.g. frontal cortex and connected structures), do not permit sufficiently precise

distinctions between reward, decision making and movements, and thus do not allow identification of reward and decision brain cells. Despite some progress in investigating the activity of brain cells in humans, systematically controlled experiments still require the use of animals.
A retrospective assessment of replacement will be due by 30 March 2024

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

Our study design is based on the need to produce reproducible, relevant and scientifically robust data. For example, we compare the activity of a neuron after a reward against the activity of the same neuron before the reward. We can also compare a neuron's activity between several rewards.
We also use modern machine learning tools ('decoders', 'classifiers') that predict the animal's choice by looking at the responses of brain cells to previous rewards, which demonstrates that the brain cell is involved in the decision process. We use computer models to translate behavioural theory into efficient experimental design, which limits the number of experimental tests we need to perform. We have developed advanced computer simulations that help us to understand and predict how behaviour and brain activity are related. We use these tools to make our experimental designs and research questions more specific and informative, which limits the necessary amount of experimentation.
Each neuronal study requires data from 60 or more neurones from a single animal, and a minimum of 2 animals to assure reproducibility across individuals. Sometimes 3 animals are necessary to obtain more robust results. On occasion we have found that the behavioural tests also require 3 animals.
To ensure that we make the best use of the data we gather in these experiments, we analyse the data using statistical methods including regressions, general linear models and machine learning tools. We also use these data to help us to plan and carry out the experiments in a more appropriate and efficient way, using the least number of animals and reducing the duration of behavioural training.
Our experiments are based on knowledge of formal, well established theories of how humans and animals learn and make choices. This theory based approach helps us address more effectively the scientific questions being investigated.
Our related human brain imaging studies help us select the brain structures for investigation at the single cell level in the current animal project.
Together, these approaches help us to avoid unnecessary experiments and ensure we focus only on those parts of the brain that are relevant to the behaviour under investigation. **A retrospective assessment of reduction will be due by 30 March 2024**

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

We work hard to use methods that are the most refined, and we spend considerable time, effort and manpower

changing and enriching our animal accommodation and our primate chairs. For example, at least once per month, an aquarium with animated artificial fish is placed in each room for the animals to watch. We locate the aquarium in the room where the animals live but outside their reach. We also show videos that we believe our NHPs find interesting, as judged by their behaviour.
Incidents of fighting can occur as part of the normal hierarchical/dominance structure of NHPs. We supervise special interaction time for animals that need to be separated from others, either temporarily or longer term. The supervision sessions last for several hours each day and involve our experienced laboratory technician being present inside the holding room throughout that time. An animal that needs to be separated from others over longer periods will be able to see, hear and communicate with the other animals living in the same room and, if socially compatible, will have direct interactions for grooming and other social activities under supervision.
We provide layers of wood shavings on the floor of the animals' cages in order to mimic aspects of NHPs natural foraging environment. The animals search for their daily diet (foraging), which also alleviates potential boredom.

We change the fruits and other foods frequently, which appears to keep the animals interested and stimulated. We add to this a variety of more interesting combinations of vegetables.
We use variable sized home cages which allows us to house groups of different numbers of animals. Inside the cages we provide hiding boxes, use video systems to monitor the animals' behaviour and interactions; supervised grooming periods serve to provide social encounters in socially unstable animals. We believe that the combination of all of these measures makes the life of our animals more interesting and reduces the potential for aggression and fights.
We improve the surgical techniques and materials we use and now use an even more tissue friendly material for head implants that binds well with the animals' natural tissue. We make a point of learning and evaluating different methods from new laboratory members joining us from other primate laboratories. We have improved our surgery techniques over the years through experience gained from working and talking to orthopaedic and plastic surgeons.
In addition to these specific points, we ensure that our choice of animal species, care and welfare methods, and scientific methods are the most refined by current standards as follows:
We follow the published guidelines of the NC3Rs and, together with our animal carers and technicians, regularly attend workshops and training courses on animal welfare.
We continue to refine our experimental and scientific approach. We interact and collaborate with other neuroscientists, biologists, medical doctors, statisticians, and data modelling experts nationally and internationally, to exchange knowledge and information gained from work on humans, different animal species and computer simulations.
We continue to remain up to date with the increasingly delicate details of psychological learning theories (so-called Rescorla-Wagner Theory of animal conditioning, and efficient 'Temporal-difference Reinforcement Learning' solving the Bellman value function for optimising reward) and economic decision theories (so-called Von Neumann - Morgenstern Expected Utility Theory, Kahneman & Tversky's Prospect Theory, and Revealed Preference Theory). These theories contribute conceptual frameworks for the experiments and provide more stringent approaches for addressing the scientific questions of reward processing and economic decision-making.
We look for answers to our scientific questions using a number of methods. These include advanced behavioural tasks, single-neurone recordings and computer modelling. In addition, we supplement our animal studies with human brain imaging. We do all this to ensure that our animal experiments address questions that can be answered by single-neuron recordings in NHPs; in other words, we make sure that our animal data will be relevant for humans and their pathological conditions. We refine all of these approaches so that our research can be rigorously peer reviewed by research grant awarding bodies and by the editors of the journals in which we publish our scientific data. **A retrospective assessment of refinement will be due by 30 March 2024**
The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

136. Neutrophils in infection and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

infection, neutrophil, macrophage, inflammation, cancer

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will study the mechanisms that regulate inflammation focusing on neutrophil and macrophage responses and how they are affected by changes in hematopoiesis during infection, chronic inflammatory disease and cancer.

A retrospective assessment of these aims will be due by 30 May 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Neutrophils are crucial for immune defence but are also driving immune pathology when they become deregulated. Severe infections, cancer and atherosclerosis are the major drivers of premature death worldwide. Neutrophils play a critical role in all of these diseases. Understanding how neutrophils protect against infection and more importantly how they are implicated in sepsis, cancer and atherosclerosis and other inflammatory conditions will provide new avenues of treatment for diseases that remain largely untreatable.

What outputs do you think you will see at the end of this project?

This project aims at uncovering novel mechanisms that drive sepsis, cancer and chronic inflammatory disease that could be targeted therapeutically in order to improve the lives of patients suffering from these diseases. In addition, it aims at addressing fundamental questions about the functions of neutrophils in immunity and disease. This work will be published in a number of scientific research publications and collectively present an inter-connected body of work that will advance our understanding of the mechanisms that fine-tune the production and function of neutrophils and regulate their interactions with the other parts of the immune system.

Who or what will benefit from these outputs, and how?

In the short-term (2-5 years): academics, researchers in academic institutions and the pharmaceutical industry.
In the long run (5+ years) inflammatory disease, infection and cancer patients, clinicians and the general public.

How will you look to maximise the outputs of this work?

Presentation in national and international scientific meetings and seminars at other research institutions.
Publication of high impact research papers, reviews and book chapters.
Collaboration with other basic and clinical researchers.
Disseminations via public engagement activities.

Species and numbers of animals expected to be used

- Mice: 25000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We work with mice as they are well-characterized model organisms to study the immune system and model human infection and disease. In addition, countless critical genetic resources have been developed in mice that are invaluable for our work.
Nearly all of our immunological challenges are tested on young adult mice which have robust and mature immune systems.

Typically, what will be done to an animal used in your project?

The protocols in our project employ a number of procedures such as injections or administrations of microbes, immune or tumour cells of small molecule substances, intravenously, orally or intratracheally. Moreover, some mice receive an altered diet, such as a western style high fat diet. In one protocol mice will undergo a minor surgical procedure to inject tumour cells into the pancreas. Depending on the experimental design experiments with microbial challenge last approximately 1 week. some mice may be infected on multiple occasions with small doses of microbes to evaluate the effect of chronic low grade exposure on tissues and immune cells. Some mice may be infected with higher doses that will cause pneumonia or a skin abscess. Other mice may receive microbes systemically that cause septic shock in order to understand the mechanisms that promote the condition as well as the mechanisms that protect against its onset. Tumour challenges last approximately 2 weeks, arthritis models 10 days and atherosclerosis dieting typically 6-12 weeks. Animals may also be induced to develop arthritis that spontaneously resolves after 2 weeks.

What are the expected impacts and/or adverse effects for the animals during your project?

Infections typically cause weight loss and some transient discomfort characterised by reduced activity. Skin infections may cause abscesses that in some cases may ulcerate resulting in the animals having to be sacrificed. In more severe cases such as sepsis models, mice may experience systemic inflammation with some pain, lethargy, drop in body temperature and respiratory distress, which will be endpoints in the experiment. However, monitoring the temperature allows us to cull the animals before they reach these severe symptoms if meaningful results can be obtained in earlier stages of the condition. Tumours do not usually cause visible symptoms but some weight loss may occur. Large metastatic tumours may cause more significant weight loss and respiratory problems which will be endpoints in our experiments The atherosclerosis model does not cause any visible harm aside from weight gain and vascular plaques that are asymptomatic. The arthritis model will cause some limb swelling and may impact on mouse mobility to some degree.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of our protocols are of mild or moderate severity. Only one protocol employing a model of microbial sepsis is classified as a severe protocol as mice are expected to develop symptoms associated with systemic hyperinflammation. However, the mice will be closely monitored and will be sacrificed as soon as these symptoms begin to appear.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 30 May 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our projects investigate the functional and mechanistic basis for inflammatory diseases. While certain aspects can be addressed using in vitro cultured experiments, to establish the relevance in vivo and to dissect the events that drive these diseases functionally in in vivo requires the use of animal models of disease, particularly since none of the diseases we are studying can be fully recapitulated and modelled in vitro using organoids. Sepsis is a complex disease implicating several different organs and cell types. Similarly, atherosclerosis and the interactions of immune cells with tumours must also be examined in their native in vivo environment.

Which non-animal alternatives did you consider for use in this project?

We are employing human primary neutrophils and other myeloid cells to conduct many of our mechanistic experiments before proceeding to in vivo validation. We are also conducting descriptive studies with human clinical samples of sepsis and atherosclerosis. This approach reduces the number of mice we use in our projects. However, for certain projects as in sepsis we have relied on mouse experiments guiding subsequent mechanistic in vitro studies. The only real alternative to in vivo studies are organoids but they are not applicable to the diseases we are studying.

Why were they not suitable?

All of the aforementioned approaches are complementary to in vivo experiments, but unfortunately cannot replace animal work given that the questions that we are investigating have to be examined in the native disease context.

A retrospective assessment of replacement will be due by 30 May 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Pilot experiments and biological replicates
When setting up a new experiment, rather than using large groups of animals and having to repeat these large-scale experiments to refine the experimental parameters, we start with very small groups (23 animals /group) and test several parameters we predict to be important for optimization.
Subsequently, we follow up the selected conditions that provide good experimental data with additional experiments consisting of small groups that we add to the original study until we reach statistical significance. This phased sequential experimental design reduces the overall number of experimental animals used in our

studies since it limits the number of animals that participate in studies under suboptimal conditions.

In addition, we keep experimental groups small and divide mice over a larger number of independent experiments (biological replicates) in order to obtain better statistical significance from a smaller total number of experimental mice.

Power analysis
Prior to designing experiments we use published data and our own past experience to set the appropriate sample sizes. For most of the quantitative experiments, sample sizes may be set using power analysis, generally using a significance level of 5%, a power of 80%, and a least practicable difference between groups of 20%.
Imaging
We are also implementing imaging techniques that in many cases are non-invasive and allow us to monitor the progression of infection, inflammation and tumour growth, without sacrificing animals. In this manner we can constantly monitor experimental animals and select optimal timepoints to terminate experiments rather than using multiple animal cohorts sacrificed at different timepoints in order to capture the best timepoint for measuring parameters. This approach minimizes the premature termination of experiments which would require unnecessary repetition and prevents unnecessary suffering by not allowing experiments to proceed beyond the optimum time point.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As specified above, we conduct small scale pilot experiments to guide power calculations prior to expanding our studies. In many cases long term experiments are performed with in smaller groups and in a phased manner, allowing us to increase the total sample size progressively until the required statistical power is achieved. The early results of the magnitude of changes between experimental groups are filtered through online power calculation tools to estimate accurately the sample sizes required for publication. Through small sample sizes and pilot experiments we can also refine variables like microbial and treatment doses for subsequent experiments

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

1. Breeding: We monitor the breeding of our mice closely to ensure that only breed the number of animals we need for experiments without breeding excess animals that will not be used in any experimental protocols.

2. Multiple uses of tissues, future proofing: From each experiment we collect the maximum number of tissues, even though we may not need them all for the purposes of the present experiment. Given that we employ standard experiments in many of our projects, we keep frozen tissues and samples from all these mice and organise them in a database. This allows us to easily access the tissues in the future without needing to replicate the experiment with new mice. This practice has reduced the number of experiments we have been conducting in the past.

3. Small pilot studies always inform our group sizes, as well as avoid unnecessary large scale experiments that do not show promising results in the small-scale pilot studies. If pilot studies fail to demonstrate signs that experiments may yield interesting data, then no follow up large scale experiments will be conducted and projects will take other more promising directions.

A retrospective assessment of reduction will be due by 30 May 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will employ several murine models of pulmonary and systemic infection using fungal and bacterial pathogens. We will also employ two models of sterile chronic inflammatory disease: murine atherosclerosis using the administration of high-fat diet and a transient model of rheumatoid arthritis using injection of auto-reactive antibodies against collagen. Finally, we will employ several models of primary and metastatic tumours.

Why can’t you use animals that are less sentient?

These murine models are optimised to cause the least amount of suffering. They last anywhere from 24 hrs to several weeks and therefore the animals cannot be anaesthetised for this period of time. However, they are temporarily anaesthetised when undergoing certain procedures. Murine models of disease are very similar to human disease and recapitulate many of the attributes and mechanisms of pathology observed in human patients. They also have a very similar immune system with that of humans that is extensively characterised. In addition, over several decade a multitude of genetic tools and reagents that are specific for mice have been developed that are essential for our research.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Over the years we have refined several of our protocols, particularly by fine-tunning the rate of monitoring and infection doses in our severe sepsis protocol which allow us to predict relatively accurately when WT and GA mice will develop sepsis. We have also refined the breeding pairs needed for maximal use of mice in experimental protocols. These are constantly adjusted according to experimental needs. The time-courses for atherosclerosis experiments have also been well characterised from our prior work, allowing us to estimate with accuracy the length of time allowed to obtain the degree of plaque formation needed for specific experiments. We have also refine our anaesthetisation protocols which reduced the recovery time for mice and reduced the appearance of unexpected symptoms in response to infection.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are aware of NC3Rs. We also discuss with colleagues in other research groups new improvements that lead to refinement. In addition we follow the literature and improvements in commercial reagents in a constant search for more efficient and better refined alternatives. This has led us to improve our arthritis model which is now 100% penetrant, requires fewer injections and much less time and is much more predictable and consistent than

the traditional immunisation protocol.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute regularly distributes newsletters and holds seminars to inform us on 3Rs and ways of improving our methods reducing the number of mice we use and refining our techniques both en mass and at a personal level. We also regularly seek advice from our veterinarian on how to improve our procedures.
A retrospective assessment of refinement will be due by 30 May 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

137. New biomaterials for healing of non-union bone defects

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Bone regeneration, Non-union fractures, Biomaterials, Growth factors, Stem cells

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this research project is the development and testing of advanced biomaterials, seeded with or without stem cells, to enhance the effects of growth factors (GF) during tissue healing. The use of microenvironments that direct the effect of the GFs in tissue healing, or carriers that efficiently control the local delivery of these biological molecules in the site of injury, will generate a platform to enable tissue repair, demonstrated on non-union bone defects in mice.
In particular, we want to assess the translational potential of our biomaterial systems in bone healing, as a novel, robust and safe system to promote bone regeneration in non-union bone defects.
This project will be developed under the principles of the 3Rs described in this licence and all animals used under this licence will be reported.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Non-union fractures, arisen from trauma or disease, are growing in occurrence due to an ageing population and are a major burden for the National Health Service (NHS). In the UK there are approximately 850,000 new fractures each year. A rate of 5–10% are non-union fractures and the treatment costs to the NHS, associated to this kind of fractures, have been reported to range between £7000 and £79000 per person. The development of a platform that enable tissue repair, in an efficient and safe way, will significantly improve societal health by increasing regenerative potential while reducing the life-threatening issues and high cost associated with the use of current high growth factor doses.
This research work will provide a pathway for the translation of this platform into a variety of clinical applications in tissue repair and regeneration, and it is important not only from the point of view of human medicine but also considering animal health, as experts from veterinary schools and practices report many traumatic injuries including non-healing bone defects.

What outputs do you think you will see at the end of this project?

We expect our proposal to overcome key barriers to translation of bone regeneration technologies into a clinical application. We will obtain essential information about the efficacy of our biomaterial systems to promote bone regeneration in animal-based models and treat non-union fractures, which will be critical in the clinical translation and commercialisation of our technologies for bone repair.
We expect to publish the results arisen from this project in high impact journals, which will lead to establish new collaborations and secure new research grants.

Who or what will benefit from these outputs, and how?

The proposed research will generate a unique platform to promote the regeneration of non-union bone defects, using biomaterials that maximise the efficacy of GFs in tissue healing. These studies will provide a pathway for the future translation of the developed technologies into the clinical practice.
This research is important from the point of view of human medicine but also considering animal health, as experts from veterinary schools and practices report many traumatic injuries including non-healing bone fractures.
We envisage results of this project to support technologies that can be translated to veterinary and human clinical practice to promote bone regeneration in complex fractures (e.g. fractures with infections). We believe

that the treatment of these fractures is a stepping stone towards more demanding and prevalent conditions such as osteoporosis and bone tissue tumours.

How will you look to maximise the outputs of this work?

The availability of this animal model will allow us to establish new collaborations with experts in the field of bone regeneration.
The results arisen from this work will be presented in international conferences (e.g. annual meeting of TERMIS) and submitted for publication in high impact journals. Outcomes of our work within our previous licence with this model already gathered the attention of clinicians, which led us to successfully treat our first veterinary patient using our technology. This work gathered the attention both in press and TV and, up to date, has allowed us to treat more than 10 clinical cases of dogs and cats.

Species and numbers of animals expected to be used

- Mice: 300 NSG mice, 200 C57BL/6

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have many similarities to humans in terms of anatomy, physiology and genetics. Adult mice reproduce quickly, easy to handle, and of appropriate size.
We expect to use C57BL/6 mice, a very common line of mouse used in lab research, in up to 8 weeks long experiments. In those cases where human mesenchymal stem cells (hMSCs) are implanted we will use immunocompromised mice (e.g. NSG strain, commercially available) in order to avoid rejection issues and ensure the survival of hMSCs after implantation.
Since this project will evaluate the potential of different material systems to promote bone regeneration, adult mice will be used in order to prevent the interference of the spontaneous bone growth of animals in a more immature life stages with the outcomes about the efficacy and efficiency of our technology.

Typically, what will be done to an animal used in your project?

All surgical procedures will be performed under aseptic conditions by trained personnel.

a) Mice will be anaesthetised and analgesia will be injected.

b) The radial bone of the mice will be exposed and a bone segmental defect will be created by using a double-blade bone cutter.

c) A polyimide implant tube, loaded with the material to be tested, will be implanted in the area of the defect, fitted to both bone ends. Then, the wound will be sutured.

d) Following implantation, mice will be monitored continuously until fully recovered from anaesthesia and ambulatory. Analgesia will be provided through the food up to few days after surgery.

In those cases where mesenchymal stem cells (MSCs) are implanted, and in vivo cell tracking will be performed, a dose of luciferin will be injected into the mice and animals will be imaged before allowing the animal to recover from anaesthesia (t=0).

e) At different time points, up to 8 weeks, mice will be anaesthetised, and a dose of luciferin will be injected into the mice. 20-60 min after injection, animals will be imaged. Mice will be monitored continuously until fully recovered from anaesthesia and ambulatory.

f) At the endpoint of the experiment, 8 weeks after implantation, animals will be humanely killed by Schedule 1 protocols.

What are the expected impacts and/or adverse effects for the animals during your project?

- Some animals (less than 15%) can show light weight loss, some swelling in the arm, limping and/or attention to surgical area (lameness) - Up to few (2-3) days after surgery.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All surgical procedures will be carried out using aseptic techniques. All animals are expected to make a rapid and unremarkable recovery from the anaesthetic.
The level of severity for each procedure is as follows:
- Surgery to create a critical-size bone defect - Moderate severity in all the animals (100%).

- Luciferin injection and animal-based imaging - Mild severity in all the animals (100%).

The experiments will be done following the 3Rs and any unexpected adverse effect or severity will be reported.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research proposed in this project is in the field of tissue engineering; it is related to bone repair strategies and, consequently, can be considered to be medical research. It involves chemical, biological, biophysical and biomechanical factors that are not possible to reproduce using lab-based experiments. Therefore, animal experiments are a crucial element of the project, to validate the efficacy of the platform and as an essential pre-clinical validation of the new technologies.

Which non-animal alternatives did you consider for use in this project?

We use lab-based platforms to test the biological response to the new biomaterials. We maximise the use of lab-based experiments in order to reduce the number of animals to be used. In this sense, the lab-based platforms will be used to optimize the composition of the material systems, so that only a selected number of material compositions will be evaluated during the lab-based experiments.

Why were they not suitable?

The responses of cells and proteins properties to the implanted materials used are not possible to fully reproduce in the lab, and often different in an animal or in a cell culture. Therefore, animal experiments are a critical step on this project, to validate the efficacy of the platform in an environment similar to a human body, and are an essential validation in these technologies before a clinical application.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated the number of animals based on our previous animal-based studies and our current ongoing projects involving the use of animal experimentation. We have also engaged with statisticians and we will seek their advice to optimally design our experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We expect to perform these experiments for a minimum number of material compositions of the supporting scaffolds, depending on the final outcome from the lab-based cellular experiments.
To keep the number of animals necessary for these experiments as low as possible, minimum number of animals per each group are calculated by using a power calculator (e.g. PS Power and sample size), considering an adequate estimate of standard deviation as well as a statistically significant number of replicates from previous studies using this model, in order to achieve statistical relevance and meaningful results. We will seek advice from mathematicians and statisticians to optimally design each experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you

plan to use in your project?

Before starting the animal experiments, we have planned extensive research on cell cultures to select the most promising systems, e.g. those inducing higher cell viability, adhesion and/or osteogenic differentiation. In this sense, the lab-based platforms will be used to optimise the composition of the material systems, so that only a selected number of material compositions will be evaluated during the animal-based experiments.
Since variability between the outcomes from lab-based to animal-based studies can be found, we will include animal-based pilot studies with reduced number of experimental groups that will allow us to select only the most promising systems to be fully evaluated.
Non-invasive animal-based imaging techniques (e.g. IVIS Spectrum In Vivo Imaging System) will be used to track the viability of the implanted cells during the healing process, without severely hurting the animals and making it possible to get periodical information using the same imaging test in the same animal over time. This will drastically reduce the number of animals to be used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

A segmental radial bone defect model in mice will be used in this project. We consider the model of critical-sized, non-healing segmental bone defect in the murine radius as a clinically-relevant and yet least invasive model to evaluate the potential of implanted biomaterials to induce bone regeneration. We strongly believe that non-healing models are necessary as they are rigorous test-beds for bone repair strategies, and this model has been successfully used in our group.
This bone repair model has significant and particular advantages for this research:

- 2.5 mm defect does not spontaneously heal during the course of the experiments providing a rigorous critical-sized model to evaluate bone repair strategies.
- The smaller animal model allows for easy use of animal-based imaging approaches (e.g., IVIS).
- The ulna provides sufficient stabilisation of the defect and no fixation plates/hardware is required, thereby considerably simplifying the surgical procedure, reducing the risk of infection, and at the same time reducing animal pain. Therefore, this model allows for efficient screening of several experimental conditions, a major advantage over the rat calvaria and segmental femur defect models that were previously used, and also considerably reduces pain during recovery after surgery.

Why can’t you use animals that are less sentient?

Mice are used due to their anatomical, physiological, and genetic similarity to humans. They have a short life cycle and reproduce very quickly.
Regarding the life stage; since this project will evaluate the potential of different material systems to promote bone regeneration, adult mice will be used in order to prevent the interference of the spontaneous bone growth of animals in a more immature life stages with the outcomes about the efficacy of the treatment.

To be able to evaluate bone regeneration for a defined period of time after implantation, all surgical procedures will be performed under general anaesthesia with recovery.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Following the Home Office advice, the aseptic conditions during the surgeries have improved significantly in order to guarantee the animal welfare. A different set of sterile materials (including sutures, drapes, surgeon gloves, etc) and surgical tools is used for each animal. New extra sets of surgical tools have been purchased for this purpose, including the custom-made bone cutters. The use of glass bead sterilisers to sterilise instruments between animals has been replaced by the use of the autoclave.
At present, the animal facility provides us with a technical assistant who has already experience assisting our surgeries, which helps to reduce the duration of the surgeries.
Where mutant immunocompromised mice (e.g., NSG) are used, they will be maintained in a suitable barrier environment in order to prevent any unwanted infections.
Analgesia will be provided by intra-operative administration and post-operative delivery in the water.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All the animal experimentation will be performed by following the Guidance on the Operation of the Animals (Scientific Procedures)
Act 1986.
I undertake responsibility for the overall implementation of the programme of work and for ensuring that the programme is carried out in compliance with the conditions of the license (including the principles of the 3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group and collaborators have been extensively working in the field of bone regeneration for many years and have a wide expertise and up-to-date knowledge of the current animal models used for the purpose of this project.
We are also in continuous contact with the staff from the biological services (NTCO and NVS) and we have implemented advances effectively following the Home Office advice.

Home Office

NON-TECHNICAL SUMMARY

138. New cancer drugs targeting the DNA damage response

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, DNA damage response, Bone metastasis, Cancer treatments, Multiple myeloma

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To validate novel compounds targeting the DNA damage response for the treatment of cancer and effective therapeutic combinations.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cancer is responsible for over one quarter of deaths in the UK. Many chemotherapies currently in the clinic are good at killing cancer cells, but they also kill normal healthy cells.
Cancer cells duplicate themselves much faster than heathy cells. As they do this, they make many mistakes in their DNA (the genetic material that encodes life). By stopping cancer cells from being able to repair their DNA, they will die. Many existing chemotherapeutics work by blocking this pathway, including 5-fluorouracil and methotrexate. Unfortunately, this process is important for all cells, so these treatments also kill healthy cells.

We have identified some parts of this process that are unique to cancer cells and have developed new compounds to block them. This means that unlike the drugs that are already in the clinic, our new compounds selectively kill cancer cells, without killing normal heathy cells. We have shown this in cell culture and in a mouse model of leukaemia. We have also identified a number of cancers that are sensitive to these compounds in cell culture, including leukaemia, myeloma, colorectal cancer, lung cancer and breast cancer, but these new compounds are likely to be effective in many other cancers.

What outputs do you think you will see at the end of this project?

The major outcome of this work will be identifying a clinical strategy for translation of novel cancer therapeutics into patients and will directly influence phase I clinical trials as a mono or combination therapy. This work will be published in frontline journals and will provide valuable insights and new information about these targets and their role in cancer. Once we have published our findings and protected our new drugs (e.g. through patents) the drugs developed in this work programme will be shared with other researchers who think they may be useful for the treatment of other diseases.

Who or what will benefit from these outputs, and how?

In the short-term, this work will benefit the scientific community by providing valuable knowledge on the DNA damage response in cancer and the roles of individual proteins. It is likely that the targets investigated here will also be implicated in other diseases, and the novel compounds will be made available to other researchers for further exploration.
In the mid-long-term, the ultimate benefit of this work will be to cancer patients. During this project we identify biomarkers to predict sensitivity and resistance to the compounds, for identification of patients who are likely to respond to the treatment.

How will you look to maximise the outputs of this work?

We will collaborate with industry and academic partners for the safety and toxicity testing of these compounds, who are better equipped to perform these experiments. This will streamline the process of taking new compounds through pre-clinical testing, allowing us to more quickly move forward promising compounds into clinical trials. We have close ties to the NHS through which we will be able to coordinate clinical trials. We will disseminate our findings at conferences and in frontline journals and where possible include negative data in

these.

Species and numbers of animals expected to be used

- Mice: 2900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use mouse models of cancer as these are well established, reproducible and reliably mimic much of the disease in patients. Many studies will use human tumour cells, to most reliably replicate the human disease. However, implantation of human tumour cells must be done in mice with a deficient immune system. For some studies it will be important to have a fully functioning immune system, for example for drugs targeting the immune system, in this case mouse tumours will be used.
For each experiment, the model used will be guided by studies in cells and patient screening. In each circumstance, the advantages and disadvantages of each mouse model will be weighed and the model that most appropriately addresses the experimental aims, while adhering to the 3Rs, will be used. Where possible we will use tumour cells genetically altered to allow specialised imaging of tumours that allows for tracking of tumour growth over time, to reduce the number of mice needed in each study. We will use mice of an appropriate age for each model that allows for effective engraftment and tumour growth, this is typically a young adult mouse.
We will perform as many experiments as possible in cell and/or organ cultures and screen patient samples (where possible) before we do any experiments in animals. Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but not as effective when treating a whole animal. This is because of the complex environments and signalling networks within animals that may prevent the therapy from working, as yet this cannot be modelled in a dish or by a computer. For example, sometimes drugs do not get through the body to the cancer very effectively, or the body might remove the drug before it can do its job.
We will use cell/organoid culture and screening of patient samples to identify sensitive cancer types and effective drug combinations. We will combine this with computer modelling to understand as much as possible about how the drugs work before treating animals, e.g. how drug resistance may develop. Studies in mice will only be performed after this to show that the treatments are effective in a whole animal model, and also to identify which new or approved drugs should be used in combination.
Studies will be designed in line with the NCRI Guidelines for the welfare and use of animals in cancer research (Workman *et al*. 2010). Throughout the study we will re-evaluate the models used in line with the 3Rs (replace, reduce, refine), to ensure we are using the best and most ethical animal models and where possible use non-whole animal models.

Typically, what will be done to an animal used in your project?

Some animals will be injected or implanted with cancer cells. Where possible, this will be done in the way that most accurately mimics with disease in patients (e.g. injected into the blood for blood cancers, or into mammary tissue for breast cancer), sometimes this will require a surgery under general anaesthesia. In some cases, tumour cells will be injected under the skin as this provides easy access and monitoring of the tumour, and avoids complex surgical procedures.
Some animals may be fed a modified diet for a part or throughout the study as this can improve how effective some therapies are in reducing tumour. Some animals will be fed or injected with compounds that we are

developing to treat cancer, or a placebo, this is usually once a day or once a week. Animals may also be treated with other cancer therapies including radiotherapy. Animals will be weighed at appropriate intervals to monitor weight loss, as this is a sign that they are unwell.
To monitor tumour, animals will be put under general anaesthesia for specialised imaging, this is usually once a week. We will also take a small amount of blood from a vein in the tail once a week to measure markers of response which can be detected in blood. For some tumours, other specialised techniques may be used to monitor the disease. For example, for cancers which cause bone disease we will use micro-computed tomography to scan an affected bone under general anaesthesia.
The duration of each study will depend on the model used, studies using more aggressive tumours may only last 3 weeks, whereas less aggressive tumours can develop over several months. Experiments to study the effect of compounds on normal biology without tumours present, will last for a defined treatment period, usually this will not be more than 2 months. The studies will end when the treatment period is complete, when tumours reach a certain size or when we detect relapse (tumour regrows despite treatment) or metastasis (spread to other organs).
Animals will be humanely killed at the end of the study or when they show signs of becoming significantly unwell, whichever is first.

What are the expected impacts and/or adverse effects for the animals during your project?

Occasionally some mice will experience adverse effects, but provisions will be made to minimise these. For example, the cancer or treatment may make some animals feel sick and they may stop eating or drinking resulting in weight loss, their activity may change or they may look scruffy. We will weigh and check the mice regularly to carefully monitor for signs that they may be unwell. We will also measure the tumour regularly, and not allow the tumours to grow beyond reasonable limits. If the mice lose too much weight and don't recover within 24 hours, seem unwell or if their tumour gets too large, they will be humanely killed.

When blood samples are taken, if too much blood is taken the mice can become anaemic. To make sure we do not take too much blood mice will be weighed and only an appropriate amount of blood will be taken from each mouse on each occasion (https://www.nc3rs.org.uk/mouse-decision-tree-bloodsampling).
The drugs and compounds we will treat the mice with are not expected to have any adverse effects at the doses we will use. The injection or feeding of these drugs will not cause any more than a short discomfort at the time of administration.
General anaesthesia for surgery, imaging or tumour implantation is not expected to have any adverse effects with appropriate monitoring and pain relief. Mice will be closely monitored during anaesthesia and if breathing becomes irregular then mice will be humanely killed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Animals will experience a maximum of a moderate severity level.

It is expected that 98% of animals will experience a moderate severity, some animals in which tumours fail to grow will only experience a mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Our goal is to develop new treatments for cancer. To do this, we will perform experiments using cells, patient samples and computer modelling as well as mouse models of cancer. While non-animal models of cancer are very helpful in understanding aspects of biology and how drugs work, unfortunately they do not model the entire body. Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but do not work when treating patients. This is because of the complex environments and signalling networks within humans and animals that may prevent the therapy from working. As yet this cannot be modelled entirely in a dish or by a computer. For example, sometimes drugs do not get through the body to the cancer very effectively, or the body might remove the drug before it can do its job.
We will perform as many experiments as possible in cells and test patient samples before we do experiments in mice. As much as possible we will replace animal models with non-animal models and we will continue to investigate non-animal alternatives throughout the duration of this licence.

Which non-animal alternatives did you consider for use in this project?

Animal experiments are one key part of this work programme required to achieve our aims, which we will also combine with non-animal models.
We will use 2D and 3D cell culture to study the biology of new targets and to test novel compounds. This will include identifying if the drugs kill cancer cells and how they do this. By screening in cells from a wide range of cancers we will be able to identify sensitive cancer types and 'biomarkers' that can be used to predict which patients will respond well or poorly to the drugs. We will also test our new drugs on tumour samples from patients. We are also investigating the chick embryo assay to see whether they can replace some of our animal models (https://www.nc3rs.org.uk/development-chick-embryoreplacement-rodent-models-tumour-metastasis). This may be useful for some tumour models using human cancer cells. However, limitations to these models mean they cannot fully replace the mouse models here. After performing these studies, we will use mouse models of cancer before doing clinical trials.
Throughout the study we will continue to investigate non-animal alternatives through resources such as the NC3Rs and the Norecopa 3R Guide. Alternatives will be implemented when relevant.

Why were they not suitable?

The non-animal experiments are all suitable models for early investigation of new drugs for cancer treatment, and we will use these to complement studies in mice. However, experiments in a dish or computer are unfortunately not capable of reproducing the effects in a whole organism.
Many cancer therapies are highly effective at killing cancer cells when treated in cell culture, but either do not work or are less effective when treating a whole animal. A whole animal has many natural barriers that can prevent a drug from working the way it would on an individual cell. After entering the body the drug may never reach the tumour or the drug may be broken down and removed too quickly to have an effect. On top of this, tumour growth and spread (metastasis) can also be controlled by other cell types in the body, like immune and bone cells, and these cells can also influence drug responses. Finally, there can also be systemic effects, like hormone levels, that may change the response to the drug. There are no non-animal models that exist that take into account all these factors. However, we will continue to investigate alternatives.
The chick embryo assay can be used to study cancer, but there are limitations to this assay that mean it is not the ideal model for many of the drugs we are testing. Firstly, it cannot be used to study cancer in bone, which form a big part of this work. This model may be useful for some models looking at primary tumour growth.

However, the immune system is important in cancer, and this model lacks an immune system, meaning mouse models offer the models which most closely represent human cancer patients.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals we will used is based on previous quantitative published data and experience.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have planned to use a number of non-animals models (e.g. cell models and screening of patient samples) before any experiments in animals to reduce the number of animals required.
Experiments were planned using using specialised software and best practice guidelines. This includes the NC3Rs Experimental Design Assistant and the Norecopa PREPARE guidelines and the National Cancer Research Institute's *Guidelines for the welfare and use of animals in cancer research* (Workman *et al.* 2010 *Brit J Cancer*).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

If we do not have previous data to estimate the number of mice we should use for an experiment, we will perform a pilot study to estimate the minimum number of mice required. For complex experiments, we will seek advice from specialist statisticians to help in experimental design.
We will use mouse models of cancer as these reliably and reproducibly mimic the growth and spread of cancer in humans. We will use modified cancer cells so we can use specialised techniques, like non-invasive tumour imaging. We will also use other specialised monitoring techniques for specific cancers, e.g. micro computed tomography for cancers that cause bone disease. This will reduce the number of mice required for experiments, by performing measurements over time in the same animal rather than requiring multiple groups to investigate different timepoints. We will also use inbred mice because this minimises variation between mice, thereby reducing the number of animals required.
Where possible we will store tissue that may be of interest to investigate in the future, even if analysis is not planned in the original design. This will minimise the risk of having to repeat a study to obtain more tissue/data. We will also make this tissue available to other researchers upon reasonable request.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use two types of mouse models of cancer to study the effects of new potential cancer therapies.
The first uses human tumour cells or tissue implanted into mice that lack part of their immune system. This is required so that the body does not reject the human tumour cells. The second model, uses mouse tumours implanted into mice with a fully functioning immune system. This is also important as the immune system can influence tumour growth and response to therapy. These models have been extensively used by us and others, so there is a wealth on information available on these models and they are considered to be reliable and reproducible. These models have be optimised to minimise pain, suffering, distress and harm to the animals.
I have over 10 years experience working with mouse models of cancer, and during this time have developed refined mouse models of myeloma. These models are more representative of patients, and use specialised imaging to monitor tumour rather than relying on symptoms of mice being unwell or in pain. Our colleagues have similarly developed refined models of breast cancer, which we will use in our studies. We have extensive experience working with these mouse models, with world-leading techniques for monitoring tumour and bone disease plus analysis of tissues to understand how new drugs work.
We will also use general practices that minimise stress, harm and pain to animals. This includes nonaversive methods for handling mice (e.g. not picking up by the tail), the use of single-use needles to avoid pain from dulled needles and NC3R guidelines on blood sampling.

Why can't you use animals that are less sentient?

To study effect of treatments on tumour growth, metastasis and relapse requires a whole organism model. Mouse models have been extensively used by us and others, so there is a wealth of information available on these models and they are considered to be reliable and reproducible. Mice are also very similar to humans genetically, and many processes in relation to development and growth of cancer are conserved between these species. Mice that lack part of the immune system can also grow human tumours, allowing us to study the effect of new treatments on human tumours.
Some less-sentient species, such as zebrafish, can be used to study specific tumorigenic processes. However, these models cannot be used for studying the effects on intervention on processes like metastasis. They also do not provide the ability to model treatment strategies that are used for patients. For our studies, in order to determine whether our new treatments are effective at treating growth of primary tumours and/or metastasis, mice are the most reliable model and we cannot currently perform these experiments in a less-sentient species. We find mouse models of cancer are most reliable and representative in adult mice and they cannot be used at a life stage where mice are less-sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Tumours will be regularly monitored through non-invasive methods. Mice will also be weighed to check for signs of weight loss that may occur in response to the tumour or treatments. Mice will be regularly checked for signs of being unwell, for example changes to the coat condition, behaviour and movement. We will also continually attempt to identify earlier endpoints for studies, to minimise harm to animals.
Invasive surgeries will be performed under general anaesthesia. Mice will be given pain-relief to manage pain and kept warm while they recover. Mice will be monitored following surgery and any procedures that may have immediate adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgeries will be performed under sterile conditions following best practice guidelines, e.g. LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Procedures for establishment and monitoring of tumour growth, metastasis and animal welfare will follow best practice guidelines (e.g. NCRI Guidelines for the welfare and use of animals in cancer research, Workman et al. 2010 Br. J. Cancer). We will also consult the NC3Rs website and Norecopa for information on the 3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the NC3Rs and Norecopa websites, the literature and colleagues/collaborators for information on the 3Rs. Any relevant advancements that can be implemented will be used.

Home Office

NON-TECHNICAL SUMMARY

139. Novel molecular targets for the development of new analgesics

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this work is to benefit medical and veterinary pain patients by providing routes to the development of new analgesics that will reduce their pain and improve their quality of life. Pain following nerve damage in patients is especially difficult to treat and represents a real unmet need. We are trying to understand the basic mechanisms involved in this to help to produce new safe and effective analgesic treatments where none currently exist.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pain relief remains inadequate for many pain states (with limited efficacy and often severe or dangerous side-effects), especially when the pain state involves damage to nerves (neuropathic pain), where specialised molecular changes are triggered. To gain a full understanding of what might be an appropriate intervention, it is important to elucidate how these changes differ from those in inflammatory pain. Effective treatment of chronic pain (especially neuropathic pain) represents a major unmet need with all currently available analgesics showing very limited efficacy (a low percentage of patients experiencing significant pain relief) and unacceptable or dangerous side-effects, that limit how even they can be used. A new, more effective strategy is urgently needed.

What outputs do you think you will see at the end of this project?

We will have new insights into the neurobiology of pain and analgesia, identifying novel molecular targets for innovative treatment strategies. We have a strong track record of identifying new potential analgesic targets over several decades and have recently identified several highly promising and entirely novel new targets, which will be the focus of the current work. Results will be presented at national and international meetings, published in high impact, peer-reviewed journals and made freely available on the internet by Open-Access arrangements.

Who or what will benefit from these outputs, and how?

Academic and pharmaceutical industry researchers will be the short term beneficiaries. In the medium term, the work can potentially lead to the development of novel, more effective, analgesic drugs to deliver improved pain relief and quality of life to clinical and veterinary pain patients. Long term benefits should then include reduced pressure on healthcare systems and a reduction in the economic burden of treatment costs and lost working hours.

How will you look to maximise the outputs of this work?

We will seek maximal distribution of our findings by widespread presentations at scientific meetings and publication in leading Journals, at which we will ensure free Open Access. Both academic and industrial collaborations will be encouraged, to facilitate fundamental understanding and translational development of our findings to benefit patients. We are eager to enter into drug development programmes with our previously established medicinal chemistry and pharmaceutical industry partners (as well as new interested partners), in whatever way will optimise the overall outcome for relieving suffering from chronic pain.

Species and numbers of animals expected to be used

- Mice: 530
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats and mice are the most appropriate for these studies as their nervous systems reflect most of the properties of that in man. Gaining good understanding of fundamental mechanisms of pain processing and its modulation by endogenous mechanisms, that may represent new targets for analgesia, should be readily translatable to application in a clinical context. The vast majority of relevant research literature and understanding relates to work done in these species, so we can readily gain from that knowledge and better predict experimental outcomes. Adult animals are used in the experimental protocols so their nervous systems are fully developed and findings better reflect the situation in adult humans who represent a very large proportion of chronic pain patients.

Typically, what will be done to an animal used in your project?

In the experimental Protocols (1 and 2), animals would normally be anaesthetised for either nerve injury surgery or cutaneous injection of inflammatory agents and then allowed to recover for the relevant period to allow development of the model. For behavioural testing, animals would be habituated to the testing environment, for brief, threshold level paw withdrawal testing and baseline measurements recorded. Animals would then be anaesthetised (generally only briefly) for the administration of selective pharmacological or other agents, designed to interrogate specifically the mechanisms of pain and analgesia. After recovery from anaesthesia, further behavioural testing would be carried out to measure the effect of these agents. Finally, animals would be killed by a humane method, usually then taking tissue for biochemical assessments. Protocol 3 represents solely the breeding and maintenance of externally-derived genetically altered animals.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals in protocols 1 and 2 are expected to recover from nerve injury surgery or inflammatory agent injection without incident. When the models have developed, the animals display a mild degree of hypersensitivity at threshold stimuli levels, in the affected paw and likely some reduced weight bearing on that paw. Grooming and exploratory behaviour are unaffected and occasionally, but not usually, there might be a slight reduction in the rate of weight gain. Behavioural testing is brief and at threshold level, resulting in no discernible changes in the animals' overall behaviour. The specific pharmacological and other agents are expected to have no discernible impact on the overall physiology, experience and behaviour of the animals. No impact/adverse effects are likely to occur in Protocol 3 – standard breeding and maintenance of externally-derived genetically altered animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For Protocols 1 and 2 the animals will be moderately affected in a restricted location by the nerve injury or peripheral inflammation. All other interventions represent reliably only a mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It is not possible to gain valid understanding of the processes of pain hypersensitivity as targets for potential new analgesics without some use of animals such as rodents. This is because processes closely resembling those that occur in man do not occur in simpler organisms with a less highly developed nervous system. Neither can such processes be adequately studied in cultured cells. We use the minimum possible number of animals by carefully planning the experiments and co-ordinating our studies to utilize tissue for corroborative biochemical measurements. For this, we developed new protocols using extremely small samples of tissue, thereby helping to minimise animal use.

Which non-animal alternatives did you consider for use in this project?

Cell lines or computer-based modelling.

Why were they not suitable?

Cell lines are not appropriate as they lack the complex communication between different cell types that would be necessary to gain any meaningful understanding of the complex changes that occur in a mammalian nervous system in response to pain state models and how these changes can be reversed.

Computer-based modelling is not appropriate as far too little is known of the processes and their interactions to even contemplate a meaningful model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Experiments are carefully designed on the basis of our extensive experience using statistical methods that are widely used to predict the minimum number of animals likely to be needed to achieve clear and significant results. The estimates are based on numbers used in similar, closely related projects over the course of my previous PPL, knowledge of typical effect sizes from the literature, predictive statistical calculations and advice from local statisticians. Further, we ensure that whenever possible all animal tissues are also utilised for sensitive biochemical assays. As a general aim to reduce animal usage we have worked to miniaturise many of our biochemical assays so that only tiny samples of tissue are needed and a range of different questions can be answered using the tissue from a single animal. A small additional number of genetically altered mice are needed as breeding stock.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use online tools and seek advice from local statisticians and NC3Rs Experimental Design Assistant as appropriate.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Beyond best practice at all stages of procedures, we spend a great deal of effort on ensuring that drugs,

antibodies and other reagents are truly specific, so results will be equivocal in interpretation and avoid the need for further experiments to re-validate any findings. Behavioural, pharmacological and biochemical experiments are all carried out by highly experienced investigators who can pre-empt any difficulties and ensure experimental opportunities are used to full advantage.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use rats and mice as these have provided the vast majority of research information in the field and simpler species do not have equivalent pathways that can reflect how pain messages are processed in humans. The literature suggests that rodents provide faithful models of human pain states. We take all possible opportunities to minimise intensity and duration of such models in our work, which generally seeks to validate new improved strategies for relief of pain. All of the tests we use to measure sensory responses are brief threshold-level tests that do not distress the animals. According to 3Rs principles, we have successfully worked to move as many of our assessments as possible to recording responses of tiny tissue samples in biochemical assays.

Why can’t you use animals that are less sentient?

We cannot use less sentient animals as no meaningful results could be obtained that give insights into the aims here, which require investigation of adaptive changes in a complete and fully functional mammalian nervous system in order to understand novel targets for unmet analgesic needs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We are careful to use local anaesthetic gel (both pre- and post-operatively) to minimise any local discomfort following surgery and we are assiduous about frequent post-operative monitoring of animals to ensure all are well. For behavioural testing, all animals are well habituated to the test scenario and returned as quickly as possible to their home cage. Even minor procedures such as drug injections are only ever carried out following brief anaesthesia in order to minimise stress and discomfort.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We consult the Norecopa PREPARE guidelines as well as the NC3Rs ARRIVE guidelines and their Experimental Design Assistant site to ensure the most refined experimental design.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly look for updates on 3Rs from the NC3Rs site and also consistently attend local advisory update meetings for animal users. New advice is shared with (and implemented by) all in the group.

Home Office

NON-TECHNICAL SUMMARY

140. Novel seeding models to mimic proteinopathies

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Central nervous system, Proteinopathies, seeding human extracts, spreading, cognition - dementia

Animal types	Life stages
Mice	adult, juvenile, neonate, aged
Rats	adult, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The main objective of this project is the development of novel animal models that closely mimic both the underlying pathology and clinical phenotypes associated with neurological and neurodegenerative diseases, which as an underlying pathology have the aggregation of proteins. These models will be utilised to further our understanding of the mechanisms underlying the development and progression of the diseases and testing of potential therapeutic agents.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The present research is vital with the increased life expectancy and a larger proportion of the population aged over 65 years, which in turn has resulted in an increased prevalence of individuals with age related neurological disorders and neurodegenerative diseases including dementia (Alzheimer's, Frontal Temporal Lobar or Lewy body) and Parkinson's disease.

This research will enhance our understanding of brain processes involved in the onset and progression of the diseases which in turn could facilitate the development and testing of new/improved treatments for patients.

What outputs do you think you will see at the end of this project?

- This work will further our understanding of progression of diseases including dementia and Parkinson's disease by studying changes in both neural and behavioural processes.

- The key aspect of this study will be the development of novel more refined animal models of neurological disorders and neurodegenerative diseases including dementia and Parkinson's disease. These models will closely mimic and resemble the pathology, physiology and behavioural symptoms associated with the human diseases whilst presenting with a similar progression that will be more translationally relevant. These models will facilitate the development and testing of new treatments.

- Findings and data from this project will be published in peer-reviewed scientific journals.

Who or what will benefit from these outputs, and how?

The data generated from this research project will guide and inform both our research and could also have benefits for the wider research community. They will have translational value and may be instructive in future clinical studies on how to stratify patient cohorts.

In the long-term it is envisaged that this model will not only facilitate a better understanding of the disease, but it could also be utilised in pre-clinical testing and the potential development and screening of new treatments/compounds by pharmaceutical companies and the NHS and therefore in the longer term it will benefit patients along with their carers/families.

How will you look to maximise the outputs of this work?

The findings and data from this project where possible will be published in peer reviewed journals and will also be shared with the wider research community via presentations at both national and international scientific conferences.

Species and numbers of animals expected to be used

- Mice: 12,200
- Rats: 2,800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

During this project we will try and develop novel animal models that closely mimic human neurological and neurodegenerative diseases including Alzheimer's disease, Parkinson's Disease, Fronto-temporal lobe dementia and Lewy Body dementia.
Mice and rats will be used for the purpose of this project as they have genetic similarities to humans and their genetics and physiology can also be easily manipulated to induce models that resemble the disease profile associated with human conditions. A number of GA models have been developed that are able to model the human diseases and these can be generated in a short-period of time. However, as not all forms of diseases have a genetic cause it is also necessary to induce models that address the 'sporadic' form of the disease onset and this can be done via manipulation of the physiology of the mouse. These seeding procedures may be used in conjunction with GA lines to accelerate their phenotypes and combine familial and sporadic forms of dementia.
Dementia and other degenerative diseases are age-related disorders with symptom onset and development usually evident in elderly patients (over 65 years old), using mouse and rat models allows us to accelerate the disease onset and progression. This can be induced in young adolescent animals with symptom onset and progression evident at approximately 6 - 12 months of age and presymptomatic testing is therefore possible in younger animals. Animals will be kept up to a maximum of 18 months of age.

Typically, what will be done to an animal used in your project?

Novel animal models will be developed using aseptic surgical techniques in order to induce similar pathology in the brain of the animal to that which can be observed in the human disease. This will involve the injection of extracts or substances into the brain regions of interest of the animal.
Appropriate analgesia and care will be given to the animal throughout the surgery and recovery period.
Animals will be given a suitable recovery period following surgery, and time will also be allowed for the pathology to spread within the brain before further assessments of symptoms relating to the disease progression are performed. Assessments may include tests for behavioural symptoms including cognitive impairments, differences in activity, changes in emotional states e.g. anxiety, motor deficits and changes in sensory ability e.g. olfaction. There is a wide range of behavioural tests that could be performed depending on the disease being modelled.
Due to the co-morbidity of neuronal diseases and metabolic disorders in humans e.g. Alzheimer's disease and diabetes, animals may also undergo metabolic assessments to determine if these are also present in the animal model during disease progression.

Following the determination of behavioural and/or metabolic symptoms that correspond with the clinical symptoms associated with the human disease, animals may be given drug treatments to ascertain if these are able to alleviate the symptoms and slow the disease progression.
Behavioural and metabolic (physiological changes) can be assessed independently of one another although due to our knowledge of the disease profiles in human patients the combination of these two approaches may offer a more holistic approach to understanding the disease onset and progression (see Table 1 for protocol summary and complexity).

What are the expected impacts and/or adverse effects for the animals during your project?

- Pain experienced during surgery is transient and will be treated with appropriate analgesic and postoperative care regimes where necessary. Following surgery animals can also display weight loss but again this is typically transient.

- Animals may experience side effects following administration of novel drugs/drug classes but this will be unusual and short-term. Animals will be closely monitored for weight loss.

- No abnormal behaviours are expected as a result of procedures performed under this project, with behavioural changes normally subtle and only observed using specialist and sensitive behavioural equipment.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Severities under this project range from sub-threshold/mild to moderate. The majority of animals will be undergoing surgery and are therefore classified as moderate severity (approximately 80% of rats and mice) due to the surgery itself although they are not expected to suffer further harm following surgery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are the only option for the analysis of behavioural functions correlated with brain activation. Towards this end, we seek to identify disease relevant biomarkers (relevant for dementia) in the behavioural domain. These will be correlated with physiological recordings (glucose handling etc.), but also with pharmacological profiles of transmitters and enzymes. Inclusion of post-mortem ex vivo analyses provides an enormously powerful tool to determine the mechanisms underlying the disease and to identify novel drug targets and novel treatment options.

Which non-animal alternatives did you consider for use in this project?

There is no suitable replacement or alternative e.g. cell culture, computer model, organelle, nematode, insect

etc. to using the whole animal to study behavioural / physiological changes and related brain function. For this we have opted to work with rodents as their behavioural repertoire is close to human, GA variants are readily available and translation between patient and animal can be achieved.

Why were they not suitable?

The experimental techniques and behavioural assessments which will be utilised in this project can only be performed on the whole animal. Animals are needed in order to understand how changes in brain function can be related to behavioural / cognitive phenotypes observed in neurodegenerative and neurological disorders, and this cannot be achieved using alternatives listed above. Although our laboratory also conducts in vitro / ex vivo based activities using neuronal cell cultures and molecular and biochemical technologies, these preparations alone cannot determine the behavioural objectives of this project.
During this project we will continue to improve and refine our experimental techniques and where possible minimise the number of animals used.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- The animal numbers used during the course of this project will be the minimal necessary to draw statistically robust conclusions. We typically perform power projection analyses based on our expertise (behavioural, physiological, pharmacological and GA models) whilst taking into account that variables including age (we typically work with 6 weeks to 18 month old subjects) gender, species and background strain can influence sample sizes. Alternative means of power calculation may be derived from the literature.

- Keeping up to date with the latest developments ie monitoring of the literature and attending conferences will ensure that we don't duplicate or repeat procedures with animals where data has already been obtained. An exception to this being when validation of the study via replication of the data is necessary (confirmatory experiments). Our laboratory is currently involved in projects funding reproducibility issues in preclinical studies (both within laboratory and between-laboratories) with an impact on the Reproducibility Network UK and the 3Rs. We draw valuable information from this network in terms of study design and data robustness.

- Given our experience and expertise with the techniques and tests proposed in this licence, we would typically estimate a group size between 12-14 subjects in young subjects with clear genotype/drug-dependent differences of 30%. Otherwise, cohort sizes may need to be bigger and variance will need to be established for novel tests and techniques.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- This project will employ a within-subject experimental designs where possible allowing repeated testing of an individual animal in a longitudinal design either across different experimental conditions or at different

stages of development/age. Longitudinal designs have been found to reduce animal numbers by at least 50% compared to cross-sectional between-subject study designs.

- Multi-disciplinary/multi-factorial approaches will be employed in order to maximise the information obtained from a minimum number of animals e.g. implementation of a test battery of different behavioural assays.

- At all stages of experimental design, we will follow ARRIVE 2019 guidelines with experimental blinding and randomisation in order to avoid any bias. We are also seeking to implement a novel 'Data Quality System' as pioneered by one of our collaborators.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

- Pilot studies involving smaller numbers of animals will be utilised when exploring novel procedures. The data generated from these initial tests would be subjected to a power analysis in order to inform the appropriate sample sizes for subsequent studies required. However, sample sizes around n=5 are not really instructive for power calculations and can only be a used as a guide.

- Utilisation of advanced and sensitive analysis tools (incl. video analysis software, Matlab routines etc.) can also reduce the number of animals required to make endophenotypes reliable.

- Tissue will be harvested from all of the animals at the end of the study and will be analysed thoroughly (including pathological and metabolic markers) allowing us to attain the maximum amount of data from a given animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

- During this project we will develop and use novel animal models that more truthfully mimic the diseases. Advantages of using mice for studying human ageing and disease models include that the genetic and physiological parameters can be easily manipulated and they can be generated in a short period of time.

- We will utilise different GA animal models where necessary to closely mimic the underlying pathology of the diseases and enhance our understanding of both the onset and progression of the different disorders. Most of these animals are normal in their day-to-day home cage behaviour with behavioural phenotypes observed using our sophisticated scientific equipment.

- While behavioural testing (cognition, movement abnormalities, and sensory dysfunction e.g. olfaction) is the main read-out this project, it is difficult to draw conclusions on the underlying mechanisms of disease progression from these tests alone. Therefore we will use additional endpoints, such as pharmacological treatment and metabolic read-outs to determine the mechanisms underlying the disease progression.

- Aseptic surgical techniques will be utilised at all times and will be performed to the HO Minimum Standards for Aseptic Surgery and the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery. Peri-operative care will be implemented following consultation with the NVS.

- We will also use rat models (normal and transgenic or knock-out) where required as they have genetic similarities to humans.

Why can't you use animals that are less sentient?

There is no suitable replacement or alternative to using the whole animal to study behavioural changes and related brain function. We need to use the whole animal in order to understand how changes in brain pathology/activity relate to behavioural/cognitive phenotypes observed during disease onset and progression. Many of the diseases (e.g. dementia) are age dependent and only appear following aging in the animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- The development of new animal models that more truthfully mimic the symptoms seen in patients will allow us to understand the diseases better.

- Animals undergoing surgery that need to be single housed post-surgery will be single housed one week prior to the surgery in order to try and minimise the stress induced in the animals following surgery.

- Self-dosing of analgesia will be utilised in animals with analgesia given via drinking water, we have also implemented bespoke analgesia regimes depending on the strain of animals used and our experience of using them for surgical techniques. This has involved the administration of analgesia via drinking water prior to surgery.

- For behavioural testing we will utilise advanced video observation tools and novel computational analysis tools/software to facilitate a more sensitive and effective profiling of an animals behaviour.

- We have introduced standard operating procedures to regulate and standardise all methods and techniques used in our research to ensure consistency and high quality data with all researchers fully trained and assessed for competency. To try and minimise the harm and stress that the animals undergo they will be group-housed as much as possible during testing.

- All surgical procedures will be carried out using aseptic techniques and performed to the HO Minimum Standards for Aseptic Surgery and the LASA Guiding Principles for Preparing for and Undertaking Aseptic surgery. Peri-operative and anaesthetic care measures will be implemented following consultation with the NVS.

- Ageing rodents will be assessed and observed using scoring systems and humane end points established by other researchers with experience of ageing colonies and postoperative care typically includes the appropriate use of analgesics and fluid food rations to support recovery. Selection of behavioural testing will account for frailties in their state of health (for example reduced movement, sensory impairments like visual, auditory or olfactory).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

- We currently seek to implement a new Data Management System on the conduct of studies, their design and analysis tools, specifics required when working with collaborators from industry or academia and so on.

- At all stages of experimental design, we will follow ARRIVE 2019 guidelines with experimental blinding and randomisation in order to avoid any bias.

- We also use Design assist amongst other software tools for power calculation etc. We routinely use Matlab for writing new code for analysis scripts.

- Also, we follow the guidelines provided by commercial breeders (CRL: Guidebook on mouse and rat colony management) for housing and breeding of our colonies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continuously strive to apply the 3Rs to our work. In order to do this we will follow the literature, NC3Rs, CRACKIT and Norecopa.

Home Office

NON-TECHNICAL SUMMARY

141. Novel therapeutic targets for chronic kidney diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

diabetes, kidney complications in diabetes, chronic kidney disease, novel therapeutics

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to perform therapeutic proof-of-principle experiments to demonstrate that modulation of a certain cellular property called "alternative splicing" (either using chemical compounds or changing expression of certain genes) is a viable strategy for new treatments for chronic kidney diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Chronic kidney disease (CKD) is a major health problem worldwide. In US it is estimated that ~13% of the general population has CKD and in Europe the prevalence is higher at 16%. CKD is associated with increased risk of cardiovascular disease and mortality. It is therefore important to further our understanding regarding the molecular determinants of CKD and find new ways to use them for drug development. A large proportion of CKD is due to diabetic nephropathy, one of the complications of diabetes. In the Western word and UK, diabetic nephropathy is the leading cause of terminal renal disease and kidney replacement therapy (almost half of all patients with terminal disease) an immense burden on healthcare costs. It is estimated that 40-45% of patients with type I diabetes and 30% of patients with type II diabetes have nephropathy. Currently, there is no specific treatment for diabetic nephropathy – finding such treatments would be very useful, as slowing down kidney function degradation in diabetes would lessen the burden of caring for chronic renal patients.

What outputs do you think you will see at the end of this project?

The two parts of the project, as outlined in the background section, are at different stages of development, so the benefits will be explained separately:

1. Use of compounds that switch VEGF splicing

In previous work, both in vitro and in vivo, we have shown that the VEGFb isoform is beneficial to the kidney and it is lost in development of diabetic nephropathy. We have compelling evidence to move to next phase – test the hypothesis that compounds that are able to switch VEGF splicing will rescue diabetic nephropathy phenotype in proof-of-principle therapeutic experiments.

The data that will be collected is a thorough analysis of the kidney function to assess whether these compounds are indeed working to rescue the phenotype. This will be done in mouse models of type I and type II diabetes. Findings from this work will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences. In the last 5 years, we have published 12 papers related to alternative splicing in chronic kidney diseases and the potential to switch splicing therapeutically. The licence holder has been invited to present these findings at 10 international conferences and members of his group presented the data at 5 more conferences. We expect our scientific output to be similarly productive in the future.

The work proposed here is expected to be novel and to provide new concepts to the field of diabetes complications in two ways:

i. possibility of specific treatments to slow progression of kidney damage in diabetes – currently there is no specific treatment, only good glycaemic control is recommended

ii. proof that a new class of compounds – modulators of alternative splicing – may be used as new therapeutics in kidney diseases

2. The splice factor PTBP1 in polycystic kidney disease

This part of the project – while fitting in the big picture of contribution of alternative splicing to kidney diseases – is in a more early, basic science phase .

We will analyse comprehensively the kidneys and urine from the transgenic mice described in the background section. This data will be crucial to understand the mechanism on how PTBP1 mutation or deletion may affect the kidney and form the polycystic phenotype.
Findings from this work will be made available to other scientists through publication in peer-reviewed journals and presentations at scientific conferences – as described above .
The main novel contribution to the field by the work proposed in this project will be that a splice factor – PTBP1 – is able to promote a polycystic kidney phenotype, something that has not been reported before.

Who or what will benefit from these outputs, and how?

- **Molecular and splicing biologists**

Beside trying to develop novel therapeutics, this project will elucidate how several compounds signal to the splicing machinery resulting in a group of molecules that can be used as modulators of alternative splicing for further basic science studies. Furthermore, the project will link the science of splicing with functional intracellular and in vivo physiology readouts, i.e. link molecular pathways involving the genes proposed to be studied with the whole system functional biology of the kidney.

- **Diabetes and kidney researchers**

Splicing control is under-investigated in many diseases and this proposal uses as a model the diabetic nephropathy. Scientists working on diabetes and its kidney complications will become aware of a new area of the cell biology that they might not have thought of before – alternative splicing – and link various splicing molecules to their own research.
- **The Pharmaceutical industry**

may investigate the suitability of splicing control as a novel therapeutic strategy or use the link between splicing and diabetic nephropathy to test for potential effects of drugs.
- **Biochemists and chemists**

and those investigating how chemical moieties affect the interaction of molecules within the spliceome and/or spliceosome.
- **Clinicians and Patients**

One of the aim of the project is to develop drugs based on modulation of splicing that are able to conserve kidney function in diabetes and therefore may be investigated further by clinicians working in the field; in longer term we hope that new drugs to benefit patients with kidney diseases to result from this research
.

How will you look to maximise the outputs of this work?

To disseminate our research with colleagues, we have been, and will be in the future, regularly presenting our research at national and international conferences. These conferences will benefit us in terms of scientific discussion and new directions for the project, as well as forming collaborations within the diabetes research community.
To engage our research with diabetic/diabetic nephropathy patients, we will use diabetes focus groups already set up within our university. Research participants will be invited to seminars on our research held within the department, as well as specific presentations of our research in lay terms to Patient and Public Involvement (PPI) groups, which we hope to involve at least 10 patients. This will help us to evaluate the impact of our research to people affected by diabetes. We believe this is of particular importance as alternative splicing is a new and not well understood (in lay terms) area of research; therefore, more awareness of its importance is very much required. To achieve this goal, we will also attend our university's "Impactful Public Engagement with Research" course. Costs for a yearly seminar to a PPI group, including room hire and catering, as well as training costs are covered by our department.
Finally, the disseminate our research with the general public, we will use the Pint of Science platform, in which the postdoctoral researcher working on this project is a volunteer. This will aid us in communicating our research in lay terms, as well as opening up a wider scientific discussion of the importance of alternative splicing in diabetes.
Species and numbers of animals expected to be used

- Mice: 3000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The function of the kidney is fully linked to the so-called "glomerular filtration barrier" - a dynamic structure that constantly has blood filtering through it. This is highlighted by the fact that in adult man 180 litres of fluid crosses this barrier every day. In the glomerulus there are 3 different cell types present, podocytes, glomerular endothelial cells and mesangial cells that are able to communicate with each other. The only way the glomerular filtration barrier can be assessed for how all these cells function together is with an animal model. The function of the glomerular filtration barrier in vivo is easy to assess by measuring the amount of protein excreted in urine and examining glomerular structure on histology slides. Where possible we will use our in vitro models but to fully investigate biological function we also need animal models. For instance, when investigating new drugs, we will do experiments extensively in vitro on cell lines derived in the kidney which will tell us, by measuring various cell properties, whether the compound is able act on their molecular target as intended and postulated or whether, for instance, it is particularly toxic. These experiments will be important in judging whether or not a compound is worth taking to the in vivo studies steps.
We are using adult mice as the simplest animal in which the kidney is very similar to tee human one.

Typically, what will be done to an animal used in your project?

Some of the mice from the so-called transgenic models will have a kidney condition that deteriorates in time because of the intrinsic genetic modification that they were exposed to. Some of the mice will receive a substance to make them diabetic or will be exposed to surgical procedures to artificially compromise kidney function.

Typically, in these experiments we will either have mice that are diabetic or mice that have renal dysfunction and we will administer these substances (compounds) either through injections or orally, in the drinking water. We will collect urine and blood and measure kidney function. At the end of the experiment we will collect the kidneys which will be analysed in detail through histological and electron microscopy techniques. We hope to obtain evidence that the administration of these substances slows the progression of kidney failure.

What are the expected impacts and/or adverse effects for the animals during your project?

The most common adverse effects are weight loss, polyphagia (excessive hunger), polydipsia (excessive thirst) or polyuria (excessive urination) from development of diabetes. Some toxicity signs may appear as described above, due to substances administration; however, we expect this to be minimum (less than 5% animals) since every single substance studied here will be either used before by us or assessed in pilot experiments as described above.

Careful monitoring of the animals is crucial for our studies, and we have strict criteria when animals are to be killed, depending on the status of their kidney function or metabolic disease. Animals will be inspected twice daily and the presence of signs of distress assessed. The design of our experiments will be such that we will minimise animal use but maximise data collection; often animals will act as their own controls, and repeated measurements minimises the number used. We will systematically monitor various signs and symptoms: weight, clinical signs post-anaesthesia (loss of coordination, abnormal breathing), swollen abdomen, gastrointestinal problems (diarrhoea), hunched posture, piloerection, restlessness, less mobile and alert, isolated, vocalisation, self-mutilation. Appropriate action will be taken e.g. monitor carefully/ consider analgesics, consult NACWO and NVS, consider termination.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

mild - 20% moderate

- 80%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The function of the kidney is fully linked to the so-called “glomerular filtration barrier” - a dynamic structure that constantly has blood filtering through it. This is highlighted by the fact that in adult man 180 litres of fluid crosses this barrier every day. In the glomerulus there are 3 different cell types present, podocytes, glomerular endothelial cells and mesangial cells that are able to communicate with each other. The only way the glomerular filtration barrier can be assessed for how all these cells function together is with an animal model. The function of the glomerular filtration barrier in vivo is easy to assess by measuring the amount of protein excreted in urine and examining glomerular structure on histology slides. Where possible we will use our in vitro models but to fully investigate biological function we also need animal models.

Which non-animal alternatives did you consider for use in this project?

We regularly use in vitro cell cultures with various kidney cells to test our hypothesis.
For instance, when investigating new drugs, we will do experiments extensively in vitro on cell lines derived in the kidney which will tell us, by measuring various cell properties, whether the compound is able act on their molecular target as intended and postulated or whether, for instance, it is particularly toxic. These experiments will be important in judging whether or not a compound is worth taking to the in vivo studies steps.

Why were they not suitable?

We can assess various properties of kidneys cells in culture, however, we cannot assess the kidney function as a whole organ just by culturing cells.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Mice numbers were estimated depending on how many experimental animals will be needed. Statistical power calculations using data from diabetes experiments routinely performed by the
applicant show that n=10 experimental and n=10 control mice are needed to see a significant difference ($p>0.05$) in albuminuria with a power value of 0.80 (>80%). More specifically, we have used raw data from our previous experiments in db/db diabetic mice in which albuminuria was compared with their lean controls over time and was shown a significant difference between the two groups. From these data we calculated the averages and standard deviations for each time-point. Because the two populations have different standard deviations, for power calculation we have used an online tool which is appropriate for comparing two populations with unequal variance:
http://epitools.ausvet.com.au/content.php?page=2Means2
Using these calculations we have found the most appropriate group size to be formed of 10 mice. These calculations were done together with a statistician.
Maintenance of transgenic colonies – the average number of mice in a colony to be able to provide at least 3 breeding pairs and enough litters to supply the experimental cohorts is estimated at 10.
Experimental numbers of mice were estimated based on the number of compounds we plan to use under this licence, over 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will minimise the number of animals necessary by following the principles of reduction by thorough statistical analysis as taught on module 5 of the Home Office licensing course.
Many of our studies require cross breeding of animals with different genetic mutations. To limit numbers, we will set up colonies in which we optimize the number of offspring that have the correct genotype. This will mean that fewer mice have to be sacrificed prior to being part of an experimental study.

If giving the mouse a substance and the response to different doses needs to be ascertained, we will initially perform pilot studies to ascertain the correct magnitude of drug required to induce an effect and then go on to a formal hypothesis driven experiment. If using novel drugs, we will include a prior stage to ascertain safety, quality of manufacture and suitability (e.g. vehicle and pH) of the drug. This will be performed by an extensive literature review of the drug (or associated drugs) and their safety profile. We will then perform a pilot experiment in a single mouse using a low dose of the medication and will closely monitor the mouse for side-effects before using it on greater numbers. We will consult an expert statistician before embarking on our studies to ensure the minimal number of animals to derive meaningful results is studied. To this respect I have a continuous collaboration with a statistician from our university
.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Mice breeding and colony maintenance will be done in accordance with the ASRU Efficient Breeding of Genetically Altered Animals Assessment Framework. Mice numbers will be kept to a minimum by using crossing designs that result in minimal animal numbers (e.g. we will use homozygous breeding pairs when possible), demand will be assessed before breeding and crossing, colonies will only be maintained while there is an experimental plan and funding allocated.
We perform breeding calculations before we plan our experiments and only produce the numbers of animals that we need.
We have a database that tracks all this information and also gives me historical data. It is very easy to see how many animals there are in each colony, how frequently they are producing litters and the size of the litters. It is easy to see when the pairs need to be replaced.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We are using several mouse models:

- a transgenic mouse in which a certain protein is missing (knocked out) from the kidney; this is the only way to understand the role of this protein in the kidney and is modelling what happens in the kidneys in human patients when this protein is missing

- transgenic mouse models of diabetes; the ones we selected are the best to study diabetic kidney disease, as in many other mouse models of kidney disease the kidney is not damaged; therefore to be able to study the kidney function in diabetes these kidney-sensitive mice will be kept the shortest time possible

- chemically-induced diabetes model – a chemical named streptozotocin is injected to destroy some of the pancreatic cells; this will provoke the appearance of diabetic disease similar to what is seen in humans; fairly quickly in this model, after a couple of weeks, signs of diabetic disease of the kidney also appear, and therefore we can perform our experiment sin the shortest of time possible

The methods we are using are the minimal needed to be able to analyse the kidney function - urine collection, blood sampling and blood pressure measurements; we will also test substances that we believe are able to preserve kidney function but this will be done only after pilot studies in which we test toxicity and make sure the mice will not suffer
.

Why can’t you use animals that are less sentient?

To be able to study the complexity of the kidney as an organ we need to do this in mammals like mice. Embryonic forms cannot be used as kidneys are in development
.

Models less sentient, like zebrafish, do not have a kidney similar to the human kidney

.
Experiments are needed for a longer time period and need to mimic diabetic disease, so cannot be done in terminally anaesthetised animals
.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I constantly think on how to refine the procedures we are using. We review with my team all the procedures before the start of each experiment and discuss whether there are better ways to do them; make sure that animals are well accommodated (e.g. always leave at least 7 days from delivery to the start of the experiment); make sure there is proper monitoring (e.g. once the mice become diabetic and show clinical symptoms like excessive urination we assess their welfare daily and sometimes twice daily).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Several of the NC3R guidelines: https://www.nc3rs.org.uk/guidelines

https://www.nc3rs.org.uk/3rs-resources/ https://www.nc3rs.org.uk/3rs-

toxicology-and-regulatory-sciences https://www.nc3rs.org.uk/3rs-

resources/blood-sampling https://www.nc3rs.org.uk/how-to-pick-up-a

mouse

Other: http://www.procedureswithcare.org.uk

LASA (Laboratory Animal Science Association) guiding principles:

http://www.lasa.co.uk/PDF/AWERB_Guiding_Principles_2015_final.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am a registered user on the NC3R website (National Centre for the Replacement, Refinement and Reduction of Animals in Research); as such I receive regular updates and newsletters with new advances in the field.

I am constantly in touch with the Named Animal Care and Welfare Officers as well as Named Veterinarian Surgeon at our institutions and we discuss various novelties in animal care and techniques.

Home Office

NON-TECHNICAL SUMMARY

142. Ocular gene therapy

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult, embryo, neonate, juvenile, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The overall aim of this project is to develop new methods to treat various blinding eye diseases by using gene therapy
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The eye diseases we are targeting are currently either poorly treated or there are no effective treatments for them at all. Although many of these diseases are relatively rare, their impact on the individual patient and the community is substantial.
We are already performing clinical trials of gene therapy for retinal dystrophy and we will initiate several more clinical trials on inherited and acquired disease in the coming years based on the work proposed here. We hope that accomplishing these clinical milestones will be an essential first step in the development of a treatment for these untreatable, blinding diseases.

What outputs do you think you will see at the end of this project?

The overall aim of this project is to develop new methods to treat various blinding eye diseases by using gene therapy. Potential outputs include novel gene therapy vectors for use in clinical trials. Findings will also be documented in Intellectual Property (IP) filings as well as peer-reviewed research publications and conference presentations.

Who or what will benefit from these outputs, and how?

The eye diseases we are targeting are currently either poorly treated or there are no effective treatments for them at all. Although many of these diseases are relatively rare, their impact on the individual patient and the community is substantial.
Preclinical proof of concept and toxicology data acquired from the proposed studies, will lead to successful candidates for treating retinal degenerations entering clinical phase development. This will include Good Manufacturing Practice (GMP) material manufacturing and Phase I/II clinical trial initiation (as managed by other departments of our company).

How will you look to maximise the outputs of this work?

Where needed, we will seek additional academic or third party collaborations to expedite the development of these novel gene therapy vectors to treat forms of blindness.

Species and numbers of animals expected to be used

- Mice: 5000
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The visual cycle is a complex process that occurs in the photoreceptor cells and as such in vivo experimental platforms are much more informative that in vitro ones. Animal models often lack function of the orthologue gene that occurs in mutated forms in patients and as such are excellent models of disease for proof of concept studies.

Depending on the underlying mutation, these animal models develop retinal regeneration at different ages and treatment within certain periods of development can help establish the window of opportunity for treatment in patients.

Typically, what will be done to an animal used in your project?

Once an animal reached the appropriate age for intervention based on the underlying cause of disease, an intraocular injection with an investigational gene therapy vector will be performed.
In-life non-invasive assessment of vision will be performed at various time-points. Duration of the in-life phase depends on the severity of the retinal degeneration and/or efficacy of the gene therapy vector. It can extend to maximum 14 months. Following necropsy, all relevant tissues (i.e. eyes and major organs) will be assessed for efficacy of the tested drug.

What are the expected impacts and/or adverse effects for the animals during your project?

All animals are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours following intraocular procedures.
Uncommonly animals that fail to do so or exhibit signs of:

- pain,

- distress/significant ill health (i.e. general signs of ill health such as hunched appearance, piloerection, lethargy etc.)

Animal exhibiting these signs be killed by a Schedule 1 method unless a programme of enhanced monitoring and care is instituted until the animal fully recovers
Any animal not fully recovered from the surgical procedure within 24 hrs (eating, drinking and return to normal behaviour) will be humanely killed.
Additionally, any animal exhibiting a maximum 15% loss of weight at any point, will also be humanely killed.
Specific adverse effects from intraocular administration include ocular infection. This is rare but in the case it occurs, treatment advice from the NVS will be sought. If the animal does not respond to the treatment within 48hrs, it will be killed by Schedule 1.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild: 5000 mice (100%), 100 rats (100%)

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although therapeutic vectors are tested in cultured cells prior to use in animals, treatment efficacy can only be proven in animals, as the diseases we aim to treat (like retinal degeneration) are complex disorders, involving interactions between multiple cell types throughout the retina. These interactions cannot be tested in cultured cells.

Which non-animal alternatives did you consider for use in this project?

In vitro culture systems and/or computer modelling

Why were they not suitable?

Current knowledge and techniques are insufficient to model all these interactions, either in a culture system or using computers, well enough to reliably predict treatment outcomes. However, we are using cultures of 3D retinal organoids that harbour the same mutations as the animal models of interest in the human orthologues. Currently, no functional assessments can be performed using the retinal organoids
(this is something that in vivo work is essential for) and they are used to assess expression of transgenes and protein localisation in human tissue.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This estimate is based over 5 years based on:

- Projected number of projects (8 projects, some overlapping)
  Projected duration of each project (12-18 months depending on model)
- Projected needs for in vivo proof of concept (efficacy) and toxicology

-

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power calculations, employment of SOPs and design based on experience from previous preclinical programs that we have successfully progressed to the clinical stage as well as designs using NC3R's EDA software.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be employed where appropriate (Protocol 2 and 3) and breeding advice will be given by the staff of the establishment where breeding and maintenance of animal lines will take place.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The models employed will have certain forms of retinal degeneration. The intervention will mirror the safest surgical approach that is aimed for patients and the majority of assessments will include minimally invasive tests while the animals are alive, and as such collecting as much data as possible from each animal.
The testing of novel therapeutics aims to improve or halt the retinal degeneration observed in these models.

Why can't you use animals that are less sentient?

Live animals need to be used so that vision can be assessed using both electrophysiology and behavioural assessments. Additionally, mice are the lower vertebrate group with a fully post-mitotic retina, and they will answer all scientific questions as adequately as larger animals.
Animal of lower order (such as amphibians or fish) lack the anatomical relevance and adequate common features in terms of retinal function in order for them to act as useful models for these gene therapy research studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have developed improved gene therapy vector production techniques, which give far better vector purity than previously established techniques and thus will further decrease the (already low) risk of inflammation post-administration.
Regular observations will be performed as required by all protocols used to ensure the welfare of the animals taking part in this project. In addition, we are looking to develop novel agents that will allow for treatment through optimised routes of delivery (i.e. intravitreal instead of subretinal delivery).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ASPA, LASA and ARRIVE guidelines will be followed together with current developments in the field in order to refine the experiments using most up-to date discoveries in gene therapy.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

Everybody involved in this project will be in close communication with the establishment, the NACWO, NVS and the regional NC3R's manager throughout the duration of the project making sure any advances in the 3Rs are implemented. Advice will be sought from Regional 3R’s Manager as required

Home Office

NON-TECHNICAL SUMMARY

143. Oxidative stress-related mechanisms of liver fibrosis.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Liver fibrosis, oxidative stress, Nrf2

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We will use mice where the Nrf2 pathway has been genetically modified to examine cell type-specific redox signalling pathways that are regulated by Nrf2 in the context of liver fibrosis. Specifically, we wish to evaluate whether activation of Nrf2 in hepatic stellate cells or in macrophages allows either liver fibrogenesis to be arrested, or established fibrosis to be resolved.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fibrosis of the liver is a global healthcare issue, with obesity-driven NAFLD (i.e., non-alcoholic fatty liver disease) reaching epidemic proportions in the Western world. A substantial number of affected patients will progress to liver cirrhosis and thus risk developing hepatocellular carcinoma. Moreover, there is currently no effective treatment for liver fibrosis other than transplantation, and this is a limited option: new therapeutic strategies for liver fibrosis are therefore urgently required.

What outputs do you think you will see at the end of this project?

We believe this project will provide new information on the development and resolution of liver fibrosis. We also expect to be able to publish several papers from the work in this project.

Who or what will benefit from these outputs, and how?

Worldwide there is an increase in obesity- and Type 2 diabetes-related liver disease that can lead to fibrosis. There is currently no therapeutic treatment other than transplantation for liver fibrosis and there is a shortage of transplant donors. Through this research we hope to translate our findings about how activation of NRF2 arrests/reverses liver fibrosis into addressing an unmet clinical need, and to inform future clinical trials.

In addition, our collaborators and other research groups within the same/similar fields will benefit from our work on NRF2 through the dissemination of new knowledge in the short-term. In the longer-term we hope that these outputs will benefit translational studies and eventually patients suffering from liver fibrosis. At the moment there are no non-invasive treatment for liver fibrosis and we hope that our research lays the foundations for the development of new pharmaceutical agents within this field and /or the repurposing of current drugs.

How will you look to maximise the outputs of this work?

We will maximise the outputs of this work through collaborations with other institutes and disseminate new knowledge through publication of peer reviewed papers.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using mice as they are able to be genetically altered which will allow us to spatially and temporally

activate the genes and cells of interest. The human diseases, e.g. liver fibrosis, we are studying most often occur in adults. We are using adult mice as these reflect the disease in humans.
Typically, what will be done to an animal used in your project?

Animals used in this project will be injected i.e. not more than twice per week with known agents causing liver fibrosis e.g. halogenated hydrocarbons over a period of 6 weeks. Some of the animals will also be treated with agents expected to induce changes in expression of genetic alterations, starting before this period and/or extending into it. All animals will be killed and tissues taken for detailed laboratory analysis.
What are the expected impacts and/or adverse effects for the animals during your project?

The expected impacts and/or adverse effects for the animals are acute liver injury or liver fibrosis. This is not usually associated with pain in humans and therefore unlikely in mice. (Scholten et al (2015) Laboratory Animals 49(S1): 4).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities would be mild to moderate with about 50% in in each category **What will**

happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Liver fibrosis is a three-dimensional process involving cells of different types. It cannot yet be modelled satisfactorily in non-animal systems.
Which non-animal alternatives did you consider for use in this project?

We considered using cell/tissue cultures and advanced computer modelling techniques. We are using human derived cells for relevant aspects of the project as an alternative to animal use.
Why were they not suitable?

Cells do not reflect what happens in the whole living body and so can only be used to answer certain scientific questions. Animal models help to ensure the effectiveness and safety of new treatments by providing information on responses within the whole organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Initial groups of 10-12 mice will be generated to assess the potential magnitude of the response to the induction of chronic liver fibrosis. Based on these initial data the number of mice will be amended appropriately in order to gain sufficient statistical power for hypothesis-testing experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We researched literature precedent, used online tools such as G*Power, and will follow the guidelines set out in the ARRIVE and PREPARE Guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To optimise the number of animals used in this project we will breed our various genetically modified lines as efficiently as possible. We will also run a small pilot study and use the results to help to determine the lowest numbers required to give statistically significant results.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice as the animal models for this project which reflect liver fibrosis in humans. The mouse genome is very similar to that of the human genome making mouse genetic research particularly useful for the study of human diseases such as liver fibrosis. The methods used will be i.p. (Carbon tetrachloride, CCl4) to initiate liver fibrosis and gavage (TBE-31/tamoxifen) to treat liver fibrosis/induce
Cre in a tissue specific manner respectively. There may be pain/discomfort associated with the initial CCl4 injection, but analgesics will be used to mitigate this, as advised by the Named Veterinary Surgeon. Liver fibrosis itself is not usually associated with pain in humans and this is therefore unlikely in mice. These methods will only cause transient pain/discomfort to the animals.

Why can't you use animals that are less sentient?

Liver fibrosis occurs most often in adults. Therefore it is important that our animal model reflects that life stage. Lower vertebrates and invertebrates have differences in the microenvironment which may contribute to species-specific responses to injury. Liver fibrosis is a progressive disease and our study aims are to resolve the fibrosis.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise the welfare costs for the animals we will monitor and weigh the mice throughout their treatment time.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The published best practice guidelines we will follow will be the ARRIVE guidelines at https://www.nc3rs.org.uk/arrive-guidelines and the PREPARE guidelines at https://www.ncbi.nlm.nih.gov/pmc/articles/PMC5862319/

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

We will stay informed about advances in the 3Rs through frequently checking the website and resources offered at https://www.nc3rs.org.uk/3rs. We will also be in consultation with our unit NACWO.

Home Office

NON-TECHNICAL SUMMARY

144. Papillomavirus Transmission, Infection and Lesion Formation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Papillomaviruses, Cancer, Infectious Disease, Virus Transmission, Viral Immunity, Viral Immunity

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rabbits	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To establish how papillomaviruses are transmitted, how lesions form and are maintained, and to find new ways to prevent transmission and treat and treat clinical disease .

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Papillomaviruses (PVs) have been discovered in a wide array of animals. More than 300 PVs have been identified, including over 200 human papillomavirus (HPV) types. HPVs infect humans and cause epithelial lesions with different clinical outcomes, ranging from non-cancerous hyper-proliferative lesions such as warts, to subclinical (not apparent) lesions that can in some instances progress to high-grade neoplasia and cancer. HPV infection is responsible for approximately 6.1% of all human cancers including cervical, head and neck, anal and conjunctival cancers, however 90% of HPV infections are cleared by the host immune response. HPV vaccines have been proven to be effective and are expected to make great impacts on HPV-related disease, but have some limitations:

a) They are only effective for individuals who have never been infected with vaccine type HPVs (i.e. they are prophylactic rather than therapeutic).

b) Because of their cost, these vaccines are not widely available in developing countries where resources are limited.

c) Vaccine hesitancy is restricting implementation even in developed countries with vaccine programs.

Therefore, there is ongoing need for the development of antiviral agents to treat existing HPV infections, and an efficient strategy for the management and control of HPV infections through screening, including cervical screening, which is currently being modified to incorporate HPV DNA testing .

As HPVs are host-specific and cannot infect other animals, and there is no precise animal model for HPV infection. However, the general strategy of all PVs to accomplish their various life cycle stages in the skin are similar, with different papillomaviruses having similar molecular functions for their gene products. Although many aspects of the infection route are not fully worked out i) PVs target the skin, which consists of multiple cell layers; ii) after PVs have infected cells in the lower (basal) layer of the skin, infected cells are maintained for years to decades, modulating proliferation and commitment to differentiation of the skin cells; iii) Once the infected cells leave the basal skin layer, the productive life cycle is triggered and new viruses are produced; iv) PV is shed inside dead cells from the surface of infected skin, and transmitted via direct or indirect contact; v) PV infection is controlled by the host immune system, which modulates viral gene expression.

Given this common strategy of PV infection, we aim to use animal models to elucidate how PVs are transmitted, and how new lesions form and are maintained, in order to develop new insight into PV transmission mechanisms, and the development of anti-papillomavirus agents/treatments and infection control strategies. These aims can be achieved using models that allow us to investigate all aspects of the virus life cycle (transmission, infection, lesion formation, and the production of new virus) in the presence of an intact host immune system.

What outputs do you think you will see at the end of this project?

During this project, we aim to better understand:

1. How mouse PV is transmitted and infects new sites, particularly how virus preparation (purified virus, cell-free virus, and virus in exfoliated dead cells (squames)) affects virus survival and infectivity. We will evaluate the efficacy of disinfectants currently used in clinical settings on virus infectivity. Together with a parallel analysis using human PV in tissue culture models, we will examine how papillomavirus transmission can be controlled and prevented. We expect to achieve this goal within 3 years.

2. The early stages of lesion formation following infection. We want to define the molecular pathways that are modulated by the virus to maintain infection in the basal (lower) layer of skin cells, and how virus genes do this (achievable in 3 years). We also want to develop ways of manipulating these pathways to inhibit the maintenance of infection in the basal keratinocyte (skin cell) layer, leading to the development of anti-papillomavirus therapy/agents. This will depend on the progress of a parallel study using keratinocyte tissue culture models to investigate the function of virus protein function on keratinocyte proliferation and differentiation. However, we expect to have a rudimentary understanding of this within the 5-year period.

3. How mouse PV gene expression patterns in mice vary at the different body sites in mice (achievable in 3 years). Our longer-term aim is to understand how virus gene expression patterns contribute to the difference in the behaviour of the infected lesion (phenotype), and to relate such differences to expression seen in clinical samples infected by HPV. We expect to have a basic understanding of this within the 5-year period.

4. The molecular process that drives lesion regression. This is a more substantial goal than those described above, but during these 5 years we aim to look at the lymphocytes (small white blood cells) and the host's immune response in the lesions that regress.

We estimate that four major publications will come from this proposed work, the first relating to ‘Papillomavirus transmission, lesion formation and disinfection’, a second relating to ‘The molecular mechanisms of early stage papillomavirus lesion formation’, a third relating to 'The process of lesion regression of papillomavirus infection; the implications of the host immune system', and a fourth relating to 'Tissue culture models of the cervical transformational zone, and the dysregulation of viral gene'.

Who or what will benefit from these outputs, and how?

The results will benefit the scientific community, by providing a comprehensive understanding of how PVs are transmitted and form lesions, and how infection is controlled by host immunity. The impact of outputs from the first objective (viral transmission) will provide a new insight into how HPV transmission can be controlled and prevented, which will directly affect clinical practice. In the longer term, the outputs from the second and third objectives will provide identify key cellular pathways that PVs regulate to form and maintain lesions at specific sites of infection. Those interested in the development of anti-HPV treatments/agents will also benefit from this work.

How will you look to maximise the outputs of this work?

The scientific results will be disseminated globally primarily through publications as well as preparation of review articles, book chapters, and lectures at scientific and other meetings.

Species and numbers of animals expected to be used

- Mice: 3710
- Rabbits: 96

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

There is no experimental model to investigate all stages of PV infection (infection, lesion formation, virus production, and virus regression) without the use of animal models. Only animal models will allow us to investigate all aspects of these stages. Each PV is highly host-specific and can infect only their natural host. However, all PVs are considered to share fundamental strategies in their life cycle. Thus, we can understand how the human PV transmits, infects and forms its lesion by investigating animal PVs. Using the mouse PV model, we can also investigate virus transmission and lesion formation using various genetically modified mouse strains. With the rabbit PV model, we can specifically investigate how the host immune system responds to PV infection and resolves it.
Some PVs, including HPV, cannot be propagated using a tissue culture model. Transplanting infected cells into mice is currently the only way that we can propagate infectious PVs for use in other experiments.

Typically, what will be done to an animal used in your project?

Small areas of skin will be gently scarified before infectious material is applied. A wart-like lesion will grow at the inoculated site and the development, and in some cases regression, of the lesion will be monitored over a period of up to 6 months.
After virus infection, animals will receive reagents or treatment (e.g. cryotherapy) that may affect the process of lesion formation/persistence. The number of procedures that mice and rabbits will be subject to will be kept to a minimum to limit discomfort, while allowing the generation of scientifically useful data. A set of procedures will be repeated no more than three times per animal, with intervals between treatments that allow for full healing (e.g. following mechanical abrasion). Ten percent of animals may receive both reagents and treatment, the rest will receive one of the two, or neither. Animals will be continually monitored for adverse effects post-treatment, and if necessary, the intervals between treatments will be adjusted or the treatment will be suspended.
Similarly, rabbits will be inspected regularly and, in some cases, biopsies (up to three) and blood samples (up to two) may be collected.
For infectious papillomavirus production, tissues/cells will be transplanted into mice under the coating covering each kidney by surgical procedure. Transplanted tissue/cells will be collected after three months, after the animals have been killed.
Genetically modified mouse strains which are not commercially available will be maintained/bred under this project, and procedures required for this will be carried out. None of the genetically altered mice are expected to develop any adverse effects.

What are the expected impacts and/or adverse effects for the animals during your project?

Proliferative lesions will develop at the site of infection (warts). In mice, the lesions are self-limiting and localised, and will not affect the general health and welfare of the animals. Animals will be killed by a humane method before they show moderate clinical signs, such as large lesions or secondary lesions that interfere with the normal processes of feeding and movement within the cage. In rabbits, the lesion naturally disappears within 4 months. In mice, the transplanted tissue/cells will not cause any clinical signs.
Animals will be closely monitored during and after each procedure, and the animal will be treated if adverse clinical signs (such as weight loss, lack of normal movement or other abnormal behaviour) are seen. If there is no response to treatment, the animal will be killed by a humane method. Bodyweight will be recorded when the experiment starts and will be monitored regularly and compared with age and ‘free feeding' matched control animals control animals.

Although we expect some transient soreness at the scarification site immediately after infection, the non-cancerous lesions that develop as a result of infection are not expected to be painful for the animal. Painkillers will be provided if required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of mice (95.4%) will experience procedures of only mild severity, with the remaining mice (4.6%) undergoing procedures of moderate severity.
Only mild severity procedures will be used with Rabbits.

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We can investigate all the stages of PV infection from transmission/infection, lesion formation, and lesion regression, to reactivation at particular epithelial sites, only by the use of animal models. Importantly, we can only investigate the role of the immune system in PV lesion regression using the rabbit PV system. By using these animal models we can produce a more complete picture of PV/host interactions interactions.

Which non-animal alternatives did you consider for use in this project?

We already make extensive use of tissue culture and organotypic raft culture (which allows the formation of skin tissues in the lab), to study the papillomavirus life cycle. We also employ a culture system to study infection and lesion formation in patient biopsy material. Additionally, we compare the results from animal experiments with clinical observation of patient material. Such comparative analysis allows us to develop our understanding of how papillomaviruses interacts with skin (epithelial) cells.

Why were they not suitable?

The raft model and analysis of clinical specimens are useful; however, we need to use animal models to address particular questions concerning early lesion formation, regression and the associated immune responses. In addition, some human papillomaviruses can only currently be grown outside of their human host, in animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Production and maintenance of genetically altered mouse colonies (2 strains concurrently) is estimated to require 2000 mice over 5 years. The standard protocols for genetically altered mice (protocols 1 - 5) may require 410 mice over 5 years, as we expect to need two strains to make the embryo stock and/or to re-establish the strain from the sperm or embryo stock.
The PV infection protocol (protocol 6) is estimated to require a maximum of 1000 mice (24 mice per experiment, for 50 experiments) over 5 years. The production of 'infectious PV protocol' (protocol 8) is estimated to require 100 mice (4 mice per PV stock, for 25 PV types) over 5 years.
The rabbit PV infection protocol (protocol 7) is estimated to require 100 rabbits (8 rabbits per experiment, for 12 experiments) over 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experiments will be exploratory, and primarily observational or qualitative. They will address different features of disease pathology and viral gene expression, such as how the host immune system controls infection, how PV changes the behaviour of infected cells to form lesions, as well as how the site of infection affects PV behaviour.
Substances which are expected to modulate virus function are commercially available, and routes of administration, dosage volumes, frequencies and durations will be based on established protocols from published literature. We will use the NC3Rs experimental design assistant tool and the PREPARE guidelines and submit a protocol amendment along with justification if our analytical requirements change in future.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We are already involved in the analysis of virus expression and virus protein function in clinical specimens and skin (epithelial) tissue culture models, and we are using these models to develop our hypothesis of how PVs interact with the skin cells (keratinocytes) that they infect. Before conducting any animal experiments, we will make extensive use of tissue culture and organotypic raft culture (a system that permits 3D modelling of virus infection in lab recreated skin tissues), to study the biology of PVs in vitro. Experiments which specifically require the use of animal models will be conducted once this has been done.
We will keep animal strains that are not commercially available as embryo stocks, and will breed and maintain living colonies only when necessary during the project in order in order to minimise the use of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Previously, the most appropriate animal model for the study of PV infections was the rabbit, and we have used the cottontail rabbit (CRPV) and rabbit oral (ROPV) papillomavirus systems in previous studies. These models are difficult to use, and we have found that rabbits may suffer weight loss upon treatment with immunosuppressant drugs. The identification of a mouse PV has taken time to achieve, but recently one has been described in the literature and is reported to produce typical papillomas (warts) in genetically modified immunodeficient mice. As a result, we can now assign the majority of our studies to the mouse PV model. However, the rabbit PV models are still useful, and essential when studying how the host immune system responds to PV during the natural course of infection. Other papillomavirus models are in larger animals (cows, dogs) or unconventional laboratory animals (e.g. the multimammate rat).
Papillomavirus lesion formation requires scarification of the skin to allow access of the virus to the lower (basal) epithelial layers. Scarification is minimised to limit bleeding and is performed under anaesthetic. The process of lesion formation causes no pain to the animal, and will routinely be carried out on the tail.

Why can't you use animals that are less sentient?

Each PV can only infect and form lesions in its natural host, and as a result we need to use mice to study the mouse PV, and rabbits for the rabbit PV. We are using animals of the lowest sentience that are susceptible to PV infection.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Working closely with the biomedical services staff, we will monitor animals on a daily basis. Animals must be allowed to acclimatise to new surroundings and personnel before any procedures are performed, to minimise stress and safeguard animal welfare and research results. Personnel will be trained to handle mice and rabbits correctly. Especially during and after procedures, animals will be monitored closely for adverse clinical signs, and the experiment/procedure will be terminated if necessary, to stop suffering. It is expected that animals will endure some discomfort associated with the surgical procedure. This will be minimised by use of good surgical technique, and pre-emptive and post-operative analgesia will be administered.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the Laboratory Animal Science Association (LASA), PREPARE (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence) and ARRIVE (Animal Research: Reporting In Vivo Experiments) guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We subscribe to the Tech3Rs newsletter published by NC3Rs, and will keep up-to-date with our department's circulated 3Rs publications and website.

Home Office

NON-TECHNICAL SUMMARY

145. Pharmacokinetics of Pharmaceuticals

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Pharmacokinetics, Medicines, Preclinical

Animal types	Life stages
Mice	juvenile, adult, pregnant
Rats	juvenile, adult, pregnant
Rabbits	adult
Guinea pigs	juvenile, adult
Cynomolgus macaques	juvenile, adult
Beagles	adult, juvenile

| Animal types | Life stages |

Minipigs	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this work is to conduct relevant studies during the development of new medicines, to assess how much and how quickly the body absorbs the test medicine, and then how much and in what ways the medicine is changed within the body and then excreted. **A retrospective assessment of these aims will be due by 09 April 2026**

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work in this project will allow drug companies to make decisions on which possible new medicines are most likely to be to worth spending more time and animal use in developing, and also then providing enough information for the government regulators to allow the safe administration of the materials to people. Without these studies, progression of new medicines to early human studies and to patients could not occur in the current regulatory framework.

What outputs do you think you will see at the end of this project?

Data collected will be information on the absorption of various potential new medicines, as well as how animals change and excrete these materials. Outputs will include simple measures like the amount of the medicine which is in the blood, urine or faeces, at various times after being given the medicine. These results can then be compared to the known or expected situation in people.
The data will be collected to the quality standards expected by government regulators in the UK, Europe and elsewhere, who will make decisions on whether these materials can be safely marketed and used in society. Improved methods of conduct of specific data collection processes may be developed during the course of the project.

Who or what will benefit from these outputs, and how?

Our clients, typically commercial drug companies, will benefit from the provision of high quality data. This will to

help them in their work to develop new and better medicines, to discontinue development of inappropriate medicines or to understand and manage the risks of new medicines given to people.
Work on this project may also provide data to inform ongoing human clinical trials.
Enabling development of successful medicines will benefit society through diagnosis, treatment or prevention of disease.
The wider scientific community may benefit from publication of refined approaches to animal use.

How will you look to maximise the outputs of this work?

Our organisation has colleagues who also have experience of such work in different parts of the world. Collaborations and information exchange with others within the organisation, helps to identify and spread information on successful and unsuccessful approaches.
The licensee and colleagues have had on-going collaborations with NC3Rs on various aspects of the conduct of studies, and associated housing and husbandry methods for the animals, over many years.
The licensee and colleagues seek to disseminate information through presenting outputs at scientific conferences and contributing to publications in the scientific literature where relevant. **Species and numbers of animals expected to be used**

- Beagles: 250
- Minipigs: 150
- Pigs: No answer provided
- Cynomolgus macaques: 250
- Mice: 5000
- Rats: 10000
- Rabbits: 100
- Guinea pigs: 50

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Many scientific studies have been conducted to demonstrate that the types of animals to be used in the project will provide results which reflect the likely outcomes for people. Where this is uncertain, comparison between results in different species may be conducted, to identify the most relevant for predictions of outcomes in people. The way in which each new medicine is absorbed, changed and removed by people may be known, or predicted from other information, or studies may be conducted to find this out. The animal type(s) to be used will be chosen based on this understanding, or to find this out. The stage of life of the animals to be tested reflects the age/stage of life of people who would receive the medicines.
Another big advantage of using the listed animal types is that these animal types may be recommended by specific guidelines on how to do this work, and the results of tests are known to be acceptable to the government agencies responsible for authorising use of the medicines in human volunteers and patients. Development of new medicines cannot currently be achieved without this approval by government agencies in the UK, elsewhere in Europe and in other parts of the world.

Typically, what will be done to an animal used in your project?

Animals will be given a potential new medicine by the same method that people would be exposed to them - most commonly by mouth, but may be by other routes, including by injection and application to the skin. The

medicines are most commonly given once only, and samples such as blood samples are taken to assess how much of the medicine has been absorbed by the body. Similarly, samples of urine and faeces and expired air may be collected to see how much and in what way the body excretes the medicine. Collecting urine and faeces and expired air requires keeping the animals, normally singly, in a small cage which allows the urine and faeces to fall through a grid, typically for about a week.
Some animals will have surgery conducted under anaesthesia, and with use of pain relief, to allow collection of bile and/or blood from animals after they have been dosed and housed as described above.
Animals may be humanely killed after the collection period, and tissues may be taken from the animals post mortem (after death), and analysed. Often, animals are kept, and after checks by a vet to confirm that no lasting harms have been caused, they may be used on repeated occasions.
Some animal use involves only taking blood samples, to conduct scientific studies using the blood only.

What are the expected impacts and/or adverse effects for the animals during your project?

The process of dosing animals, taking samples and confining for collection of urine/faeces/expired air can cause a degree of discomfort during conduct, but not expected to be long-lasting. The dose of test medicines used is not normally expected to cause any significant harm for the animals. Surgery has the potential to cause pain or discomfort, but this is generally prevented or minimised by use of appropriate anaesthetics drugs and pain relief, under veterinary control.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The harms described above are expected to fall very largely within the mild category, as most studies involve giving a non-harmful material and taking a series of blood samples. Where surgery is performed, or animals are single housed for a period of days for collection of urine and faeces, this would be noted as moderate severity, and may involve about a tenth to a quarter of the total number of animals. Severe outcomes are not anticipated; if seen in individual animals, these would be reported to Home Office.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

A retrospective assessment of these predicted harms will be due by 09 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Non-animal methods are routinely used in some aspects of the development programme for new human medicines, but they are currently not able to sufficiently predict effects on whole body systems or to provide information on how much of a medicine is absorbed, changed and excreted. This information is essential, to

confirm that possible new medicines should be developed, and to protect human volunteers and patients who may then take the medicines.

Which non-animal alternatives did you consider for use in this project?

The organisation does conduct various non-animal tests as part of the development programme for new medicines, but as noted above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes. Some studies are conducted using only blood samples taken from animals; taking the blood samples for this work is also included in the project.

Why were they not suitable?

There currently remains general scientific agreement, and agreement of government regulators, that to protect human volunteers and patients, non-animal alternatives do not, as yet, provide enough information to replace all animal studies.

A retrospective assessment of replacement will be due by 09 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated need for use to a similar extent.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There is no definitive guidance from government regulators on the numbers of animals to be used in the studies described in the project; the applicant and colleagues will use their extensive experience of related programmes, taking account of statistical significance and scientific advice as necessary, to use sufficient animals for studies to provide robust results. Generally group sizes are minimal in nature, using up to 4 animals per group or end-point.

In some studies it is possible to give more than one test item to animals at the same time, and be able to analyse the results, typically the blood levels of the different test items, thereby reducing the total number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies may be used to investigate the potential of new designs or processes to improve outcomes, before being used in larger numbers of animals. Screening studies, using small numbers of animals, are designed to identify and eliminate materials with undesirable results, and so reduce the numbers of animal which are then used in the studies required by government regulators.

The extensive re-use of some animals enables an enormous reduction in the total number of animals used in the project.

A retrospective assessment of reduction will be due by 09 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Dosing of potential new medicines is by the same way as they would be given to people; most commonly by mouth, but including various injection methods, occasionally dosing by inhalation and by application to the skin. The methods used are generally very well established and commonly used by experienced staff at the establishment. Volumes of drugs to be given are in line with published guidance on minimising discomfort, and/or are known to cause minimal discomfort based on extensive experience at the site.
Blood sampling is a common need. We follow published guidance on methods and suitable volumes which can be taken while minimising harms to animals.
Restraint or confinement of animals is a common need, to allow collection of samples, generally urine and faeces. Methods used are those with which staff have extensive experience, and the duration of time is minimised wherever possible while allowing completion of the process so that tasks do not generally have to be repeated.
Surgery is required for a small percentage of the animals to be used in the project. It is conducted with expert veterinary involvement in the creation of suitable regimes for anaesthesia and post-surgical pain relief.

Why can’t you use animals that are less sentient?

The species used are selected to answer the scientific questions and enable collection of results which will allow continuation of development of the most appropriate new medicine candidates. They are the same species as are used in follow on studies required by government regulators.
Tests are generally of mild severity for animals, and samples are required over a time period which would make continued anaesthesia impractical in almost all cases, would interfere with the outcome in some circumstances.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement of on-going procedures is commonly discussed and explored within the animal technical, veterinary and scientific groups, and also as and when any concerns are identified; for example additional assessments may be included based on initial outcomes.

The surgery and anaesthesia/pain relief protocols used in the programme undergo regular and routine assessment and refinement to improve outcomes. Habituation of animals to restraint is a routine process, and the schedule can be amended in response to outcomes for individual animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of Diehl et al: A good practice guide to the administration of substances and removal of blood, including routes and volumes.
Welfare end-points are developed in general line with publications on the topic, including the NC3Rs document from 2010 on dose level selection for regulatory toxicology studies.
Non-human primate housing is in compliance with the NC3Rs document on this topic from 2017.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Both our clients and our colleagues working in the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which propose refined approaches to conduct of work. **A retrospective assessment of refinement will be due by 09 April 2026**

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

146.Physiological and neurobiological functions of the Trappc9 locus in mice.

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, neonate, juvenile, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to analyse the phenotype of *Trappc9* knock-out mice as a model for a human neurodevelopmental disorder that is associated with *TRAPPC9* mutations. The symptoms/phenotypes mainly relate to microcephaly, intellectual disability, obesity and behavioural dysfunctions.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This project consists of basic research to improve our understanding of the (neuro)physiological functions of the *Trappc9* (*Trafficking protein particle complex subunit 9*) gene, which is essential for normal human brain development. Mutations of the *TRAPPC9* gene cause a neurodevelopment disorder from childhood onwards, which is characterised by intellectual disability, speech impairment, small brain, delays in various developmental milestones and obesity. Little is known so far about the cellular roles of the Trappc9 protein and how it exerts essential functions in specific tissues like the brain. Trappc9 is involved in intracellular vesicle transport processes and the regulation of lipid storage droplets, but the disease mechanisms of Trappc9 deficiency are unclear. So far, no *Trappc9* knock-out (KO) mouse model has been published, but we obtained such a mouse model through an international consortium to phenotype mouse mutants for all genes. Over the duration of our previous project licence, we have obtained an initial assessment of the *Trappc9* KO phenotype, which confirmed several of the human disease symptoms, e.g. small brain and obesity, thus showing the relevance of the mouse model for understanding the human disorder. This project aims to continue and expand the phenotyping work,
e.g. with regard to behavioural test, imaging (brain MRI) and obesity physiology. The mice will also be crucial for undertaking cellular studies, for example in primary neuron cultures, to investigate the cell-biological functions of Trappc9. Insights gained from this programme of work will shed light on essential mechanisms of brain development and maintenance of neural cell functions, which will also be relevant to human physiology and neurobiology.

What outputs do you think you will see at the end of this project?

We anticipate to obtain several primary research publications from this programme of work. PhD students are currently using the *Trappc9* mouse line in their projects and will achieve first-author publications from their work. Such publications should form a good basis to attract additional grant funding for the conditional knock-out objective, which should lead to follow-on publications later on. It is also likely that future PhD students will join this programme of work and produce additional data. Results will also be presented at scientific conferences organised by academic societies. Furthermore, our mouse phenotyping data will most likely be incorporated into the public database of the international consortium, which originally generated this mouse line for the scientific community.

Who or what will benefit from these outputs, and how?

In the short-term, it is mainly the scientific community working in basic research of neurobiology, cell biology and mouse genetics, who will gain new knowledge about the functions of the *Trappc9* gene in mammals. Our findings in the KO mouse model will also be of interest to medical scientists and geneticists, who are trying to understand rare human genetic disorders and the associated disease mechanisms.

In the long-term, our work might contribute to the knowledge about the molecular and cellular mechanisms of the rare human *TRAPPC9*-related neurodevelopmental disorder, so that therapies might be developed or adapted, which could mitigate at least some of the disease symptoms. Such considerations would be within the remit of the UK government-supported initiatives on research into rare diseases.

How will you look to maximise the outputs of this work?

Some of this programme of work is already undertaken in collaboration with other experts, i.e. the MRI analyses are carried out with the help of our pre-clinical imaging centre. Technical details of this work will, therefore, also feed into the MRI imaging community. We also intend to set up collaborations with colleagues in the behavioural analysis field, with whom I have collaborated previously on highly specialised behaviour tests, e.g. at another UK University and a research institute in Europe.

Apart from presenting our findings as posters or oral presentations at international conferences, we will also publish pre-print manuscripts on open-access servers, which allows public scrutiny and feedback on our results by anybody interested in the work. This gateway will also enable us to communicate unsuccessful approaches or ‘negative results’.

Species and numbers of animals expected to be used

- Mice: Over five years we estimate that we need to use up to 2500 mice for the breeding and maintenance of the genetically modified mouse strains. For experiments, we estimate that we might need altogether up to 600 mice. Most likely, fewer mice will be needed eventually.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Using a genetically modified mouse model to investigate the mechanisms of a human inherited disease that causes intellectual disability and a small brain :

Recent clinical studies have shown that a specific heritable brain disorder is caused by defects in a gene called ‘Trafficking protein particle complex subunit 9 (TRAPPC9)’. Patients, who inherited such gene defects from their parents, show the following major symptoms from childhood onwards: intellectual disability, inability to learn to speak more than a few words, small brain size and delays in developmental milestones like learning to walk. Most also become obesity. Little is known so far about the roles of this gene, and what exactly goes wrong in brain development and function when there is a defect in TRAPPC9.

Mice are a mammalian species that can be readily genetically modified to model human heritable disorders, but so far no mouse model with a defect for Trappc9 has been described in the scientific literature. We established Trappc9-deficient mice to analyse whether they show similar symptoms as human patients and to investigate the mechanisms of the disease. As a mammalian species, mice are still quite similar to humans. We found that, when compared to normal mice, these Trappc9-deficient mice also have a smaller brain when they are young adults, but not at the newborn stage. We are interested in finding out when exactly the differences in brain size start to occur and what goes wrong on a cellular and molecular level in the mouse brain. Therefore, we are interested in analysing weaning-stages, juveniles as well as older adult mice. As an approach to investigate ‘intellectual disability’, we intend to undertake behavioural tests with the adult mice, e.g. memory tests. We also found that the mice show another adult disease symptom, namely obesity, and we are planning to investigate the fat tissue and the brain regulation of body weight, food intake and overall energy balance. We know, that other laboratory animal species with defects in Trappc9, i.e. the fruit fly and the roundworm, do not show the human disease symptoms and are therefore not a good animal model to investigate the disease.

Typically, what will be done to an animal used in your project?

Typical experiments that we are planning to do include the following:

Cohorts of Trappc9-deficient mice and their normal littermates will be kept for up to one year and their brains imaged via MRI scans at various ages. For this, the mice will be transiently anaesthetised, from which they recover very well. We can measure the brain volumes and structural differences in brain sub-regions with these MRI data. Additionally, the cohorts of mice will be used for testing in several behavioural tasks, e.g. exploration of a new environment, locomotor activity and coordination, memory tasks. We can then correlate our brain MRI data from individual mice with their behavioural performance.

Other cohorts of mice might be used to explore whether brain stem cells are affected by defects in Trappc9. This could be an explanation for smaller brains. A typical experiment in this context would be to inject a dye into the abdominal cavity, which then gets distributed throughout the body and labels stem cells in all tissues. The brain tissue will then be collected and sections analysed under the microscope to quantify the number of brain stem cells.

In further cohorts of mice, we intend to analyse the obesity symptoms. This includes measuring food intake, blood glucose, insulin and other hormones. Depending on initial findings, we might also inject (via various routes) substances that have an influence on whole-body energy balance regulation, including regulation of food intake. We intend to find out whether the obesity is due to a role of Trappc9 in specific brain regions that control energy balance, or whether it is a defect directly in fat tissue.

In other experiments, we will need mice to obtain tissues for molecular biology analyses, and to grow cells in culture in the lab, for example neurons or fat cells. The cell culture experiments will give us important information on a microscopic level, i.e. which structures and molecular mechanisms inside the specific cell types are not working normally when Trappc9 is missing.

What are the expected impacts and/or adverse effects for the animals during your project?

From the analysis of brain stem cells, we do not expect any major adverse effects on the mice. The substance that labels the stem cells does not normally cause adverse effects over the duration of the experiments. In the long term, there is a possibility that it might cause cancer, but we are not keeping the mice for long enough after the injection for cancer to develop.

In the MRI experiments, mice will be kept under gas anaesthesia for relatively long periods, e.g. up to 6 hours. Their body temperature, breathing and pulse will be measured constantly and maintained continuously. Also, a protective cream will be put on their eyes, so that they don't dry out. Mice usually recover quickly from the anaesthesia. The behavioural test should not cause more than occasional anxiety. We intend to only use experiments in dry environments (no swim tests) that do not cause major adverse experiences.

In the context of analysis of obesity, some of the experiments might cause adverse effects in the longer term, e.g. feeding a high-fat diet will make any obesity symptoms even more extreme. But we are not planning to keep such mice over many months; they will be terminated as soon as the experimental objectives are achieved. Testing for insulin sensitivity (via injection of insulin and sampling of blood glucose levels at regular intervals from a superficial vein for approximately two hours) can in rare cases cause hypoglycemia. However, this would then only occur in lean mice, not in obese models, and in such a case the mice will immediately be given a glucose injection to counterbalance the insulin effect. We also intend to undertake glucose tolerance tests, i.e. injection of glucose and measuring the rise and fall of blood glucose levels over a two hour period. This should not cause any adverse effects. If we find that brain dysfunctions are the major cause for the obesity of Trappc9-deficient mice, we might test the effects of substances that influence the regulation whole-body energy balance through injection via appropriate routes. In this case we will measure the short-term effects of the substances within hours or a few days, e.g. effects on food intake, or on molecular biological markers in brain tissue, for which the mice would be humanely killed at defined time points and tissues harvested for analysis.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall, the majority of mice that are used in experiments will only experience a mild severity level of intervention. A smaller proportion of animals will experience moderate severity interventions.

In the analysis of brain stem cells, ~70% of mice will only experience mild peripheral injections of a labelling substances. However, under some circumstances we might want to investigate the effects of growth factors that keep stem cells alive or stimulate them in other ways. Such factors might need to be injected into the brain or its ventricles. For this, we would need to undertake surgical procedures to place a cannula into the brain. There is no pain sensation in brain tissue itself, however there are risks of complications from the surgery, e.g. infection, which would class this procedure as moderate.

All mice that undergo MRI brain scans will be classed as experiencing moderate severity. This is due to the length of the imaging procedure (up to 6 hours), which is carried out under gas anaesthesia. Mice usually do recover without problems from such longer periods of anaesthesia, but body temperature, pulse rate and breathing need to be monitored and maintained during the scans. All behavioural test are within the mild severity category. Some mice (~30%) might be used for behavioural tests only, without MRI data being acquired.

We estimate that approximately 50-60% of mice that will be used for the analyses of energy balance and obesity might experience moderate severity. This would include development of more extreme forms of obesity due to high-fat diet feeding, moderate transient hypoglycaemia during an insulin sensitivity test and injection of energy homeostasis-regulating substances (potentially including injections into brain / brain ventricles).

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The human inherited disorder caused by defects in the TRAPPC9 gene leads to symptoms of intellectual disability, a smaller brain, inability to learn to speak, obesity and other symptoms. These are abnormalities in complex tissues and interacting organ systems of the body, which cannot be fully understood without an animal model. Also, some of the human disease symptoms appear to be due to processes occurring during the late maturation stages of brain development. Complex processes like the development of an organ can currently not be modelled outside of an animal. The best mammalian system to model such human gene defects is the mouse, which can be genetically engineered to recapitulate the human genetic abnormality. Its brain is still similar enough to the human brain in many aspects, to enable conclusive insights into the mechanisms of disease. A mouse model will allow us to analyse the development of the brain over time, do behavioural test related to intellectual disability (such as memory tests), analyse hormone interactions and whole-body energy balance regulation.

Which non-animal alternatives did you consider for use in this project?

Some functions of Trappc9 within cells can be analysed to some extent in vitro in cultured cells, and we are undertaking such experiments in parallel to the animal work. For example, we are using cell lines in culture to investigate specific structures inside the cells, termed lipid vesicles.

Why were they not suitable?

We found that standard, permanently used cell lines have their limitations, since they are not the same as the cells that are mainly affected in the human TRAPPC9 genetic disorder, namely nerve cells in the

brain (neurons). Neurons are highly specialised cell types, which (unlike standard cell lines) do not multiply further. They have sensitivities that are not found in standard cell lines, for example regarding lipid vesicles, which appear to be regulated by Trappc9. A defect in such lipid vesicles seems to have minor impacts for standard cell lines, but can be toxic to neurons. For this reason, we found that neurons directly isolated from mouse brain tissue and maintained in culture dishes in the lab are a truer model for the disease symptoms.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have estimated these numbers of animals based on my previous experiences from maintaining and investigating genetically modified mouse models of human disease. The estimates of experimental animals required are also based on experience from past and/or currently ongoing experiments that are similar to what is proposed in this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant (EDA) to design animal experiments, maximise the data readout from a minimal number of animals and obtain estimates of how many mice might be needed for a specific experiment. I am also familiar with Power calculation software and regularly use the freely available GPower software
for the estimation of required sample sizes in experiments.

For experiments where we cannot use formal software in advance to estimate sample size, for example in novel experiments where we do not have an estimate of the expected standard deviation, we will utilise a block design or the similar ‘variable-criteria sequential stopping rule’ (SSR), whereby a subgroup (small number of wild-type and knock-out littermates) is used at a time initially. Data from several such subgroups will be collected over time and added to the total experimental N. Data will be analysed intermittently after addition of subgroups for statistical significance and Power.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise the numbers of animals produced in the maintenance breeding of the genetically modified mouse lines, we will set up a limited number of breeding pairs intermittently, i.e. three times a year. Constant breeding throughout the year will be avoided, to not produce unnecessarily large numbers of excess offspring.

Furthermore, wherever possible, we will offer tissues that we do not need for our own research to other interested scientists in order to share resources and maximise the usage of the animals for multiple aims.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will be using genetically modified mouse strains that correspond to a human inherited disorder, which is due to a specific gene disruption and causes neurodevelopmental symptoms. It is the only animal model, which reproduces the complex human disease characteristics.

As described in detail in the above section ‘Anticipated Harms’ we will be using the most appropriate methods, experimental approaches and techniques to minimise pain, suffering, distress and/or lasting harm. Data read-outs from cohorts of experimental animals will be maximised wherever possible, for example by using the same cohorts for brain MRI scans and behavioural tests over a period of time.

Why can’t you use animals that are less sentient?

We considered the roundworm C. elegans as an alternative model, but found out that lack of Trappc9 in worms results in lethality. Another laboratory animal, the fruit fly Drosophila, does not show brain abnormalities when Trappc9 is inactivated. The symptoms are related to different tissues in this animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

For many experiments in this project, we do already have experience from previous work and have established ‘best practice’ protocols, e.g. for the MRI brain scans and the associated regular monitoring of recovery from extended periods under anaesthesia. For other experiments, standard protocols are published and widely used in the scientific community, e.g. for glucose tolerance and insulin sensitivity tests, or for the stem cell labelling experiment. Here, the minimal doses and concentrations of substances that are required to achieve the aims will be used. When surgical procedures are used, best sterile practice will be implemented in our dedicated surgery rooms, and analgesia or other pain/distress-relieving measures implemented with the advice of our NVS.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Protocols, training resources and guidelines on best practices in animal experiments are available through the NC3Rs website, including handling and restraint, euthanasia, humane endpoints, welfare

assessment, micro-sampling, anaesthesia, analgesia. Personal licence holders, who are involved in this project, will be asked to familiarise themselves with this information.

We will follow the ARRIVE guidelines as recommended by the NC3Rs.

The Grimace scale of facial expressions, which is also published on the NC3Rs website, will be used to inform on animal pain condition in mice
.

The NC3R online Experimental Design Assistant will be used when new experiments are planned.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am receiving the regular NC3R newsletters via email and I am checking the NC3R websites for novel developments in the field as well. The representative of the NC3Rs for our region visits the University regularly and organises events, presentations and webinars that are well attended. Furthermore, the head of our animal facility and our local Animal Welfare and Ethical Review Body forward information on novel developments in the field to all licence holders.

Home Office

NON-TECHNICAL SUMMARY

147. Plasticity after injury to the nervous system

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants.
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Pain, Nerve Injury, Spinal Cord Injury, Plasticity, Neurotoxin

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The nervous system undergoes continuous change in terms of the structural connections between nerve cells,

the strength of these connections and how readily signals are generated. These changes are termed plasticity and they adjust and regulate the function of the nervous system according to changing requirements throughout life. When the nervous system is damaged, for example if a peripheral nerve is cut or a high velocity impact results in a spinal cord injury, this ability of the nervous system to change can help it to adjust and compensate for the damage, and helps to provide a degree of functional recovery. However, there are limitations to these plastic changes which in turn limit the degree of functional return. We aim to investigate these so that we can better understand how return of function might be optimised. We will also investigate the effect of drugs that increase the plasticity to see if these can promote improved recovery.
Plastic changes after injury to the nervous system can also have negative consequences. After both peripheral nerve and spinal cord injury, there can often be the development of a particularly unpleasant form of continuous pain. Because it is caused by damage of the nervous system, it is called neuropathic pain. This sort of pain is very debilitating and particularly difficult to treat as drugs are often ineffective. We do not fully understand why this maladaptive, pain producing plasticity occurs but we now have tools and approaches that can help us understand the circuits of neurons responsible, and how they change. The signalling of pain by the nervous system also involves several areas in the brain and one such area has only recently been identified. It will also be important to define the role of changes in these brain areas to the development of chronic pain. There are now also agents that have the potential to interfere with signalling in spinal cord and brain circuits and these may prove useful in preventing or blocking the pain signal. One group of such substances are nerve toxins. This project aims to provide a better understanding of the changes in spinal cord and brain circuits that lead to pain conditions and test whether these substances can successfully block pain. We will also investigate whether these neurotoxins can prevent the over-activity in the nervous system that leads to dangerously high blood pressure (autonomic dysreflexia) and to painful muscle stiffness (spasticity) in spinal cord injured patients. The toxins will be used at levels well below those that cause muscle weakness or other adverse effects.
A retrospective assessment of these aims will be due by 17 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The aim of the project is to improve understanding of the plastic changes in the nervous system that occur after it is injured. The potential benefits of the work are that this understanding could provide the basis for developing better treatments for restoring sensation and movement; and improved drugs for controlling the debilitating conditions of chronic pain, dangerous increases in blood pressure and painful muscle stiffness.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

The project will use rodents, both rats and mice. It is estimated that the experimental programme will require approximately 1,550 rats and 1,650 mice over the course of 5 years. In addition, 5,350 mice will be used for breeding purposes only.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

More than half of the mice will be used to for breeding and maintenance of genetically modified lines, and since the vast majority of these animals will have no behavioural abnormality, this is classified as "mild". A small proportion (estimated at 5%) of the animals (rats and mice) will undergo procedures that are carried out under general anaesthesia, from which they will not recover, and these are therefore classified as "non-recovery". A further group of animals (estimated at 45%, predominantly mice) will undergo procedures such as injection of harmless tracer substances into the brain or spinal cord, or spinal injections of agents that will activate or inactivate different nerve cell populations. These procedures are performed under general anaesthetic. These animals will receive post-operative painkillers and should experience no more than transient discomfort resulting from the operation. About 50 % of animals (rats and mice) will either have a nerve injury (a moderate procedure) or spinal cord injury operation (a moderate or severe procedure), both of which may lead to a mild form of pain with increased sensitivity to touch or warm stimuli. The animals' ability to eat and drink will not be restricted. After nerve injury and spinal cord injuries that are made with a device that applies an impact (contusion) there may be some lameness but animal’s movement is not restricted. In a small proportion of the animals (estimated at 1%, rats only) the spinal cord will be completely cut. This is a severe procedure.
These animals have a temporary inability to empty their bladder and need to be regularly assisted. They also permanently loose the use of their hind limbs. These animals feel no discomfort during the application of stimuli to test for autonomic dysreflexia or spasticity, as these are applied below the injury where there is no sensation. At the end of the procedure the great majority of animals (estimated to be >95%) will be killed whilst they are under the influence of a general anaesthetic. A much smaller proportion will be killed by another humane method.
A retrospective assessment of these predicted harms will be due by 17 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

The objectives can only be achieved by experiments using live animals because the complexity of the biological systems to be examined, and the need for events to develop consequent to manipulations such as injury cannot be reproduced *in vitro.* Neural circuits and changes in connectivity due to plasticity all require investigation in intact animals. Conditions such as pain, spasticity and altered cardiovascular function cannot be modelled in other ways. Where possible, however, our work will be informed by in vitro approaches. This applies in particular to development of agents for neural repair. In addition, we incorporated into our Project Plan, the use of ex vivo preparations. **A retrospective assessment of replacement will be due by 17 January 2026**
The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

The numbers of animals to be used in each part of the study will be the minimum required to provide reliable results (avoiding as far as possible inter-animal and technical variability). Many of the outcome measures that we obtain are based on observation and are largely qualitative or can only be treated in a semi-quantitative way.

For these types of results, we will collect results from a minimum of 3 biological replicates. Where appropriate results will be analysed statistically for significance. In addition, where data is available we will use power calculations which is a method for predicting the numbers of animals that are required to provide statistically significant answers. Experimental design is continually reviewed and our studies carefully executed in order ensure use of minimal animal numbers consistent with the experimental aims and to maximise information obtained from each animal.
A retrospective assessment of reduction will be due by 17 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Rodents are the most appropriate species as they are the least sentient animals that could be used. Non-mammalian species show a capacity for nervous system regrowth which does not happen in mammals and also show much greater plasticity. The larger size of rats makes some procedures such as fMRI more feasible. Nevertheless, mice may offer an advantage where genetically altered lines are available because this allows for the targeted manipulation of the responsiveness of particular groups of neurons.
We have experience of all of the models to be used and a good understanding of both their scientific merits and the animal husbandry required to minimise adverse effects. Together with the Veterinary and Biological Services staff, we regularly review the general procedures for animal care including analgesia, fluid replacement, and post-operative maintenance of body temperature. In addition, for more severe injuries such as spinal cord contusions and transections, we have introduced a monitoring chart, which incorporates built in end points. I collaborate widely with others to ensure that we follow the most modern and refined approaches to these severe models of disease and I contribute to published material in this area. All animals will be group housed wherever possible. **A retrospective assessment of refinement will be due by 17 January 2026**
The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

148. Pluripotent stem cell derived hepatocytes for treatment of liver failure

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

liver diseases, acute liver failure, mouse model, stem cells, therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Stem cells are special cells in the body from which all other cells develop. The aim of this project is to find out whether stem cell products could be used as a potential treatment for liver failure and inherited liver diseases, by transplanting them into rodents with these liver diseases and assessing whether the cell therapy aids recovery.

A retrospective assessment of these aims will be due by 07 March 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Liver failure and liver diseases are life threatening human diseases for which currently the only long-term treatment is a liver transplant. Due to a shortage of liver donors, for many patients this life saving treatment is simply not available. Furthermore, there are a number of long-term risks for recipients, including organ rejection and unpleasant side effects from the drugs that have to be given on a permanent basis to prevent rejection. Stem cells afford us the exciting possibility of being able to cure patients with liver failure where otherwise the only proven way of treating them is whole organ transplant. Before such cells can be used in patients it is an essential requirement that their effectiveness is tested in animals which model the human disease, and are proved safe.

What outputs do you think you will see at the end of this project?

This research could demonstrate the effectiveness of a potential new therapy for patients with liver failure and inherited liver diseases, and so benefit thousands of patients worldwide. Liver diseases comprise a significant and increasing clinical burden. The current standard treatment for liver failure is whole organ transplant, but the number of patients requiring transplant far exceeds the number of available donor organs making alternative treatment methods an urgent priority/clinical need. The short term benefits of this project would be confirmation that stem cells are potentially an effective, safe treatment for liver failure in rodent models.

Who or what will benefit from these outputs, and how?

At the end of this project we expect that we will have proved our idea that these cells are an effective therapy for liver diseases. The new therapy will then be further developed for approval by the Medicines and Healthcare products Regulatory Agency (MHRA)) for clinical trials in humans (medium term benefit). Should Phase 1 trials be successful then these cells could be given to patients in the long term and extend lives of patients with liver failure who are not selected for or cannot have transplantation surgery. In the longer-term, stem cells could replace organ transplants as a more readily available method of rescuing the failing liver without the need for complicated surgery.

How will you look to maximise the outputs of this work?

The outputs from this work will be shared through publication and by presentation at conferences, and through our partner biotechnology company, who will develop this further as a proposal to the MHRA with a view to using them on patients in a hospital setting.

Species and numbers of animals expected to be used

- Mice: 7500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice have been chosen as the experimental animals of choice because the basic features of their livers are remarkably similar to other mammalian species and of are similar complexity to the human.
Immunocompetent mice (such as C57BL/6) will be used in the study of optimization and identification of therapeutic efficacy of PSC hepatocytes of this project, as they do not reject the encapsulated human cells.
Genetically altered mice with liver injury will also be used. Human liver cells are inserted into their livers, providing a means of testing our stem cells against failing human liver tissue.

Typically, what will be done to an animal used in your project?

Some animals will be bred to produce animals with immune systems which do not work properly or with liver damage.
Most animals under this licence will undergo liver injury to bring about liver failure. Animals may have surgery to cut out part of their liver tissue or be dosed with chemicals which damage the liver. Some animals with inherited liver disease problems may also be used.
Stem cells will be delivered either into various sites on the belly or placed under the skin to try to rescue the failing liver. Blood samples and scanning will take place to monitor how the liver is working and movement of the cells we have introduced.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are expected to get sick and some with liver failure might die, they will be monitored very frequently so that they can be humanely killed where possible, to prevent further suffering if their liver failure is not responding to the stem cell implants.
Advice from the Veterinary surgeon will ensure that the welfare of the animals is maintained at the highest possible level for their condition. Any animals that show unexpected side effects of the liver injury or of treatments will be killed to avoid unnecessary suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding strains are expected to experience mild severity (70% of animals) or moderate (30% of animals) severity on this protocol.
Animals undergoing protocols to generate liver failure are likely to experience severe signs (up to 80% of animals), and some may need to be humanely killed to prevent further suffering. The disease develops very quickly and a proportion of animals may die before they can be given any treatment.
Animals undergoing studies on inherited liver diseases are expected to experience moderate severity (100% of animals on this protocol)

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 07 March 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Unfortunately there are no alternative techniques that could replace the use of animals in this project. In order to demonstrate that stem cells would be effective if used as therapy for liver diseases, they have to be tested in animals with the diseases. It is also a requirement for the techniques to be tested in animals and deemed safe before they can go on to be developed for use in real patients.

Which non-animal alternatives did you consider for use in this project?

Our approach is to use experiments in the laboratory as much as possible to replace animal experiments. Initially, laboratory testing will provide information on what cells actually do, thereby decreasing the numbers of animal experiments by screening for the most useful cell lines.

Why were they not suitable?

Laboratory methods are suitable for initial screening of cell lines for treatment potential.
These methods cannot however adequately model the all of the things cells would be exposed to in the entire animal, making animal based testing a necessity. Importantly it is a requirement of the Medicines and Healthcare products Regulatory Agency (MHRA) that products from stem cells such as these be tested in animals prior to use in human patients.

A retrospective assessment of replacement will be due by 07 March 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will endeavour to use laboratory based methods wherever possible thus limiting the numbers of animals undergoing experimental procedures.
The sizes of experimental groups and the number of repeated experiments will be kept to a minimum while ensuring that reproducible results are obtained with clear biological significance. We use statistical analyses to determine the minimum numbers of animals needed for our studies that will produce robust results. We have estimated our initial group sizes from laboratory studies, which suggest that group sizes of 3 might be sufficient to detect experimental effects. A greater degree of variation is expected in animal studies compared to that observed in the lab and we anticipate that we will need group sizes of 6-12 for our animal experiments. This will be revised as the animal work under this project progresses.
We aim to further refine our techniques through high success rate of surgical procedures and good practices of performing preliminary experiments to establish the minimum number of animals. Furthermore, we will continue reducing the use of animals as much as possible in this licence, in collaboration with the named veterinary surgeon.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Advice in experimental design has been taken locally from statistician and scientific colleagues.
Online tool (the NC3R's Experimental Design Assistant) has been referenced.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Cells to be used for implantation will be screened in the lab before they are used with animals, to ensure that they are likely to produce the effects which we are looking for.
Studies using small numbers of animals will be undertaken in initial work to determine the best methods for cells to be implanted before full scale experiments in animals with liver failure.
Where more animals are bred than we need, surplus animals will be made available to others for tissue sharing where possible.

A retrospective assessment of reduction will be due by 07 March 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse model has been chosen as the experimental animal of choice as the basic features of their livers are remarkably similar to other mammalian species and have a similar level of complexity to the human liver. Mouse models of liver failure and inherited liver disease are successfully used elsewhere in this area of research, can be reproduced and represent relevant models of the range of human diseases we are studying
Immunodeficient (less able to recover from infection) mice are necessary for some studies in order to avoid the human cells/tissues we are introducing from being attacked by the body. These animals will be subsequently bred in house.
The mouse paracetamol and partial liver removal model is the standard model of acute liver failure. Mice are also reliable models for our area of research.
Genetically altered mice provide reliable and relevant models of inherited liver disease which can be brought about as required, animals remaining normal until the disease is 'switched on'. Genetically altered mice which have, or can be made to have liver failure, do not require an initial surgery or toxic dose of chemical before stem cells are delivered. The humanised livers of these mice additional provide a method of testing these stem cells against damaged human liver cells.
For these reasons, mice are the species of choice for our studies. These animals are needed to investigate how human liver cells that have been made from stem cells work and how they can ease liver failure symptoms. The mouse models are important in providing new information and as models in which to study new ways of transplanting cells.
Suffering
All the protocols proposed in this application use well-established and tried techniques that have been refined to involve a minimum of suffering. Sterile surgery will be conducted by researchers with considerable experience in animal techniques; training and competency records will be kept. Attention will be paid to keeping rodents warm and hydrated during surgery to improve outcomes. Anaesthesia and pain relief will be administered to minimise discomfort and the animals will be assessed at least daily for any signs of distress. Experiments with a small number of animals will take place first i to refine methods, identify effective doses and avoid excessive deaths. In all the proposed animal experiments, if animals display signs of distress, advice will be sought from the Named Veterinary Surgeon (NVS) and, if distress cannot be eased, the animals will be humanely killed.
Liver failure is associated with a significant death rate and all attempts will be made to avoid this. Animals will be observed multiple times per day after we have brought about liver failure, and small samples of blood will be taken to check liver function using markers in the blood. Hand held blood analysers, as used in human patient care,will be trialled in an attempt to identify animals whose condition is deteriorating quickly so they can be humanely killed immediately rather than waiting for samples to be processed remotely in the lab.

Why can't you use animals that are less sentient?

The livers of non-mammalian species do not have the same make up as human livers are not good models of human liver disease as they relate to human patients. In addition, animals which have been bred not to reject the transplanted cells are needed for some studies, and these are generally only available in rodents.
The ability of the liver to grow new cells is less in younger animals, thus younger animals are unlikely to recover from liver injury and are not suitable as models for the human adult patient. The mouse is considered least sentient mammalian species and will be used for the majority of studies.
It is not possible for us to carry out our studies on anaesthetised animals which are killed without waking, as we need to find out how the animal recovers from liver failure.
The ability to genetically alter mice also makes them our species of choice.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We aim to develop blood tests to indicate increasing likelihood of severe outcomes such that animals can be identified at an early stage and suffering minimised.
We will use frequent observations of animals throughout the critical phases of each experiment, measuring body weight and condition and observation of eating and drinking.

Our staff have considerable experience in normal animal behaviour and we will take advice from our named people on animal welfare.
We will start with small scale experiments to determine the most efficient and best way to carry out our studies, progressing to full scale experiments once we have improved our understanding of the unknowns.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will make use of published information on methods and use resources such as PREPARE and the NC3Rs to help us keep informed about best practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will communicate with our named people throughout the project and seek advice on refinement of procedures. We well attend conferences and 3Rs events and implement any improvements to the protocols that are identified.
We will also report back to our local AWERB and our Inspector after our initial experiments to determine doses.

A retrospective assessment of refinement will be due by 07 March 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

149. Preclinical targeted therapeutic approaches in colorectal cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Bowel cancer, mouse models, therapy.
In the UK, colorectal cancer (CRC) is the fourth most common cancer representing approximately 12% of all new cancer cases (CRUK, 2015). Although the introduction of screening programs has led to higher rates of detection at early stages of disease, more than 50% of people are diagnosed at a late stage. Moreover, the treatment options for these patients has not significantly improved over the last 20 years. New targeted

therapies have been developed but unfortunately these have not translated into better survival, primarily because trials failed to stratify patients accordingly. Therefore we plan to use pre-clinical models of CRC to inform the design of clinical trials for targeted therapies in human bowel cancers.

Our objectives are:

1) Generate models of colorectal cancer incorporating genetic features of human disease, and representing clinically important patient populations

2) Use these models to identify, develop and test new therapeutic targets.

3) Use this information for the design of stratified clinical trials to directly benefit human patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Through the research outline in this project, we will establish the use of patient-relevant models of colorectal cancer for the preclinical testing of novel therapeutic approaches. The project will allow for analysis of the impact of novel therapies in the context of tumours driven by oncogenic mutations which represent A) the most common mutations found in colorectal cancer and B) the oncogenic mutations which represent the most pressing clinical need in colorectal cancer at present.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

We expect to use around 102,500 mice over a 5 year period. These mice may carry the genetic changes known to cause bowel cancer.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Mice with genetic changes which are known to be critical to formation of colorectal cancer in human patients will be bred under this licence. Of these, approximately 50% of the animals will not show any adverse effects and will only be subject to ear notching for identification purposes and for identification of genetic changes. Approximately 20% of animals will be pre-disposed to colorectal cancer - these will be continually monitored for clinical signs indicate tumour growth. These signs include paling feet because of anaemia, weight loss, swelling of the abdomen and development of palpable tumours. These symptoms will be monitored for by trained staff and if the tumours interfere with normal behaviour, reach the limits of the size allowed in the guidelines or have any consequences that are out with the guidelines, mice will be humanely culled and tissues harvested for

analysis. Tumour growth in mice may also be monitored using advanced imaging techniques which are relevant to human patient experience, such as MRI, ultrasound or CT scanning, which involves anaesthetising the mice for short periods of time during which images can be collected. Animals which have intestinal tumours may be administered with treatments design to reduce tumour growth, which have the potential to benefit human patients with colorectal cancer. These treatments can include drugs, which are administered by injection, pellets under the skin or orally, or radiotherapy, using a specially designed small animal radiotherapy machine. In some cases, the diet of the mice may be altered to promote tumour growth, or to enhance the effect of treatment, All treatments are performed by highly experienced staff, and all mice on treatment will be monitored closely for any signs of ill-health.
Tumour cells will be grown in the laboratory and may be transplanted into mice, to model colorectal cancer. These may be injected under the skin, or following general anaesthetic, directly into the colon using an endoscope guided injection to represent early tumour growth or into the spleen or liver to represent metastasis. All study animals will be killed by a humane method and tissue specimens taken for analysis after death.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

Colorectal cancer is a complex disease which involves interaction of a number of different cell types such as tumour cells, immune cells, and blood vessels. Also the environment the tumour is within plays a role in its, growth, development, ability to spread and how it will respond to drugs. There are currently no non-animal models that can reproduce this environment correctly and therefore they are not useful for studying colorectal cancer progression and the effectiveness of new therapies. Moreover there are now therapies that can reactivate the patient's own immune system, which can only be tested in animal models with a functioning immune system. To inform our experimental design and reduce the number of animals required we will perform preliminary drug studies in primary intestinal cell lines in the lab.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We will integrate pilot experiments with a small number of animals into cohort studies to minimise the likelihood of unexpected adverse effects related to genetic modification and/or therapy. The numbers required are calculated from our extensive experience of the models, and also using statistical tests to ensure the minimum number of animals are used to reach the statistical significance required. We will share animals between experimental groups e.g. when controls from one colony can serve as controls for another experiment.
We will regularly review our breeding colonies to ensure we are using the lowest number of animals to produce animals required for our studies. We will also perform transplant studies in wildtype mice, where relevant, thereby reducing our requirement for genetically altered animals.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

It is widely recognised that genetic mouse models of colorectal cancer are most closely representative of human tumours. The tumours form in the correct tissue, and follow a similar progression pathway as observed in human tumours. We will use the most up to date technologies that allow us to produce specific models in which the cancer develops in the correct tissue with as few as possible side effects. This is done using mice that produce an enzyme to reduce/activate expression of the genes of interest only in specific tissues.
We also have imaging techniques so we can monitor the growth of tumours in real time. Therefore the response of the tumour to therapies can be monitored resulting in a reduction in the number of animals needed per study. Also tumours can be detected earlier.

Home Office

NON-TECHNICAL SUMMARY

150. Preclinical therapeutic models of ovarian cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

ovarian cancer, therapy, evolution, adaptation, resistance

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Ovarian cancer is a group of different diseases with marked molecular variability both within an individual and between women with the same cancer. This causes variable treatment responses and difficulties in personalizing therapy for the individual patient. We aim to use patient-derived xenografts to discover new more effective medicines and to study how ovarian cancer cells adapt and evolve with time and treatment.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

We will primarily focus on high grade serous ovarian carcinoma (HGSC) which is the most common form of ovarian cancer and is amongst the deadliest of all women's cancer. The main reason behind this poor outcome is diagnosis of the majority of patients at an advanced stage and the complex molecular changes in each cancer. Although most HGSC respond to initial platinum-based chemotherapy, development of resistance to treatment and recurrence is frequent. Unfortunately, there are few effective treatment options for patients with resistant or recurrent disease, showing the urgent need to improve therapeutic approaches available for treatment of HGSC patients. No significant outcome improvement has been achieved over the past 20 years and only ~30% of patients with advanced ovarian cancer are alive at 5 years. Thus there is a need to a) understand the underlying mechanisms of resistance and b) to test new therapies for treatment.

What outputs do you think you will see at the end of this project?

The outputs will be data demonstrating (i) the effectiveness of novel anticancer therapies to be used in window of opportunity clinical trials, (ii) identification of which particular tumours (with specific genetic features) are most likely to respond, (iii) identification of new improved modelling of HGSC and (iv) identification of the best biomarkers that can subsequently be used in clinical trials to measure response. It will also generate new information on the underlying biology of ovarian cancer. These data will lead to scientific publications and may generate Intellectual Property. These data will enable decisions on whether to progress new treatment approaches into clinical trials in patients.

Who or what will benefit from these outputs, and how?

Short term: scientific publications are likely to arise from these studies, building a package of data to justify translation of the best treatments into the clinic. There will also be benefit from identifying those treatments that are not effective or have a poor therapeutic index in vivo, thus avoiding future patients' exposure to non-beneficial treatment. Longer term: these animal studies may contribute to patient benefit by identifying more effective cancer treatments.

How will you look to maximise the outputs of this work?

The proposed studies require collaboration with pharmaceutical/biotech companies who are developing the drugs we wish to test, and we have long-standing and productive collaborations that will continue to give us access to the best therapeutic agents that are commercially viable. Most of the companies will not have ovarian cancer as their primary tumour of interest for their drug(s) and so it is mutually beneficial for us to test their drugs in our patient-derived tumour mice models. We will have access to their scientific expertise and unpublished data regarding the agent and the best ways to measure its effects.

We will continue our existing within-centre and multi-centre collaborations and will disseminate new knowledge via publications, including unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 5,735

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Immunocompromised mouse strains are necessary to avoid the rejection of human cells. We will use young adult mice for tumour implantation and drug response treatments as we predict tumours will take a long time to relapse after successful treatment with certain drugs.

Typically, what will be done to an animal used in your project?

Due to the nature of the project the mice will undergo surgical procedures to implant ovarian cancer tissues or cells either subcutaneously or in the ovarian bursa. Also mice will be injected with tumour cells intraperitoneally to promote the development of ascites fluid. Tumour cells implanted in mice could have been genetically modified in vitro prior to implantation. Tumour growth will be occasionally monitored using imaging techniques. Mice will receive treatments to study tumour adaptation and to find vulnerabilities that could be exploited clinically. We will use standard of care drugs used in the clinic such us platinum-based agents as well as targeted-therapy associated with our recently developed copy number signatures. We will treat mice with single and/or combined drugs in such a way that we will minimize the number of administrations (e.g. when possible we will combine two drugs in one injection). Treatment duration will depend on the drug used for example when using olaparib we will administer the drug orally for seven continuous days three times leaving a ‘vacation’ week in between. Carboplatin will usually be administered intravenously for two days with a ‘vacation’ week in between. During treatments the mice will be subjected to biopsy and blood collections to a maximum of 4 times each and these materials will be used for downstream experiments and data collection and analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

We will follow the guidelines for welfare and use of animals in cancer research to minimise the adverse effects if any and use appropriate humane endpoints when needed. Animals will be kept in our designated facilities where they will be maintained and monitored daily for any health concerns. Animals will be anesthetised when tumours are implanted underneath the skin or in the ovarian bursa and full recovery after surgery is expected for most animals. Sometimes animals have post-operative complications such us non-healing ulceration due to the initial surgery and in those cases animals will be humanely killed. Animals experiencing a limitation in movement or normal behaviour due to tumour growth will be killed. Some of the mice could also lose body weight due to the tumours and/or the treatments they receive and this will be monitored carefully by comparing weight to matched healthy animals. Some animals will be treated with standard of care drugs and targeted-therapies and the main routes of administration for these drugs will be oral and intravenous. Oral administration will cause minor discomfort on the animal gut whereas intravenous administration will cause discomfort on the tail but both procedures are quickly done so the actual discomfort would last a few seconds.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

In this project licence we will only use immunocompromised mice and the overall expected severity is 45% of mice to experience moderate levels and 55% to experience mild levels. This proportions are mainly based on the surgery procedure necessary for subcutaneous and ovarian bursa tumour implantations and consequently tumour growth and potential metastasis arising from some of the samples.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We are planning preliminary experiments using cell lines and organoids, and we will only use drugs or genetically modified cells that have been demonstrated to work in vitro before progressing to experiments in animals. These in vitro experiments will give a good indication of the potential for working in vivo but there is no guarantee that would be indeed be the case. In vitro systems cannot reproduce the influence of the circulatory system and the complex tumour microenvironment, and understanding the contribution of these systems from the in vivo experiments will become crucial to determining the likely success in the clinic. In addition, the fate of populations of cells may differ when assessed in vivo as compared to in vitro.

Which non-animal alternatives did you consider for use in this project?

We are using our newly established organoid models and also cell lines for many of the preliminary drug tests and also for any lineage tracing or CRISPR genetic engineering techniques to be used.

Why were they not suitable?

Although we have developed a way of growing patient-derived organoids some of the samples we are interested in come directly from biopsy tissue and are therefore very small to be processed as organoids. Also some of the tissues that do not initially grow as organoids will do so after being grown in mice. Ultimately the fate of populations of cells might differ when assessed in vivo as compared to in vitro.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will reduce the number of animals used by doing preliminary in vitro drug testing whenever possible (e.g. if the cells are able to grow) and also lineage tracing experiments will be first tested and trialled in cell lines.

Another way of reducing the number of animals used on the experiments is by doing biopsies during treatment as this prevents the need to sacrifice the animal at every single time-point to get tumour samples. Also we have developed new methods of tracking drug response by analysing ctDNA changes in blood spot samples.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We sought advice from professional statisticians as they provide support with the randomisation and blinding of the experiment, as well as sample size calculation.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies using cell lines and organoids that will help us to design the best preclinical study for a given drug/s or genetic modification. We will use the NC3R's Experimental Design Assistant in those instances where our standard support is not available.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use immunocompromised mice as we will need cells/tissues to grow for the treatment experiments. The methods applied in this licence for growing tumours and monitoring them during time after treatment have been well-known and used in many labs around the world. Also for the last five years, we have optimized procedures to minimize potential pain, suffering or distress as well as enhance animal welfare.

Why can't you use animals that are less sentient?

We have opted to use mice as supposed to other less sentient species because there is a very extensive work already done with these animals that will facilitate our research. We need to use adult and ageing mice so that we can apply our findings to the human disease.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have implemented statistical process control charts to monitor for tumour growth and we will expand on what we delivered on our current project licence. In our current licence we also devised a better way of delivering drugs intravenously that we will continue using for the purpose of this licence. We will seek advice as we go along from our vet in order to continue to improve post-operative care and pain management.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidance on the Operation of the Animals (Scientific Procedures) Act 1986 , ARRIVE guidelines (PLOS Biology, 2020), Guidelines for the welfare and use of animals in cancer research (BJC, 2010), RSPCA and LASA Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies (M. Jennings ed. 2015) and any NC3Rs guidance.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

I have signed up for the NC3Rs newsletters and I check their website regularly. I will also contact and communicate with people that have expertise and the Named People.

Home Office

NON-TECHNICAL SUMMARY

151.Production, Breeding & Cryopreservation of GA Mice

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (e) Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

Transgenic, Cryopreservation, Chimera, Sperm, Embryo

Animal types	Life stages
Mice	juvenile, adult, embryo, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to provide a full transgenic service to researchers within the Institute and to a lesser degree the wider research community within the University if no alternative service is available.

The service will include

- Generation of new Genetically Altered (GA) lines by the most appropriate method. New mouse models will be transferred to the end user's PPL with authority to receive these mouse models for further use.
- Cryopreservation of GA lines by either sperm or embryo freezing.
- Rederivation of lines from either fresh or frozen embryos, or by In Vitro Fertilisation (IVF) from fresh or frozen sperm.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

- There is a continued demand for new animal models within the Institute and to have the expertise 'in-house' negates the need to import new GA mice from other suppliers.
- Cryopreservation of lines at an early stage in breeding programmes is required to reduce unnecessary breeding and allows users to rederive lines after several generations to reduce the risk of genetic drift.
- Onsite rederivation into a clean facility leads to a better health status, plus improved animal welfare through elimination of potentially harmful bacterial, viral and parasitic pathogens. This also has the beneficial effect of improving the validity of scientific data, as such harmful agents may adversely affect host physiology and therefore have a confounding effect on experimental results. Rederivation from frozen sperm and embryos also improves animal welfare by reducing the need to transport live animals between different research centres.

What outputs do you think you will see at the end of this project?

The purpose of this licence is to provide research scientists with a full transgenic service facility to include the production of Genetically Altered (GA) mouse lines, plus a cryopreservation and rederivation service.

Who or what will benefit from these outputs, and how?

This service will benefit the scientists of the Institute and to a lesser extent other scientists of the research community of the University.

How will you look to maximise the outputs of this work?

As a group we work closely together, we all regularly attend meetings where new and refined techniques are discussed, these are implemented within our work if we feel they will benefit the service that we provide in terms of NC3R's policies and efficiency.

Detailed record keeping is essential and ensures that any problems are identified at the earliest possible time and that output is monitored at every step.

Species and numbers of animals expected to be used

- Mice: 8000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use mice in this project as we are a transgenic core service that provides genetically altered mice for research groups in the Institute. Mouse is the species of choice for genetic modifications modelling human disease because of the availability and ease of manipulation of mouse embryonic stem cells.

The life stages of mice listed for this project reflects the fact that we expect to breed and maintain mice through all stages of the mouse life-cycle, from birth to adult. Genetically altered animals will be killed before they reach 12 months of age.

Normally females between the age of 3-5 weeks old will be superovulated for the production of embryos/oocytes for genetic modification, cryopreservation and rederivation. Females in this age bracket produce a higher yield of ova.

Typically, what will be done to an animal used in your project?

Approximately 50% of the total mice used in this project will be superovulated females which are then killed and their embryos/oocytes harvested.

Adult male mice from genetically altered lines may be used for breeding purposes, and then killed and their sperm harvested for cryopreservation.

A colony of wildtype adult females is maintained for use as embryo recipients. They are mated to genetically sterile males to induce a pseudopregnant state and then undergo either surgical or

nonsurgical embryo transfer. Once they have delivered and raised their pups to weaning age, the embryo recipient dam is killed.

Genetically altered animals that have been produced or rederived will be transferred to the end users PPL.

The majority of mice maintained on the Breeding and Maintenance protocol are killed and replaced by 8 months of age. In rare cases, we may keep a genetically altered mouse for up to 12 months of age if it is a stud male that demonstrates particularly good breeding performance, or it is of a particularly desirable / difficult to obtain genotype.

Where required, animals will be earmarked to obtain a sample for genotyping. This generally takes place when the animal is around 2 weeks old.

What are the expected impacts and/or adverse effects for the animals during your project?

Intraperitoneal and subcutaneous injections should involve only slight and transient pain.

Harmful adverse effects are rare and unpredictable in the production of new GM lines but any animal showing an unwanted harmful phenotype will be killed by schedule 1 method.

All mice that have undergone a laparotomy will have fully recovered within 24h, if not they will be killed by a schedule 1 method.

Ear notching should involve only slight and transient pain and no healing problems. If tail tipping is used then the pain will be controlled using a local anaesthetic, and any bleeding will be controlled by localised pressure.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

1. Superovulated mice; we expect 100% to be mild.

2. Founder mice; genetically altered animals produced by our service are not expected to exhibit a harmful phenotype. The majority of Chimeras are unlikely to display a harmful phenotype prior to weaning and are maintained under a sub-threshold severity until they are passed onto the end users PPL. Greater than 90% will have a sub-threshold actual severity.

3. Embryo recipient mice; approximately 70% of the recipients will be exposed to a mild severity as the embryos will be implanted non-surgically, the remaining embryos will be implanted surgically which has a moderate severity (30%).

4. Breeding and Maintenance of GA mice, we expect 80% to be returned sub-threshold and 20% returned mild.

What will happen to animals at the end of this project?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The justification for individual experiments will be covered in the end users licences. There is no substitute for a mammalian model. Mouse is the model of choice for genetic modifications modelling human diseases because of its availability and ease of manipulation of mouse embryonic stem cells.

Which non-animal alternatives did you consider for use in this project?

Zebrafish and lower vertebrates.

Although whole-animal models are necessary for understanding how human genes function in the context of normal development, much can still be achieved with cell lines.

Labs within the Institute use cell culture systems that mimic red blood cell production to generate and test hypotheses and new scientific methods.

We also ask researchers requiring a new GA line to test all constructs *in vitro* prior to requesting a GA mouse to be made.

On our request forms end users are asked to verify that they have used various search engines to see if they are able to find any non-animal alternatives.

Why were they not suitable?

Zebrafish and lower vertebrates may be appropriate for studying many developmental processes, but a mammalian model remains necessary to fully understand the effects of human genes and their disease associated mutants. This also applies to other *in vitro* systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice required has been estimated from the number used during the lifetime of the previous PPL. We anticipate that the requirement for the services provided by the Transgenic Group will steadily increase, but the number of mice used will remain constant as we become more efficient and new techniques are employed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The use of CRISPR/Cas9 technology should reduce the numbers of mice used in the production of GM mice.

Breeding colonies to supply the service will be maintained at the lowest possible levels and any excess mice will be made available to other users.

Experimental procedures will be updated as appropriate and new technologies will be introduced as they develop to minimise mouse numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Sperm freezing will be encouraged over embryo freezing as this will reduce the number of mice required to cryopreserve a line by eliminating the need to superovulate large numbers of female donors and maintaining stud males to produce fertilised embryos for freezing. Sperm can be frozen from males that would otherwise be killed.

All steps in every process will be updated as appropriate and new technologies will be introduced as they develop to minimise mouse numbers.

Animals are promptly sampled for genotyping so that any animals which are of the incorrect genotype are not kept within the colony. End users must demonstrate that the genotyping protocol is validated and robust before the generation of a new mouse model.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

One of the aims of this project is to supply GA mice to end users who have the authority to use them on their own project licence. Mouse is the species of choice for genetic modifications modelling human disease because of the availability and ease of manipulating mouse embryonic stem cells.

As a transgenic core service we have the ability to provide these mice in an efficient way that minimises the number of mice used, the pain, suffering, distress or lasting harm that those mice could experience in achieving the end product.

For example, where the administration of injectable substances is required for superovulation or the provision of analgesia, the most appropriate administration route and dosing regime is used to achieve the required outcome.

In addition, non-surgical embryo transfer methods are used to achieve pregnancy in recipient females wherever possible. However, in approximately 30% of cases, surgical embryo transfer must be performed for scientific reasons relating to the stage of the embryonic development and where the embryos have to be placed within the reproductive tract. Our protocols for performing surgical embryo transfer have been carefully refined in order to reduce the amount of pain and distress experienced by recipient females to the absolute minimum.

Why can’t you use animals that are less sentient?

The aim of this project is to provide end users with GM mice, the justification for which will depend on their own scientific goals. Typically, the justification for using mice is that lower order organisms do not exhibit the required features. Flies for example, do not have an adaptive immune system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where substances are administered by injection the minimum effective dose and the most refined route will be chosen.

Wherever possible constructs and/or manipulated embryonic stem cells will be produced and tested in the bioengineering facility in an *in vitro* system before going on to produce new GM lines.

Non-surgical embryo transfer will be the preferred technique opposed to surgical transfer, depending on the stage of the embryo.

All surgery will be performed aseptically and analgesia used wherever appropriate.

Whilst this service licence includes the option for cryopreservation of embryos, we will always recommend sperm freezing as the most refined methods of cryopreservation before we agree to carry out embryo cryopreservation.

Through the use of efficient breeding and colony management we can reduce the number of mice that are being culled surplus. Through our management process animals are generally retired from breeding by 8 months of age, this reduces any potential for breeding related complications.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgery will be done aseptically according to guidelines e.g. LASA Guiding Principles for Preparing and undertaking Aseptic Surgery. http://www.lasa.co.uk/wp-content/uploads/2017/04/Aseptic-surgeryfinal.pdf NC3R's.

Home Office efficient breeding of Genetically Altered mice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We ensure effective breeding of colonies in line with the principles of the 3R's. Advancements will be identified through the regular attendance of conferences such as LASA, ISTT and the NC3R's technical symposium. New methodologies and procedures will be implemented as they arise.

Home Office

NON-TECHNICAL SUMMARY

152.Protecting and repairing injured retinal ganglion cells

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Neuroscience, optic nerve injury, neuroprotection, axon regeneration, loss of vision

Animal types	Life stages
Mice	adult, juvenile, neonate, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand the factors that cause death of retinal ganglion neurons and prevent their nerves from regrowing after injury, with a view to developing therapeutic agents to counteract this and ultimately preserve visual function.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Traumatic optic nerve injury affects 2-5% of people worldwide with 0.5-5% also occurring in patients with head injuries, whilst 60 million people are affected by glaucoma, leading to loss of vision and eventual blindness. All of these conditions cause death of retinal ganglion cells, neurons that form the optic nerve and relay visual information to the brain. Currently there are no therapeutic agents that promote neuroprotection and axon regeneration after injury or disease to the optic nerve and hence blindness results. We wish to identify and test effective therapeutic targets and agents that will protect neurons, particularly retinal ganglion cells, from death and promote their nerves to regenerate after injury, ultimately protecting against visual function loss.

What outputs do you think you will see at the end of this project?

The primary outputs of this work will be the information on identifying new therapeutic targets to prevent the death of retinal neurons and strategies to promote their axon regeneration after injury. A major potential benefit from the work proposed will be the acquisition of new knowledge for dissemination in peer-reviewed journals. Functional outcomes after ocular damage are poor at best and presently only palliative drug treatments are available for patients. There is, therefore, an unmet clinical need for new therapies aimed at enhancing functional repair responses of damaged ocular tissues.

Specific academic outputs will be to publish the findings. This is important for the development of the project but also to provide a knowledge base for others working in this field.

Other product outputs will be to support the development of the intellectual property already filed and allow it to translate it into a commercially viable proposition for the establishment.

Who or what will benefit from these outputs, and how?

In the short term the benefits would be to provide high impact publications and work for the researchers involved and in raising the profile of early career researchers. This work will also potentially support an application to the MHRA for a clinical trial of the DNA damage inhibitors in eye injury and disease models.

In the longer term this work has the potential to have an immense impact on the lives of patients with eye injuries and diseases where death of the RGC and its nerves lead to blindness. There is currently no treatment that reverses the pathological effects of optic nerve injury/disease and the functional loss that occurs as a result. Our DNA damage inhibitors for example, would provide a clinically viable small molecule-based treatment that can potentially reverse the effects on injury and prevent blindness.

Examples of other potential beneficiaries of the success of this work are glaucoma patients who will benefit through the development of new treatments that are neuroprotective, pro-regenerative and antiscarring, since the same pathological processes occur in this group of patients. At present, no treatments are available to combat neural tissue loss/dysfunction or fibrotic diseases of the eye and this is entirely attributable to our ignorance about the injury and disease processes. Additional beneficiaries could include health care providers, particularly the NHS.

Currently the NHS spends around £25billion/year on patients with partial blindness that includes eye injuries and glaucoma. Effective therapies that protect RGC from death and promote their nerves to regenerate, if successful, would relieve the pressure on the NHS and significantly reduce the cost burden of treating visually impaired patients.

How will you look to maximise the outputs of this work?

We will maximise the outputs of the work by collaborating with academics and companies working in this field to maximise the use of the data we obtain. We will rapidly disseminate the outcomes of the tests whether, negative or positive to inform the community and support other researchers developing technologies in this area. We are already working with several small and large enterprises which we will seek to attract after proof-of-principle experiments have been successful. Some of the agents including the DNA damage inhibitors will need to be provided by companies collaborating with us, however, we are currently filing re-purposing patents for use in our disease models and hence there should be no problems with the freedom to publish our results and without restrictions. However, many companies require vetting of each publication prior to submission, but we will ensure this is completely in a timely manner.

Species and numbers of animals expected to be used

- Rats: 1500
- Mice: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Typically, rats are used for most of our experiments since they closely mimic the human molecular responses to optic nerve injury. Although mice do not faithfully reproducible the molecular characteristics of injury as well as rats, mice do offer the opportunity to assess our objectives in knockout animals, where the impact of a particular gene to aspects of neuroprotection, axon regeneration and scarring after optic nerve injury can investigated.

Typically, what will be done to an animal used in your project?

Typically, animals will undergo unilateral optic nerve crush injury followed by intravitreal injections of therapeutic agents for up to 6 weeks. The thickness of the retina will then be quantified using non-invasive optic coherence tomography followed by electroretinography to determine retinal function. Animals will then be killed and tissue collected for histological/protein/mRNA analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Optic nerve injury: This cause blindness in one eye since the optic nerve is injured (100% of animals). However, since rodents do not rely on vision as a primary sense, this does not impair movement, behaviour, feeding or drinking as measured by clinical signs.

Substances administered by injection: Stress due to restraint and transient discomfort from needle insertion

is likely in 100% of animals. These are minimised by selection of appropriate (minimum possible) sized sterile needles and syringes.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals in this project licence will experience a maximum severity of moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Whilst some elements of optic nerve injury can be modelled in cell culture, the complex, clinical picture and interaction of the whole-body systems, including in particular the immune and nervous systems cannot all be currently modelled in cell-culture or computer-based models. The use of live animals is therefore unavoidable and essential for drug discovery and to demonstrate the activity of drugs in a situation relevant to human disease. Neurons are not present outside the animal kingdom and so an animal is required. Only mammals have a sufficiently developed immune-system to readily compare to humans, and rodents are the animals of lowest neurophysiological-sensitivity required to achieve the scientific aims. It is not ethical to conduct experiments on humans in multiple sclerosis, especially where those experiments require the removal of parts of the immune or nervous system for ex-vivo investigations. Therefore, there is no feasible alternative that can entirely replace the use of a living animal that would allow the objectives to be met. However, we will use in vitro and ex vivo work prior to or in parallel with animal studies.

Which non-animal alternatives did you consider for use in this project?

There are currently no alternatives to animal work for the optic nerve/retinal injury model.
No cell culture-based models exist that encompass all of the aspects of disease for any of the models described in this project. However, individual aspects will be modelled in vitro and ex vivo. For example, we regularly use in vitro retinal cultures to detect therapeutically useful molecules in terms of neuroprotection and axon regeneration to then take forward into animal studies.
We also use ex vivo whole eyes to determined drug penetration through the barriers in the eye after topical application.

Why were they not suitable?

The fundamental reason why the use of animals is required is to understand these processes that at present no in vitro methods can model the complexities of the systems involved in this disease. It is difficult to use primary cells to culture all of the different types of cells since they require different growth mediums and factors for survival. Indeed, the reason why many new drugs fail between cell culture and in vivo studies is in the inability to full recapitulate the in vivo environment. Technologies are being developed to address this gap, including the development of 3D cultures. However, none of these model systems are yet able to phenocopy the integration

and interplay between the numerous cell types that constitute optic nerve/retinal injury.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers of animals have been based on pilot data, in-house data and published data where our own data is not available.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We used the NC3Rs EDA system to calculate animal numbers to be used for this project. We used values from several of our own and other's published data to facilitate power calculations and reduce animal usage.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will seek to refine protocols, such as the development of novel quantitative outcome measure that will facilitate “reduction”. Experiments will be planned so they can be published in accordance with the NC3R’s ARRIVE guidelines.

Wherever possible, we will use archived samples to avoid repeating controls and sham treated groups.
As part of good laboratory practice, we will write a protocol for each experiment including: a statement of the objective(s); a description of the experiment, covering such matters as the experimental treatments, the size of the experiment (number of groups, number of animals/group), and the experimental material; and an outline of the method of analysis of the results (which may include a sketch of the analysis of variance, an indication of the tabular form in which the results will be shown, and some account of the tests of significance to be made and the treatment differences that are to be estimated). We will make appropriate arrangements to randomly assign animals to experimental groups and blind studies.
At the end of the experiment we will harvest the maximal possible number of tissues. Tissues not immediately analysed will be archived and will be made available to other researchers working on similar questions.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Optic nerve injury exhibits many pathological processes including neuronal death and axonal degeneration. Our mouse/rat models have proved to faithfully reproduce human optic nerve injury and have allowed drugs to be screened reliably. Optic nerve injury will be induced by a crush injury. This is very well tolerated and with high reproducibility, limiting the need for large group sizes and many repetitions of experiments. We aim to continue to refine these models and as we apply additional outcome measures such as non-invasive optic coherence tomography, we increase power to detect drug effects and enhance the utility of the models. Through the use of a reproducible system and defined endpoints for each objective, we can limit the time in procedure and as a result the suffering that the animal will accumulate as a product of injury itself.

Why can't you use animals that are less sentient?

We cannot use less sentient species (e.g. zebrafish) for this work, because unlike mammals, most are able to regenerate their CNS spontaneously. Rats are typically used for our experiments since they share similar pathophysiology to humans after injury to the CNS. Mice are also used since there is established and reliable transgene technology, and established models of optic nerve injury. There are a large number of genetically modified mutants available and there is extensive amount of work that has already been performed and published using mouse and rat models of optic nerve injury.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All therapeutic agents are evaluated and optimised in vitro prior to in vivo application. We keep our experimental time points in longitudinal studies to a minimum and use archival control results where possible. Multiple analyses are done on harvested tissues. We use the minimum number of interventions and minimal volumes for drug delivery during experiments and continually seek methods to reduce these by studying alternative drug delivery strategies. Small numbers of animals (i.e. 6-8 rats/mice) are used in the optic nerve crush model to maximise the effectiveness of our post-disease care. These refinement steps significantly reduce animal usage and severity.

Also, we have switched to unilateral eye optic nerve crush experiments to avoid blinding animals in both eyes, avoid loss of normal blood perfusion to the eye by avoiding crushing of the retinal artery that runs parallel to the nerve and is susceptible to crushing and by moving extraocular tissues to one side rather than removing them from the orbit completely. All of these steps minimises stress and potential wastage of animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Prior to all experiments we will consult the PREPARE guidelines checklist to ensure that valuable data will be generated in the experiment.

Experiments will be conducted in accordance with the guidelines published by the Laboratory Animal Science Association (LASA).

The resulting data will be published in Open Access Journals wherever possible and in accordance with the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by advances in the 3Rs through attendance of seminars and conferences, as well as discussions with the NVS and NACWOs and NIOs.

We will review each experiment on completion to determine any refinements that can be applied to future experiments.

Continued review of the scientific literature will be undertaken on a regular basis in order to identify any newly emerging technologies and models that could be potentially adopted in order to replace in vivo animal use.

We will also stay up to date with guidance published by FELASA on the most refined experimental methods.

Home Office

NON-TECHNICAL SUMMARY

153. Protection against incapacitating agents

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

therapy, incapacitating agents

Animal types	Life stages
Marmosets	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Pharmaceutical based agents that can cause incapacitation pose a threat to the UK. This project aims to understand the threat posed by such agents and to assess potential treatments for them.
A retrospective assessment of these aims will be due by 09 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This licence will help to understand the threat posed to the UK from pharmaceutical based agents deployed either as incapacitating agents or as lethal agents. The data from these studies will aid in determining the level of threat posed and the requirements for detectors, diagnostics, physical protection, medical countermeasures, extended medical management and decontamination.
If an agent is determined to be a threat, then existing or novel medical countermeasure will be tested to assess their ability to reverse, prevent, reduce, delay or mitigate the effects of exposure. Effective medical countermeasures will be able to save lives.
These agents pose a potential threat to the civilian population, first responders, the NHS and UK Armed Forces.

What outputs do you think you will see at the end of this project?

There will be improved knowledge on the potential threat posed by pharmaceutical based agents as either incapacitating agents or lethal agents. This knowledge will aid in determining the level of threat posed and the requirements for detectors, diagnostics, physical protection, diagnostics, medical countermeasures, extended medical management and decontamination.
There will be improved knowledge on the effectiveness of new and existing medical countermeasures to reverse, prevent or mitigate the effects of exposure to pharmaceutical based agents.

Who or what will benefit from these outputs, and how?

Increased knowledge of the threat and new medical countermeasures will provide benefit to the civilian population, first responders, UK armed forces and our international partners (nations with whom the UK formally collaborates).
Outputs from this work will aid in the development of new detectors, diagnostics, physical protection and decontamination strategies for pharmaceutical based agents.

How will you look to maximise the outputs of this work?

Some of the work will be published in the public domain in peer reviewed journals.
Outputs not suitable for the public domain will be shared with international partners through formal international collaborations. These comprise regular prearranged collaboration meetings / conferences.
Where the long term output of this work is a variation to the currently licensed indications for use of a therapy (for example to add that the therapy be used in a new way to treat exposure to a pharmaceutical based agent) this will be disseminated via medicinal product information and will be accessible to healthcare professionals.

Species and numbers of animals expected to be used

- Marmosets: 358

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using adult marmosets as we know that they have a similar response to man for the compounds we will be studying.
We also know that other species such as mouse, rat, rabbit and pig respond differently to these compounds and / or are a poor predictor of the human response.

Typically, what will be done to an animal used in your project?

Most animals will receive an inhalation exposure to a pharmaceutical based agent (PBA). This will require they are restrained for exposure which also enables the measurement of respiration during the exposure. Exposure to the PBA will likely cause a range of effects such as: sedation, anaesthesia and respiratory depression. This respiratory depression may become fatal. Animals will be observed following exposure until they recover. Some animals may be exposed to PBA via a different route, including injection.
Some animals may receive potential medical countermeasures to assess their ability to block or reverse the effects of PBA exposure. Medical countermeasures may be administered before or after PBA exposure and will be administered by injection. Some animals may be surgically implanted with a drug delivery device containing medical countermeasures. Some animals may be implanted with a device that enables access to blood vessels via a sampling / injection port.
Animals will have blood samples taken to measure the concentration of PBA and / or medical countermeasures in the blood.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals exposed to PBAs are expected to experience effects such as drowsiness, sedation, anaesthesia and respiratory depression. This respiratory depression may result in death, however, the animal will be anaesthetised by the PBA if this happens. Animals that survive will make a complete recovery. The effects are expected to last for hours.
Medical countermeasures are likely to fully or partially block or reverse the effects of exposure to the PBA.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity limit of all protocols is moderate.
It is expected that across the protocols, 56% of the animals will reach moderate severity with the remaining 44% reaching mild severity.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 09 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Exposure to fentanyls can cause a complex range of effects with respiratory, cardiovascular and neurological changes. It is important to understand the doses required to cause a range of incapacitating effects and to cause death as this provides crucial information on the threat posed. It is also important to understand the window of opportunity in which to treat exposure and how long the effects may last. Such data cannot currently be gained without the use of animals to model the whole body response to fentanyls.
Some data can be gained using *in vitro* assays, such a opioid receptor binding potency, however, whilst fentanyl effects are driven by activity at the opioid receptor, fentanyls also affect different signalling pathways. The efficacy of nAChR partial agonists in a rodent model of opioid induced respiratory depression shows that opioid induced respiratory depression and its mitigation involves complex signalling within the central nervous system. Therefore it is important to understand the effects of exposure and countermeasures in an animal model.
In vitro systems can be used to determine if opioid antagonists are able to displace fentanyls from opioid receptors, however information is still required to determine the length and extent of protection that can be afforded, whether planned doses of opioid antagonists are able to counteract predicted challenge levels and whether they can treat all effects of exposure.

Which non-animal alternatives did you consider for use in this project?

We have considered in vitro systems and simple model organisms for this project.

Why were they not suitable?

Such approaches can provide useful data, however, they will not be able to achieve aims of our project and would not provide accurate predictions to man which will focus on one class of chemical agent. However, supporting information on novel compounds will be potentially be provided by in vitro systems, simple model organisms and other non-primate animals.
A retrospective assessment of replacement will be due by 09 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based upon work that is currently planned and group sizes that have been used successfully in previous studies in this area.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Advice has and will be taken regarding study design from statisticians with respect to statistical designs of studies and the analysis of data from this project. Advice has and will be taken from pharmacokinetics experts regarding design of kinetics studies.
If multiple treatments are to be tested, then a shared control group will be used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Before treatments are tested, a pilot study will be carried out to assess the selected challenge dose to determine its variability and suitability.
If multiple treatments are to be tested, then a shared control group will be used.
A retrospective assessment of reduction will be due by 09 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animals will be exposed to pharmaceutical based agents which will themselves cause analgesia, sedation and anaesthesia and will reduce the potential pain, suffering and distress that the animals may experience. Any adverse effects from the exposure will occur once the animal has become anaesthetised by the exposure. If treatments against exposure are effective, then this will prevent or reduce the effects of the exposure.
Some animals may undergo surgical procedures to either allow monitoring of physiological parameters or to administer treatments over an extended period of time. These animals will be given analgesics during their recovery from surgery.

Why can’t you use animals that are less sentient?

The project is to understand the potential threat from pharmaceutical based agents, many of which have an anaesthetic action. Therefore, it is not possible to do the study in terminally anaesthetised animals.
Lower species have been shown to be a poor predictor of human response for the class of pharmaceutical based agents that will be initially studied.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be continually monitored following exposure until they have made a full recovery or reached a humane endpoint.
For animals undergoing any surgical procedure, appropriate analgesics will be given pre- and / or post-surgery. Animals will be monitored as they recover from anaesthesia and will be regularly checked post-surgery to ensure appropriate level of analgesia and monitor the progression of wound recovery. Sub-cuticular stitching will be used wherever possible to minimise any discomfort due to stitching.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Available guidelines on the NC3Rs website regarding blood sampling will be followed. This references "A Good Practice Guide to the administration of substances and removal of blood, including routes and volumes" by Diehl et. al. This will also be followed regarding the administration of substances.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Updates on advances in the 3Rs are regularly distributed by our Named Information Officer. The licence holder is actively engaged in our establishments Animal Welfare and Ethical Review Body (AWERB). Any appropriate advances will be discussed with our veterinary staff and, where appropriate and compatible with the scientific aims of the project, these advances will be incorporated. I will maintain my required annual CPD, attend relevant external scientific meetings and have meetings and teleconferences with international collaborators working within this field. **A retrospective assessment of refinement will be due by 09 January 2026**
The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

154. Protein kinases and ion transporters in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Kinase, Ion transporters, Cellular chloride volume regulation, Kinase inhibitor, Therapy

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This proposal will elucidate the role of a key enzyme in cellular chloride volume regulation. We will use genetic

models of mice and a drug that specifically target this pathway to aid the study.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Chloride is a very important ion in the brain, because nerves use it to give negative signals in synaptic inhibition, an 'off switch' for nerves. For this to work, however, chloride needs to be kept very low inside nerves. On occasions, nerves lose the ability to remove chloride, and when this happens, this synaptic inhibition no longer works well. This can present serious problems for brain function, and may give rise to seizures, spasticity, severe pain and multiple other neurological conditions, such as epilepsy, stroke and autism etc.

Despite the clear importance of maintaining a good chloride balance, we know little about how this is achieved in healthy brains, or why it might go wrong. Epilepsy is a family of diseases, defined as the experience two or more seizures occurring more than 24 hours apart with no immediately identifiable cause. Epilepsy is common (>50 million people with epilepsy worldwide, and >600,000 in the UK), casting a huge socio-economic impact because it is often a lifelong condition. Moreover, about 30% of people with epilepsy remain refractory to currently available medication, meaning that there is a strong imperative for developing novel therapies.

We discovered a malfunction in the way key proteins are transported within the brain after epilepsy leads to excess chloride levels and swelling, which can cause severe damage. When these proteins are activated after epilepsy, it is just like a water tap is being switched on, and out of control, thus the sink is overfilled with tap water. So the key is to find a switch that can control the tap. We then identified a pathway could directly control the activity of these proteins which bring too much chloride into the nerves, and this pathway is like the "switch" for the tap. This 'switch' is a drug target, for the treatment of epilepsy.

We have developed and patented a new compound that specifically targets this pathway. Our tests in cultured cells have shown that the compound may be able to stop cell swelling (increased chloride volume). This drug effect is unlike any other anti-epileptic medication on the market, so represents an entirely new way of treating the condition. The drug is still in the laboratory and requires further development. So far it shows promise in effectively reducing brain swelling in conditions of stroke or epilepsy. We expect another 3-5 years' work to optimize the drug properties, before it gets ready for a clinical trial.

We have developed models of mice in which certain parts of the pathway are altered to prevent other proteins' actions. The mouse models and new drug will now allow us to perform many experiments to extend our understanding of this important pathway. And crucially, these will also allow us to test the drug, and other related drugs as they are developed. In particular, we will provide the first tests of how this pathway is involved in epilepsy, using several different mouse models, and also test whether the drug can make the condition better. This are critical studies in the steps towards designing and performing clinical trials of these new drugs.

It is these questions that we intend to explore in this project license.

What outputs do you think you will see at the end of this project?

This project will provide a robust framework of knowledge of how these pathways operate and regulate chloride levels in cells. The new compound we have developed has good potential for the treatment of epilepsy. This information is crucially important for the development of effective drugs in this area. Research data will be presented in scientific conferences, and published in high impact journals.

Who or what will benefit from these outputs, and how?

Our research has the potential to lead to the development of a new treatment for epilepsy, a potentially life-altering complication of epilepsy that currently has only limited and expensive therapeutic options. Thus, this

work may have a positive impact on a number of important beneficiaries expanded on below.
Briefly: (1) Patients with epilepsy or high blood pressure; (2) Healthcare professionals, the NHS and the Pharmaceutical industry; (3) Wider scientific community (4) Researcher working on the project; (5) Society; (6) Public engagement; (7) Local economy.

(1) Importantly, in the longer term, this work should benefit people with epilepsy and their families. Epilepsy is a disorder of the central nervous system characterized by recurrent seizures unprovoked by an acute systemic or neurologic insult and has significant impact on the quality of life and psychological welfare of sufferers and their families.
A new therapy to halt the progression of epileptogenesis could lead to the therapeutic use of these drugs in other conditions.
(2) Healthcare professionals including physicians and epilepsy specialist nurses will benefit from increased patient satisfaction and greater patient confidence since current therapies for epilepsy are limited. Epilepsy may require chronic treatment with antiepileptic medication and, in some cases, surgery. A major drain on resources is that many epilepsies remain refractory to the available medications. New therapies, to minimise epilepsy-associated damage and prevent life changing disabilities inflicted by epilepsy, are desperately required.

(3) The wider scientific community will benefit. This project will improve our understanding of the mechanisms of how chloride level is regulated in cortical networks, and through advancement of methods used to study this expanding field of research. We make our results and methods freely available to national and international collaborators in a diverse range of projects. In the long term, this project will aid our understanding of epilepsy and may highlight new pathways for therapeutic intervention.

(5) Society. With an estimated incidence of 34 to 76 new cases per year per 100,000 people, epilepsy affects about 70 million people worldwide. This represents a significant cost to society in terms of time off work as the disease progresses, disability allowance, caring for individuals with epilepsy, i.e.
healthcare services and family if they need to give up work to become carers. Additionally, sufferers can experience depression and anxiety and the cost of treating these associated conditions would be reduced.

(6) This project will have a positive impact on public engagement with science. The potential to develop a new therapy for a debilitating and feared disease will engage public interest and raise awareness of the researchers themselves, their academic institutions and the MRC.

How will you look to maximise the outputs of this work?

Scientific Publications:
Primary research results will be published in high impact journals that are widely circulated. The research findings will initially be published in preprint servers, e.g., BioRxiv, then they will be submitted to a high impact peer reviewed journal. Particular emphasis will be placed on publishing the work as Open Access in order to maximise access and benefit from the work. We anticipate one major publication will be generated from this work. Given the impact of the discovery, we anticipate submitting the work to Science or Cell, and if unsuccessful with these we will then submit the work of Molecular Cell or EMBO J.
In addition to primary research articles, reviews, commentaries, and highlights will be published to summarise and promote the research findings. These types of publications often have a different kind of audience to those of primary research articles. Thus, this will make it possible to reach an even bigger audience.
E-communications, Press releases and Media:
Press releases from the involved labs on the proposed research will be highlighted in news items on University webpages. These are often circulated to the Universities' staff and students to maximise exposure. These sites will be regularly updated with any publications from this work that describe exciting discoveries, so that their combined efforts in highlighting our work can make it reach wider audiences and therefore maximise the impact

of the research. A great emphasis in communicating the outputs of this project will be placed on social media. University, and the Medical School social media channels, Twitter and Instagram, will be used to communicate the key findings of this project. Additionally, the investigators' Twitter, LinkedIn, ResearchGate, Scopus and Instagram will also be used to populate this project's research findings. A pdf copy of the Open Access papers generated from this work will be placed in various platforms such as ResearchGate to maximise access to our published work. For the social media outlets, purposefully produced figures aimed at grabbing the attention of the readers will be designed. This approach has already been adopted in disseminating his recent publications on social media and it led to significant viewing figures. For instance, our recent Nature Communications paper with the discovery of the novel drug was reported in India, USA, UK, Germany, China, South Korea, Singapore and Australia through 47 different articles/broadcasts. This gave a potential reach of 16,396,000 (based on how many people view the website each day and could potentially have read the article on the research) within the first week of the publication.
Oral and Poster Presentations:
The Principal Investigator will actively encourage the researchers involved with the work to present the research results in national and international meetings in every possible occasion. We envisage sending the researchers working on this project to at least one national/international meeting per year.
In particular, the EMBO meetings as well as meetings and conferences organised by the Epilepsy Society UK, Biochemical Society and the British Pharmacological Society, which are always well organised and attract excellent speakers. Also, such meetings often cover research topics that are of interest to the project investigators and the proposed work.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

According our previous studies, most of the mouse models we intend to use, do not exhibit any overt adverse effects. Some mouse models could manifest with high blood pressure,
We will use genetically altered mouse models and drug treatments for our studies. We will generate cell lines from mouse embryos or pups (postnatal day 0-7) for most of our studies. For some studies we will need tissues taken from adult mouse brains to see if our drug is effective for the treatment of epilepsy *in vitro*. For our final studies we will need to use adult mice treated with our drug.

Typically, what will be done to an animal used in your project?

For generation of cell lines, mouse embryos, mouse pups or adult mice will be humanely killed and tissues harvested for *in vitro* studies. .
In some studies, animals will receive injections of our drugs and will then be humanely killed and tissues taken for *in vitro* study.

What are the expected impacts and/or adverse effects for the animals during your project?

General breeding.

Genetic alteration does not cause any overt adverse effects for these two genetic modified models of mice. They have normal phenotype and lifespan. According to our breeding experience on these models of mice, they did not cause any short term mild pain, suffering or distress on the basis of the welfare assessment performed on the established lines.

Potential but unlikely adverse effects:

Most animals produced under this protocol are not expected to exhibit any harmful phenotype but are expected to experience mild levels of severity. Signs of adverse effects are described below.
Some animals may have the potential to develop a harmful phenotype, e.g. tumours, neurological signs, after a certain age but in all cases we anticipate animals will be killed before reaching that age and before the onset of clinical signs. . Animals exhibiting any unexpected harmful effects will be humanely killed

Pharmacological administration

Potential or unexpected adverse effects:

During pharmacological administration, there may be some unexpected signs, e.g. drop of body temperature, hunching, piloerection, loss of righting after the drug administration. Unexpected effects of injection site irritation, such as erythema, itching, discomfort and pain, including more severe manifestations such as ulceration or necrosis, may be seen very occasionally after the drug administration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

It is 'mild' for all studies.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals will be necessary for the success of the research programme because mouse genetics is one of the most powerful technologies to examine the physiological roles of proteins in health and disease. Animals will be required for two major purposes:

1) To generate cells for our cell culture systems.

Cell culture will be our main model system for studying these pathways in the nervous system. Cells taken from embryos or very young mice are the preferred choice for these purposes. We have found that our culture systems are good predictors of the effects seen *in vivo*. These cultured cells are short lived and therefore must

be generated on a regular basis for our experiments.

2) To test the effects of our compounds on the development of epilepsy in whole animals.

In the second phase of the research programme, it will be imperative to extend our observations made using cell culture systems into living animals and test new strategies for the treatment of epilepsy. A neural circuit is a population of neurons interconnected by synapses to carry out a specific function when activated. Neural circuits interconnect to one another to form large scale brain networks. Unfortunately, it remains impossible to reconstitute this complex pathological response in cell culture systems. Thus, we need mouse brain slices for *ex vivo* studies, to see the drug effect for the treatment of epilepsy.

Which non-animal alternatives did you consider for use in this project?

Cell lines, Non-regulated species: for examples *Caenorhabditis elegans* or *Drosophila*, the use of early developmental stages of protected animals, functional magnetic resonance imaging (fMRI) in human patients, and computer modelling etc.

Why were they not suitable?

I have studied information from the SyRF website and Fund for the Replacement of Animals in Medical Experiments (FRAME) website for alternatives to the use of animals for these studies. There are some possible alternatives, however, they are not appropriate for use in this study:

- Cell lines: Cell lines will be used to validate the molecular activity/specificity of any pharmacologic agents *in vitro* before they are used in animals reducing the number of animals used.

- Non-regulated species: *Caenorhabditis elegans* or *Drosophila* for examples, have simple nervous systems with synaptic circuits. However, these species do not have the level of neuronal network complexity observed in mammalian species and often do not have the same or even analogous molecular machinery associated with neuronal function. In addition, the types of complex behaviours associated with diseases of cognition cannot be easily modelled in these species.

- The use of early developmental stages of protected animals: As the focus of this work is on the effects of epilepsy and developmental brain, both prenatal and postnatal developmental stages are required. In this case, it is impossible to use only earlier stages of development.

- Functional magnetic resonance imaging (fMRI) in human patients: fMRI can provide useful clinical information regarding activation of certain brain areas whilst patients are performing certain cognitive tests. However, fMRI effectively records changes in blood flow to brain area, which is a surrogate marker for neuronal activity, and it is thus open to interpretive errors.

- Computer modelling: These approaches rely on high quality experimental data to inform and test the predictions of the models. Furthermore, due to the highly complex systemic nature of epilepsy, it is impossible to model with a computer (*in silico*) due to the infinite number of variables both known and unknown in the neuronal networks found in the mammalian brain.

During the course of this project, I will undertake regular reviews of the literature to keep abreast of *in vitro* techniques and approaches that could be used to replace animal use for the context of this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used is based on our estimate of the minimal number that allows for sound statistical testing.
We have taken advice from statisticians, plus taking into account the variabilities according to previous experience and current pilot data, we calculate a total number of mice required to be 2500. 2000 mice are required for breeding and generation of cell cultures. This is calculated on 4 lines likely to be used over the course of the project. This agrees with our previous experience for the average number required for maintaining lines, and generation of primary cultures. A further 500 mice are required for use in Pharmacological Investigations. These numbers are in agreement with previous animal projects that I have been involved in.
Once specific research programmes come to an end, archiving of the line via cryopreservation of embryos or sperm will be used and the breeding stopped. We intend to breed and maintain GA mice in accordance with the ASRU GAA framework. We will continually measure production and breeding performance and ensure the minimum numbers of animals are used in the program.
The science outputs (i.e. research papers) from this project will be published in international peer viewed journals that support the ARRIVE guidelines.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All sample numbers for mice experiments are based on calculations made using statistical software, for example: http://powerandsample.com and https://www.nc3rs.org.uk/experimental-design-assistant-eda. In our prior studies, we consistently found very large effects in every case, indicative of the importance of the pathway, and clear results using our transgenic models. For most of our studies we have found that we can generate results with fewer than 6 animals per group. In this proposal, we plan to use sample sizes of n=7 to include both adequate numbers of both male and female mice. If we observe trends indicating that gender has an effect in our model we will stratify the groups by gender for analysis. We believe that our study will be able to detect any differences between genders in our models of mice. As experiments may be started over a period of days a randomised block design will be implemented, whereby animals are randomised to treatment type and order of dosing on any given day. This will reduce experimental variability, and thus animal numbers. When possible, collaborations with experts in the field will be sought to ensure that experiments are performed as efficiently as possible.
Additionally to the sources above, statistical advice will be sought through the University Statistics Helpdesk.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All *in vivo* and *ex vivo* experiments will be carried out in as controlled a manner as possible to reduce the animal-to-animal variability and thus reduce the number of animals used. Variable controls include:

- Wildtype littermate control bred under the same conditions and transgenic models will be used as a control comparison wherever possible.

- Age range of animals for a particular study minimised.
- Gender ideally kept the same. Where it is not possible or impractical to use a single gender for a study, a careful gender balance will be maintained and appropriate statistical analysis carried out.
- Environmental disruption (e.g. noise, light changes etc.) minimised (for *in vivo* experiments).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This proposal outlines proof-of-principle studies that will elucidate the role of a specific pathway in epileptic pathophysiology. We will use cellular assays of neuronal function to extend our knowledge of this pathway, and ultimately investigate its involvement in epileptic pathology, by testing the effects of a newly developed drug and its modified analogues in several different models of epileptic activity ***ex vivo***. We will utilise a range of transgenic animals, we designed previously, to interfere with the pathway at different sites; these provide powerful tests of our hypotheses about the pathway's role in disease.
All GA mice included in this project plan have already been established through targeting strategy.
Genetic alteration did not cause any overt adverse effects for these genetic modified models of mice. They have normal phenotype and lifespan. According to our breeding experience on these mouse models of mice, they did not cause any short term mild pain, suffering or distress on the basis of the welfare assessment performed on the established lines.
In particular, some mice have lower activity of a protein in the kidney, which would prevent animals from suffering high blood pressure according to our recently study. We expect these mouse models to be protected from developing epilepsy. With these mouse models, we will generate primary neuronal culture from **their earlier life stage**s, for cellular based assays. Adult mice will be humanely **killed**, and brain slices will be obtained for ***ex vivo* studies**, to see the drug effect for the treatment of epilepsy.
Our compounds and its modified analogues, will block the same pathway, mimicking the genetic effects. We will administer our compounds to adult mice to investigate drug efficacy. Compounds will be administered via Intraperitoneal (i.p.) injection at doses that are not expected to cause adverse welfare, on mice.

Why can't you use animals that are less sentient?

We need to use mammalian animals with a certain degree of neuronal complexity in order to achieve our scientific outputs. We use animals at an immature life stage where possible, for example, embryos or mouse pups for making cell cultures. Induction of epileptiform activity will only be conducted in brain slices taken from adult mice (*ex vivo*).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Minimising animal suffering: We have several measures in place in order to reduce animal suffering, such as daily monitoring, extra bedding, and a welfare scoring system.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I have been following published practice guidance, for examples, "Guidance on the Operation of the Animals (Scientific Procedures) Act 1986" and "Guiding principles on good practice for Animal Welfare and Ethical Review Bodies, 3rd Edition – September 2015" to ensure experiments are conducted in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I follow the NC3Rs twitter, and I have subscribed to NC3Rs newsletter, from which I get the latest articles, events and funding opportunities from NC3Rs in my email inbox every month. I will also engage with our local NC3Rs representative.
I will also regularly attend appropriate courses to keep my ASPA knowledge up to date, such as ASPA refresher course, Sch1 training courses and the 3Rs Symposium.

Home Office

NON-TECHNICAL SUMMARY

155. Radiation Combinations for Cancer Treatment

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Radiation, Oncology, Rodent

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To test anti-cancer agents in combination with ionising radiation with the aim of improving current clinical therapies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Radiotherapy provides significant benefit and is used in over 50% of all cancers. To combine radiotherapy with novel anti-cancer agents may significantly enhance the therapeutic outcome and has the potential to translate into highly significant clinical benefit.
In order to determine potential clinical benefit we need to have pre-clinical animal models that will demonstrate and characterise improvements in anti-tumour activity and relevant potential clinical benefits thus directing clinical development.

What outputs do you think you will see at the end of this project?

Data to support clinical trials. Improved radiation protocols combined with novel anti-cancer agents to be used in the clinic leading to improved efficacy and tolerability. We will share pre-clinical data with principal investigators to influence clinical trial designs. Publication of both successful and unsuccessful data in high impact journals.

Who or what will benefit from these outputs, and how?

Radiotherapy provides significant benefit being used in over 50% of all cancers. As the patient population treated with radiotherapy is so large, enhancing therapeutic outcome for even a relatively small proportion has the potential to translate into highly significant clinical benefit. To have pre-clinical animal models that will demonstrate and characterise improvements in anti-tumour activity will lead to more relevant potential clinical benefits thus directing clinical development.
In this license we will be testing the combination of potential anticancer drugs and ionising radiation with the aim of improving current anti-cancer therapies. With this license we will be able to investigate if new compounds sensitise human tumours to irradiation or if new dosing schedules are better tolerated and/or more active than the current ones. With all this information, new clinical trials can be designed that eventually may change clinical practice.

How will you look to maximise the outputs of this work?

Dissemination of knowledge at conferences via poster sessions and seminars. Publication of both successful and unsuccessful data in relevant journals. We will share pre-clinical data with principal investigators to influence clinical trial designs. We work in collaboration with many scientists and groups in which we are able to share data and learning.

Species and numbers of animals expected to be used

- Mice: 11000
- Rats: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use animal studies in mice and rats alongside many other experimental approaches and they are crucial in building up a complete picture of cancer biology. Our research using animals has helped drive advances in cancer treatment that are benefiting people with cancer all over the world today.
Our work mainly uses mice (90%), which can grow tumours which mimic those of human cancer patients. Studies of cancer in mice mimic the complex way tumours grow and spread in people with cancer.
Mice can be easily genetically altered to allow us to study the genetic causes of cancer and reproduce tumour types which naturally occur in humans in the correct tissues and body systems.
We also conduct some studies in rats (10%). Some compounds that we want to test may not have sufficient levels in the blood to have an effect on the tumour in the mouse and therefore we need to use the rat as an alternative species. The rat is also usually the species of choice for toxicity studies. These studies would be conducted under a different project licence but it may be necessary to directly compare the dose level of a drug that causes an effect on the tumour to the dose level that produces unwanted side effects. This is to ensure that there is a big enough margin between activity and safety.

Typically, what will be done to an animal used in your project?

In a typical study animals are implanted with a tumour. As our work is not focused on one area of cancer but across all cancer types with focus on lung, prostate, breast, ovarian, pancreatic, bladder and haematological cancers there are a wide variety of tumour types that may be used within this licence. The majority of tumour models are derived from human tumours. As the human tumour tissue is foreign to the animal, the animals immune system would reject the tumour tissue and therefore we need to grow human tumours in either mice or rats that have an impaired immune system. This allows the tumour tissue to grow and not be rejected.
Tumours are usually implanted as cells using a needle, this is done on the lower left or right side of the back (flank) of the animal. In some cases the tumour is not available as cells and therefore a very small piece of tumour tissue needs to be surgically implanted into this area. This is done under anaesthesia and requires a very small cut in the skin and a pocket made under the skin where the tumour tissue can be placed. The cut is then sealed using either stitches, special tissue glue or clips. This area also allows the tumour to be easily monitored and measured and does not affect the animals ability to move around.
Once the tumour has started to grow the animal's tumour will be irradiated using an x-ray machine. Only the area where the tumour is will be exposed to the x-ray beam, the rest of the animal will be protected with a lead shield. The animals will be anaesthetised to ensure that the animal does not move whilst being exposed to the x-ray beam. The animals may also receive doses of an anti-cancer drug. In a typical study an animal may receive one dose of radiation each day for 5 days. Anti-cancer drugs are usually dosed orally and the animal may receive up to two doses per day for 28 days. The animals are closely monitored every day and body weights and condition of the animals are recorded to ensure that the animals are healthy. The effect on the tumour growth is compared to an animal which does not receive any active drug and/or radiation. The hope is that the anti-cancer drug in combination with radiation significantly reduces the growth of the tumour compared to either giving the drug alone or radiation alone.
During the study blood samples may be taken. This is to check the level of the drug in the blood.
At the end of the study the animal is killed and the tumour tissue and other tissues are taken which can then be

used for further investigation.

What are the expected impacts and/or adverse effects for the animals during your project?

The tumour is continually monitored and measured and although the tumour may continue to grow this does not appear to cause the animal any pain or discomfort and they continue to behave normally. The size the tumour can grow is limited by the use of a measurement/condition/size scoring system to ensure that it does not cause any pain or discomfort to the animal.
The doses of radiation are targeted to the tumour area only and the rest of the animal is protected therefore no adverse side effects are expected.
The dosing procedure for dosing of the anti-cancer drugs does not usually cause any issues but the drug itself may have some side effects. Side effects may include weight loss or abnormal behaviours such as being less active or not socialising or interacting with their cage mates. Very strict criteria are put in place to minimise any unwanted side effects to avoid any pain, suffering or distress to the animals. The side effects usually only last for a short period of time.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 90% of animals used within the licence will be mice and 10% rats. It is expected that 90% of both the mice and rats will be returned within the moderate category and approximately 10% within the mild category. This will be for all strains of mice and rats used within this project licence.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed in our research to help us understand the mechanisms that underpin cancer, such as the growth and spread of tumours, and to develop new ways of diagnosing, treating and preventing the disease. Cancer is a very complex disease and animal studies are essential to understand these complexities within living organisms. They are also required by regulatory authorities before any trials of new drugs can be tested in humans. Animal studies are only performed after every feasible test has been conducted on cancer cells in the laboratory and where no alternative exists.

Which non-animal alternatives did you consider for use in this project?

Multi-cellular 'organ on a chip' models are available, but as yet have not reached the reliability and multi-system complexity of the rodent model, especially when shaping the treatment of patients in the clinic. Non-animal alternatives are used in the identification and selection of compounds. These generally include measurements of the drug's activity on particular target cells. Activity in particular cell types however cannot predict the activity

in humans due to a complexity of issues such as availability of the drug in the body and whether it is able to reach the target cancer cell.

Why were they not suitable?

They are not suitable because they cannot mimic the living organism and the processes that under-pin cancer in a living organism.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This licence reflects a well-established cancer research program and the numbers of animals used within this project licence are based on the diverse areas of cancer that are being investigated.
We typically run approximately two studies per month, each study usually has ~100 animals per study.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All studies are designed to ensure that the minimal numbers of animals are used to achieve the question being asked. This is done with help and guidance from a statistician who is a maths expert who uses huge amounts of data to figure out how likely it is that something will happen or not. They ensure that all studies are designed to ensure that we are able to use the minimal numbers of animals to see an effect of a potential anti-cancer drug if there is an effect.
Good experimental design principles such as randomisation are incorporated into all experiments. All study designs are approved by a statistician.
All experiments are performed in accordance with Good Laboratory Standards (GLS). This standard sets the minimum laboratory requirements for all our research and development. This ensures that procedures and results are accurate, reliable, traceable and reproducible and where appropriate, comply with the appropriate regulatory authorities' legislation.
All experiments are performed in accordance with the PREPARE guidelines - Planning Research and Experimental Procedures on Animals: Recommendations for Excellence.
All research that will be published will be published in accordance with the ARRIVE guidelines - Animal Research: Reporting of In Vivo Experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When multiple project groups want to investigate the effect of their compounds in the same tumour model wherever possible we run these within one study that share the same control group therefore reducing the requirement for multiple control groups if the studies were run independently, leading to an overall reduction in numbers. Such opportunities are identified at monthly demand meetings I chair where projects are looking at exploring their compounds in combination with radiotherapy treatment.
To minimise any side effects associated with treatment of potential drugs, a small pilot study in 2- 3 animals is

performed to ensure the treatment does not have any unwanted side effects before progressing into larger numbers of animals.
Wherever possible multiple tumour and/or tissue samples will be taken from the same animals and may be frozen down and used in other non-animal experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a wide variety of different tumour models in both mice (90%) and rats (10%). The majority of the tumours are implanted as cells in an area on the animal (the lower left or right side of the back (flank)) which allows the tumour to be easily monitored and measured and does not affect the animals ability to move around. The size the tumour can grow is limited to ensure that they do cause any pain or discomfort to the animal.
The doses of radiation are targeted to the tumour area only and the rest of the animal is protected therefore no adverse side effects are expected.
The dosing procedure for dosing of the anti-cancer drugs does not usually cause any issues but the drug itself may have some side effects. Side effects may include weight loss or abnormal behaviours such as being less active or not socialising or interacting with their cage mates. The drugs are tested in a very small number of animals initially (2 to 3 per group) and only drugs that do not have unwanted side effects can be used in larger numbers of animals.

Why can’t you use animals that are less sentient?

Using less sentient animals for example a non-mammalian species such as the fruit fly, is not possible since they lack a closed circulatory system and so you cannot replicate a number of the complex processes that underpin cancer such as the growth and spread of cancer.
Earlier life stages of vertebrates such as zebrafish is an option, and early studies of human xenograft models do show promise of tumour inhibition studies . However the small size and difficulty of collecting meaningful blood samples makes pharmacokinetics essential in our work, currently impossible in that model.

https://www.sciencedirect.com/science/article/pii/S2352396419307881 Costa et al 2020 in the EBioMedicine (The Lancet) Developments in zebrafish avatars as radiotherapy sensitivity reporters — towards personalized medicine.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be acclimatised for 7 days from arrival before they undergo any experimental procedure.
Animals will not be handled by the tail and will be handled by an alternative method, for example tunnel handling, modified cupping and/or ‘pinch’ scruffing. The tail will only be used for the initial catching of an animal in exceptional circumstances or when absolutely necessary (for example if an animal has escaped and priority is to regain control).
All surgery is performed in concordance with 2017 LASA Guiding Principles for Preparing for and Undertaking

Aseptic Surgery. Any animals that undergo a surgical procedure will be provided with analgesia (pain killers) prior to the surgery and maintained in a warm environment until full recovery to minimise weight loss. Analgesia may be administered post-operatively within an edible jelly. The mice and rats will have access to a non-medicated form of the jelly prior to surgery to become accustomed to eating it.
Explore if there are options to apply any palliative treatments to minimise any adverse effects of dosing.
All parental dosing routes will be done using a single needle. For cell implants this will be done with a single needle unless documented exceptions are in place.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Guidelines for the welfare and use of animals in cancer research (Workman, P., Aboagye, E., Balkwill, F. et al. Br J Cancer 102, 1555–1577 (2010))
Animal research: Reporting in vivo experiments: The ARRIVE guidelines. Br J Pharmacol. 2010 Aug; 160(7): 1577–1579.
PREPARE: guidelines for planning animal research and testing (Adrian J Smith, R Eddie Clutton, Elliot Lilley et al. Laboratory Animals Volume: 52 issue: 2, page(s): 135-141
LASA Guiding Principles

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I actively participate in continuous professional development as a fellow member of the Royal Society of Biology. I receive The Biologist newsletter every month which often provides a good source of relevant 3R's initiatives. I also follow the NC3R's website to keep myself updated on relevant 3R's initiatives (https://www.nc3rs.org.uk/news/using-award-scheme-promote-3rs-innovation). We also actively discuss and implement new 3R's initiatives and run a yearly 3R's poster session competition, sharing information across different establishments.
I am an active member of AWERB and annual refinement goals are set annually by AWERB, for example alternative mouse handling.

Home Office

NON-TECHNICAL SUMMARY

156. Radiation-induced Leukaemogenesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Radiosensitivity, leukaemia, low dose/dose rate, Haematopoietic stem cells, metabolism

Animal types	Life stages
Mice	juvenile, adult, aged, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

In this project we aim to use mouse models to obtain mechanistic and quantitative data on events occurring in bone marrow cells which lead to the development of leukaemia following exposure to Ionising Radiation (IR). This data will eventually contribute to the development and refinement of leukaemia risk projection models for IR-exposed human populations, particularly at low dose/dose rates, and to investigate factors which may modify this risk.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Human populations are exposed to Ionising Radiation (IR) from a variety of environmental and manmade sources e.g. Radon, medical imaging and radiological accidents. Studies of Japanese atomic bomb survivors and other exposed populations provide clear support for an increased leukaemia incidence following high-to-moderate IR exposure, especially Acute Myeloid Leukaemia (rAML) and risk models have been developed for these exposures. However, to is harder to model risk at lower dose exposures due to insufficient available epidemiological data. These low dose/dose rate exposures are the most relevant to the general population and have increased significantly in recent years due to increased use of medical imaging e.g. CT scans.

rAML is cancer of white blood cells (leukocytes) of the myeloid lineage originating within haematopoietic tissue (bone marrow and spleen) which produces and maintains the blood system. This process, known as haematopoiesis, is dependent on the ability of Haematopoietic Stem Cells (HSC) to divide asymmetrically to both self-renew and to produce daughter progenitor cells (Haematopoietic Stem/Progenitor Cells (HSPC)). The HSPCs continue to differentiate, eventually producing mature blood cells of different lineages.

Leukaemogenesis is the process by which HSPC are transformed into leukaemic cells by acquisition of certain specific mutations and modifications to DNA sequences which then effect gene function and expression. It is also influenced by multiple internal and external factors, such as inherited genetics and diet/metabolism. A good understanding of how radiation-induced DNA damage occurs and how it is repaired has been developed over many years. However, more research is needed to understand how the sequence of early molecular/cytogenetic events occurring in HSPC, and the multiple factors which influence this, lead to the development of rAML. Lack of knowledge in these areas inhibits development of risk estimates and new approaches for rAML prevention or detection.

Radiation-induced leukaemogenesis is a complex multi-step process that can be difficult to study in humans due to the scarcity of appropriate samples, their relative genetic and etiological complexity and the inability to study pre-leukaemic events. Therefore, mouse models of rAML are invaluable in providing a better understanding of the molecular mechanisms of tumour initiation and development.

The work proposed in this project aims to use genetically modified versions of an established mouse rAML model to investigate radiation-induced leukaemogenesis and the factors which influence this process by monitoring the progression of initiated, 'pre-cancerous' cells *in vivo* and *in vitro* as they acquire critical characteristics in a stepwise fashion after radiation exposure towards rAML progression.

The insights gained will contribute to developing and refining radiation leukaemia risk projection models, particularly in relation to low dose/dose rate exposures relevant to the general population and will also eventually contribute to the development of Radiation Protection Health and Safety guidelines. Additionally, identifying factors which influence rAML risk is of interest to the Radiation Protection field, as this may lead to interventions which can mitigate the effect of exposure to IR.

What outputs do you think you will see at the end of this project?

The scientific outputs of this project will be new and increased knowledge of the radiation-induced leukaemogensis process, such as identification and characterisation of the target cell at risk within the bone marrow, quantitative measurements of target cell radio-sensitivity and the effect of oxygen metabolism on this process, identification of new mutations which may provide alternate leukaemogenesis pathways, and also identification of potential mitigating factors such as dietary alterations and further understanding their influence on radiation-induced leukaemogenesis development. This will take the form of scientific publications in peer reviewed journals, poster and oral presentations at scientific meetings.

Who or what will benefit from these outputs, and how?

Current risk estimates of the UK population suggest 9000 cancer cases per year are attributable to IR exposure from average annual exposure to a member of the general public of 2.7 mSv, made up of natural background radiation, dental x-rays, medical imaging etc. However over- or under- estimation is possible due to the uncertainty on the true risks and occupational doses can be higher. Information obtained in the proposed project would eventually feed into the development of refined models for risk estimation in human populations, particularly following low dose radiation exposures.
Animal studies have contributed to the evidence base for providing advice and guidance to international organisations (e.g. The International Commission on Radiological Protection (ICRP),
International Atomic Energy Agency (IAEA)), government agencies (e.g. Health and Safety Executive, Nuclear Installations Inspectorate, Ministry of Defence and Environment Agency), and the nuclear industry. Radiation Protection guidelines are under constant revision and any new information added to the evidence base will be taken in to account in these revisions. These new guidelines eventually form the basis of Radiation Protection Health and Safety advice given by Government Departments.
Additionally, improved basic knowledge of radiation-induced carcinogenesis will be obtained during this project and in the longer term this work will aid the identification of early markers of radiation exposure and associated disease. Such biomarkers can be used to identify people within exposed populations (e.g. radiotherapy patients) which may have a higher risk of developing radiation-induced leukaemia, so they can be monitored for early identification of leukaemia development, improving clinical outcomes. Additionally biomarkers can be used for biodosimetry, where quantitative measurements of biomarker presence give an accurate estimate of radiation exposure to an individual in a situation where this is unknown e.g. radiological accident. This then allows remedial action to be taken dependant on dose, such as a close monitoring of individuals at higher risk of developing radiation effects including cancer. Identification of new biomarkers of radiation exposure, particularly those which can be identified with a rapid PCR-based test is a research priority within the Radiation Protection field, as currently available methods are labour-intensive and relatively slow, so are not optimal for large radiological incidents.
Identifying and investigating possible mitigating factors for radiation-induced leukaemogenesis, such as dietary alterations, calorie restriction and availability of micro-nutrients could eventually contribute to clinical interventions for radiotherapy patients to reduce the therapy-related leukaemias risk.
Additionally, understanding the mechanism by which these dietary factors mitigate rAML risk, possibly through changes to oxygen metabolism in the bone marrow target cell, could lead to the identification of potential new theraputic targets or compounds (e.g anti-oxidants, or signalling proteins involved in reactive oxygen species metabolism) in the longer term.

How will you look to maximise the outputs of this work?

All studies that yield sound results will be submitted for publication in the open scientific literature and thus add to the knowledge base available to researchers worldwide. This evidence will be consolidated through dissemination of project results and their implications to radiation protection specialists at the stakeholder meeting in the final year of funded projects, in addition to other appropriate scientific conferences and meetings e.g. European Radiation Protection Week (ERPW).
We continually seek to collaborate with other research groups across the UK and Europe, which provides significant benefits, as we are able to provide access to tissues, cells or other biological materials from our specialised mouse models for use in experimental systems which we do not have available to us. For instance, for previous collaborations we have provided mouse AML material for Transcriptomic and Proteomic Array analysis with colleagues in Europe, which lead to a joint publication, and we are currently preparing spleen and brain samples for Whole Genome Sequencing. We also provide rAML incidence/latency data and other endpoint data to researchers specialising in statistical analysis and mathematical modelling of risk.

Species and numbers of animals expected to be used

- Mice: 6300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We breed and use specialised mouse models sensitive for radiation-induced Acute Myeloid Leukaemia for our experimental studies. These models are used because they allow study of mechanistic aspects of the rAML process which is not possible in humans or in *in vitro* cell culture, such as early genetic and molecular events. The mice are young adult mice (10-12 weeks old) when irradiated at the start of the experiments, to allow enough time for rAML to develop (between 9-18 months post-irradiation).

Typically, what will be done to an animal used in your project?

Our studies generally involve irradiating our mouse models with X-rays, which involves transferring mice in to the X-irradiator in their sibling groups in cages for the duration of the irradiation (usually no more than 10 minutes). Mice are then maintained for lifespan (up to 2 years) with twice daily health checks, or until they reach their scientific end point, when they are humanely euthanised and biological samples are collected at post mortem for use in our analysis.
Some of our mice undergo blood sampling each month throughout lifespan, which involves collecting a small amount of blood from a vein in the tail with a sterile needle.
Some of the mice will be placed on altered diets, either for short periods (a few weeks) or for lifespan. These may involve reducing the calorie intake so the mice weighs 20% less than an *ad-lib* fed counterpart, periods of fasting (24 hours) alternating with periods of *ad-lib* feeding, and addition or removal of a particular nutrient (vitamins, amino acids). These mice undergo weighing and other checks several times a week to ensure that they do not lose too much weight.
Some of the mice will undergo bone marrow transplantation procedures. This involves either giving the mice a high radiation dose to remove their bone marrow, or using a mouse strain which is engineered to have defective bone marrow, then injecting specially sorted stem or progenitor cells isolated from mouse bone marrow in to the tail vein. The mice are then monitored for lifespan with tail vein bleeding to check for growth of the injected cells.

What are the expected impacts and/or adverse effects for the animals during your project?

During lifespan studies mice would be expected to develop leukaemias and other cancers associated with radiation exposure. Twice-daily checking by trained staff and use of a welfare sheet developed after extensive experience with these types of experiment mean that virtually all of these mice are humanely killed as early as possible when symptoms are identified.
In bone marrow transplantation studies, mice are vulnerable to infection and the transplant failing. Extensive measures are in place to monitor animals undergoing such procedures, and to prevent infection and provide extra nutritional and fluid support. If, despite these measures, a mouse begins to show symptoms of infection or failure of the transplant, they are removed from the study and humanely killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority (around 80%) of experimental mice we use will experience moderate severity.
The majority of mice used for breeding will experience mild severity (around 90%), the others will experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

It would not be not possible to achieve the objectives of the project without using animals, because currently no *in vitro* system exists that adequately recapitulates the process of leukaemogenesis *in vivo*. For instance, it is very difficult to maintain haematopoietic stem and progenitor cells (the cell of origin of radiation-induced acute myeloid leukaemia) for more than a few weeks in *in vitro* culture as the cells begin to differentiate and lose their stem cell characteristics. Also, we wish to investigate the effect of the bone marrow microenvironment on the process of leukaemogenesis which is impossible to recreate in single cell suspensions or colony assays *in vitro*. Therefore, to study radiation-induced genetic and molecular events in leukaemic target cells weeks and months post-irradiation it is necessary to irradiate *in vivo* and harvest the cells from the whole bone marrow when the timepoint is reached. However, in some circumstances cell culture assays can be employed and these are used wherever possible. Results from animal and cell culture approaches are complementary. For instance, we can use in vitro approaches to determine the effect of individual amino acid, individual vitamins or other micronutrients on leukaemic target cells, which allows us to screen possible rAML risk modifiers before applying them to in vivo diet studies.
Also, it is difficult to obtain primary human radiation-induced AML samples to study both for ethical reasons and because of the relative rarity of these tumours in the general population. Even if samples were available it can be difficult to identify the exact exposure dose an individual may have received, and these samples cannot be used for mechanistic studies to identify early pre-leukaemic events.

Which non-animal alternatives did you consider for use in this project?

There are an increasing number of methods and techniques available, provided by specialised suppliers or described in the literature, for short and long term culture of haematopoeitic stem and progenitor cells. These include cell culture plates containing 3D matrix, which mimics the microenvironment of the bone marrow stem cell niche, availability of HSPC growth medias specially created for Mouse HSPC, and isolated growth factors and other cytokines to add to murine HSPC culture media. We are continually developing and refining cell culture conditions for HSPC expansion and long term culture in our laboratory to reduce the number of mice needed to study these cell types.

Why were they not suitable?

Most of the methods described still do not produce reliable, stable long term culture of the haematopoeitic stem and progenitor cells beyond about 6 weeks. However, we are able to use them to optimise our short term culture techniques where this is appropriate, for instance, developing assays for radio-sensitivity and metabolic changes induced by radiation exposure. We have significantly increased reproducibility and reduced previous problems by customising the media/cytokine combination used, optimising the seeding cell density and using low O_2 incubators, allowing progress with characterising cellular (proliferative/clonogenic assays) and metabolic e.g. mitochondrial/glycolytic changes, after X-ray exposure *in vitro*, replacing the need to irradiate individual mice *in vivo*.
These studies generate important data and also informs experimental design for related *in vivo* studies

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Throughout the course of this project licence experimental animal numbers will be kept to the minimum required using statistical analysis techniques with advice on this being obtained from qualified and experienced statisticians available in house and with colleagues in other laboratories. These numbers will be based on previous experience and data generated in past studies, along with published studies in the literature with the same strains or techniques. This means that numbers of mice used will be the minimum required to give sufficient statistical power to each experiment.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To determine the minimal numbers of animals needed to achieve the scientific output for each experiment, we use various resources, including related experiments or techniques described in the published literature where there is a well-established experimental design available, consultations with technical experts at specialist companies to optimise *in vitro* assay methods and therefore reduce the number of *in vivo* irradiations or donor mice needed and also the guidance available on websites such as the 3Rs and ARRIVE guidelines.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We continually revise and improve protocols for harvesting and high quality preserving of tissues and extracted biological material (e.g. DNA, RNA and protein) from experimental animals, allowing increased harvest from individual animals thus increasing the data available from each experiment. Tissues, or materials extracted from tissues, will be stored for future use, both by us and for making available to collaborating laboratories for analysis techniques we do not have access to. These improvements have also allowed the use of archived historical material for cost-effective large scale screening methods, such as DNA sequencing, unavailable when the samples were first collected, therefore reducing the need for passage or repeating of AML-induction experiments to obtain more material.
We will use pilot studies for altered diet protocols which will allow calculation of statistically significant group sizes for larger studies
Both male and female mice can be used as a source of bone marrow cells and for early event studies, thus reducing the number of mice needing to be bred.
We maintain breeding colonies of specialist Genetically Altered mice which allow study of specific aspects of the rAML mechanism. These breeding colonies contain the lowest number of animals necessary for maintenance of the colony and we will be cryopreserving lines we are not currently using experimentally to avoid over breeding

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The CBA mouse model of radiation-induced leukaemogenesis is well established and has been used by laboratories worldwide for many years. It has a consistent induction rate of 20% following 3 Gy whole body irradiation, with a very low spontaneous background rate and can be reliably used in AMLinduction, dose response and early event studies. For some of our studies we will be using dietary alterations to identify possible modifiers of radiation-induced leukaemia risk.
The whole body irradiation methods we use do not require restraint whilst being carried out, minimising the stress of handling, and our experimental model mice can be group housed under standard normal conditions throughout. The optimal radiation dose for radiation-induced leukaemia induction in this model does not produce any short term adverse effects on the mice. Some of our studies require a bone marrow cell transplant to take place where the host mouse bone marrow has to be removed. For these types of studies, where possible, we will use a genetically-altered host mouse which does not require large doses of radiation to be applied to remove the bone marrow prior to transplant. When, in certain studies, a non-genetically altered host has to be used, the higher radiation dose will be given as split doses to reduce any adverse effects produced.
We use a specialist mouse tail vein injection platform when carrying out tail vein injections and when taking blood samples from our mice, which does not require head or body restraint, reducing the stress of handling and we are able to use a very small amount of blood for our experimental uses, minimising the risk of excessive blood loss on the mice. When carrying out injections we use the smallest injection volume possible with the smallest sized needle after applying local anaesthesia to minimise pain and discomfort at the injection site.
We have developed reliable checking systems to be carried out twice a day by trained staff for early signs of leukaemia symptoms in our mice to allow for humane euthanasia to be applied as early as possible, minimising any suffering. In certain experimental studies using blood sampling we are able to identify animals in a pre-leukaemic state and are able to apply an earlier endpoint before leukaemia symptoms appear.

We will develop and refine our dietary alteration methods by using pilot studies based on methods described in the literature, allowing us to identify the most appropriate checking and monitoring systems to minimise the risk of adverse effects developing and to design experiments using the minimum number of animals possible. The methods we are using do not require animals to be individually housed, minimal handling is required, and they are monitored throughout with regular weighing and body condition scoring to ensure they remain at a healthy weight.

We have developed a scientific understanding of this model system that allows us to design experiments that produce the maximum amount of data in the minimum number of animals. We also have substantial experience in the experimental techniques required e.g. FISH, QRT-PCR, FACS

increasing the chances of success of the project. The extensive amount of genetic and proteomic data available on bioinformatic websites for the mouse make this organism amongst the best model for human disease.

Why can't you use animals that are less sentient?

We are unable to use less sentient species, or mice at an immature life stage as to meet the aim to study the mechanism of radiation-induced leukaemogenesis requires development of leukaemia with tissues and data collected throughout lifespan, or at time points post-irradiation. So we have to choose a species which develops leukaemia in the same way that humans do, and use animals throughout their lifespan.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will minimise animal suffering by identifying potential adverse effects and ensuring that humane endpoints are developed and applied under these circumstances. We have developed welfare sheets and will ensure that staff involved in the day-to-day care of the animals are trained in using them. We will use under guidance from the NVS the appropriate anaesthesia when carrying out tail vein injections and blood sampling and use trained staff to handle the animals undergoing such procedures so as to minimise stress.
Mice on protocols which lead to leukaemia development are checked twice every day to identify symptoms at the earliest opportunity. Where indicated by the protocol, animals will be housed in isolators with sterile food, water and bedding, to reduce the chance of advantageous infection.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We base our leukaemia diagnosis and symptom presentation as set out in guidelines described in the Bethesda proposals for classification of nonlymphoid hematopoietic neoplasms in mice
(Scott C Kogan et al, Hematopathology subcommittee of the Mouse Models of Human Cancers Consortium Blood . 2002 Jul 1;100(1):238-45).

We also use the advice on the 3Rs website (www.nc3rs.org.uk/the-3rs) and also the ARRIVE guidelines (https://arriveguidelines.org/) to refine experimental techniques/protocols and experimental design

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We regularly review the scientific literature and consult with technical experts at specialist companies for new methods or techniques relevant to our research area, particularly for improvements to cell culture techniques involving haematopoeitic stem and progenitor cells, which we may be able to apply or use in our project to generate data and to inform *in vivo* experimental design, and so reduce the number of mice we need to use. Regular attendance at scientific meetings and presentations also provides information about up-to-date methods and techniques in the field which can be used to maximise the data we obtain from our research and provide opportunities to organise collaborative projects where we can share material/tissues generated in our *in vivo* studies, increasing the scientifc output from each sample set throughout the course of the project.

Home Office

NON-TECHNICAL SUMMARY

157. Red deer and the impacts of human disturbance

Project duration

5 years 0 months

Project purpose

- (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Animal behaviour, Animal movement, Disturbance, Ecology, Reproduction

Animal types	Life stages
Red deer	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to collect fine-scale data on the activity and movements of red deer, simultaneously with high quality data on aspects of the environment that could influence those. By doing so, we aim to identify the impacts of recreational land use on red deer, and to provide insights into whether those impacts could be mitigated, reducing land use conflict.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In Scotland, red deer are important to the rural economy and an economic asset for some land managers. Many estates are also attractive destinations for recreational hikers. This can lead to conflicts between these legitimate interests, and some landowners believe that disturbance from recreational hiking changes the distribution of deer across estates, reduces deer reproductive success, affects the numbers of deer available for stalking and shifts the pattern of the deer's grazing impacts. Although human disturbance of red deer has been studied before, widely varying impacts have been reported. Moreover, it is clear that deer movements need to be studied in detail along with the factors that affect them - including human movements. By conducting such a study, we aim to bring objective data to bear on a source of land-use conflict, providing information that can be used to help relieve the conflict and promote coexistence in upland areas.

What outputs do you think you will see at the end of this project?

Outputs from this project will include:

- Data on the movements of individual deer across the annual cycle, showing patterns of habitat use and whether deer movements and habitat use vary with different degrees of disturbance.
- Additional data on the movement, behaviour, and spatial distribution of red deer.
- These data will be used to generate project outputs in the form of a PhD thesis, publications in academic journals, and various public outreach media to disseminate findings to the widest range of people that will find it helpful.

GPS collars are widely used in deer studies that investigate movement and behaviour in deer, and their value for achieving these project goals is well established in the literature. Even a modest amount of data collection, owing to unexpected adverse field conditions or unusual levels of equipment failure, will substantially improve the quantitative basis for addressing existing conflicts, moving the debate away from polarised opinion, and towards measurement and mitigation. In the highly unlikely event of substantially reduced data collection (owing, for example, to extreme weather events at key times), a demonstration of the value and potential insights to be gained from such data would reassure funders and serve as both proof of principle and pilot data for a future field campaign.

Who or what will benefit from these outputs, and how?

Conflicts arise when land-user activities are at odds. The impact of recreational land users on deer, in particular, is suggested to conflict with deer stalking in the area by dispersing deer away from the area, and by reducing deer population size via impacts on deer energy expenditure, their foraging behaviour and, ultimately, their survival and recruitment. These effects have implications for management activities, in addition to economic and ecological impacts. Furthermore, there are welfare implications for wildlife under pressure from disturbance by humans.

With this in mind, the benefits of the project will be to resolve conflict by providing objective information on the

significance of disturbance of deer by hillwalkers, and to provide informed management options to mitigate the effects of disturbance. More generally, this research is critical on both local and global scales as human recreational activity encroaches ever more into wildlife habitat. In Scotland, the fine scale movement data gathered on deer in the study site will also help to inform deer management, filling a knowledge-gap around movement at this scale.
We anticipate that these outputs will be useful, as follows: 1) to inform management decisions, for example setting culling targets that consider the additional pressure of disturbance and potential changes in deer distribution, or suggesting diversions of public footfall at key times of the year away from particularly sensitive areas – such as calving time and locations; 2) to raise public awareness of the potential impact of hillwalking on deer to encourage responsible behaviour and adherence to established paths; and 3) to contribute to the wider discussion on deer management in Scotland which is commonly lacking fine-scale information on deer movement. Long term benefits will be seen in the contribution to the development of sustainable practices for recreation and deer management to benefit wildlife and conservation, landowners, and the public.
How will you look to maximise the outputs of this work?

To test for pregnancy, we will be taking blood samples from deer whilst they are under anaesthesia. We will make residual blood (not required by our tests) available to collaborators for purposes including the genotyping of individuals for immune response-relevant genes. This collaboration maximises utility from deer captures.

Our work will lead to applied outcomes and we will seek to publish those in journals relevant to the discipline and to communicate them to stakeholders more widely through articles in industry magazines and presentations to stakeholder groups. In addition, fine-scale movement data provide a resource for behavioural ecologists with potential application to a much wider range of aspects of ecology. These include understanding monitoring and the relationships between absolute abundance and indices of abundance; parameterising predator-prey models to understand predatory success rates; and understanding how forager searching strategies mediate the relationship between area use and daily travel distance. All of these are active themes of research within the group and the data collected will be useful for advancing all of them.
Species and numbers of animals expected to be used

- : 30

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The aims and objectives of this study specifically relate to the response of wild red deer to disturbance. Alternatives, such as farmed deer, are unlikely to respond in the same way as wild deer and would fail to answer our research questions. We will focus on adult females, as (1) adults are fully independent and will be able to re-join the herd following the procedure; and (2) females - especially those with young - are particularly vulnerable to disturbance (Recarte et al. 1998, https://doi.org/10.1016/s03766357(98)00037-0), whilst condition and energy availability among adult females has a determining influence on reproduction and, hence, population growth (which encapsulates one of the ultimate impacts of disturbance).
Typically, what will be done to an animal used in your project?

Animals will be anaesthetised using a dart gun, in order to reduce stress. A collar with a GPS-enabled tracking device will be fitted. We will take a small blood sample to assess whether the animal is pregnant. We will also fit an ear tag and take an ear notch so that the animal can be recognised subsequently and not inadvertently

admitted into the human food chain. The animal's recovery from anaesthesia will be assisted with a reversal agent. The whole procedure is expected to take about 30 minutes at most. We will not attach collars to more than 30 animals over the duration of the study (a maximum of 3 years). Each collar will continue to collect data over a 12 month period and will be programmed to drop off the animal at the end of that time.

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts include pain from the intramuscular dart injection, prior to the anaesthetic taking effect, and transient discomfort from the injections and ear notching as well as, potentially from the unfamiliar collar. We do not expect any of these transient effects to last more than 72 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The procedure is expected to have mild severity for 100% of animals.

What will happen to animals at the end of this project?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The specific focus of the research is on the red deer in its natural habitat. It would not be meaningful to substitute it with another species.

Which non-animal alternatives did you consider for use in this project?

Direct observation, pellet group (dung) surveys to indicate space use, camera trapping.

Why were they not suitable?

This project will investigate deer movement and behaviour in time and space. An equal focus on temporal variation in movements means that typical spatial distribution methods, such as pellet surveys, are insufficient. Given our interest in direct, short-term responses to mobile stimuli, as well as the spatial scale over which we are working, camera trapping also has limited value. Alternatives such as direct observations are limited by observer bias, difficulty in tracking multiple animals over large distances, potential influence of observer presence on the deer, and the amount of time required. By using GPS collars, the project limits interaction with the deer to a short capture operation, whilst maximising data quality and quantity to build a comprehensive response to our research questions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have been guided by precedents among published studies employing the same techniques, and by our calculations of the number of animals needed to supply enough data to answer our research questions robustly.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are focusing on a specific demographic group (females of breeding age) to minimise unwanted variation between subjects, thereby minimising required sample sizes. We are also using collars made by a reputable company and the model is well tested in the field. Prior to deployment, all collars will be rigorously tested to ensure working condition. Data obtained from the collared animals will be maximised by supplementing it with data from additional sources (including pellet group surveys, direct observations, camera trapping and vegetation surveys) to complement GPS and behavioural data from the collars. All functions of the collars will be utilised, including the built-in accelerometer that indicates activity levels and head position, and the VHF beacon for relocations in the field. The GPS data, themselves, will provide multiple data analysis options to answer the research questions. For example, GPS locations can provide information on temporal distributions, in addition to a subset of the locations being used to determine habitat selection. GPS and activity data can also be combined to look at activity in response to specific disturbance events. Taken together, these features of the collars mean that we will need to collar fewer animals to gather large quantities of data to provide a robust answer to our research questions.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Additional measures include the use of data from related studies, that allow us to run computer simulations to bolster our confidence that the number of animals used will be adequate.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Red deer have been chosen for this study because they are the only relevant species in the context of the research question, with alternatives such as domestic ungulates or farmed deer unsuitable. Red deer, and other wild deer species, are commonly and successfully used in similar research projects involving capture and fitting GPS collars.
Methods for capture have been developed with veterinary advice to ensure they are the most refined for the purpose, including anaesthesia with recommended drug doses and combinations. A number of further steps will be taken to minimise animal suffering and stress during the capture procedure and immediately thereafter, and for the duration of collar deployment (which will not exceed 12 months).

Why can’t you use animals that are less sentient?

The focus of this study is on the red deer, which is the specific organism of economic, cultural and economic

interest in this context. The research questions and context would not apply to another species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The protocol will be conducted by vets and will only be conducted by other suitably qualified personnel if the vets are satisfied of their competency by repeat performance under supervision, as agreed with the NTCO.
Capture and collaring will take place in winter. Specifically, we will not commence darting until 4-6 weeks after the end of the rut (mating) period (to avoid disrupting mating or early pregnancy). and we will not continue darting beyond the end of March, which prevents us from darting during late-stage pregnancy. Offspring are no longer suckling or substantially dependent on their mothers during winter. Collaring in winter also reduces the risk of heat stress in anaesthetised deer, whilst doing so before the later stages of the winter period ensures that animals are not in poor condition as a result of prolonged exposure to low food availability and low temperatures.
The primary method of capture is to use a dart gun to administer the anaesthetic to an unconfined animal. Veterinary advice is that, to ensure that enough animals can be captured, it is possible that clover traps could be used to confine the deer for a short amount of time. If confinement is deemed necessary, it will be limited to 12 hours, during which time the deer will not suffer from dehydration and appropriate feed will be available. If remote darting is not practical, anaesthetic will be administered intramuscularly to an animal once safely restrained.
We will only conduct darting where there are no features in the terrain that may cause injury on induction and recovery. Failure to re-join the herd is not a documented problem but, to avoid concerns, we will work only with fully independent adults. Using an expert and competent team for darting and collaring ensures that the time away from the herd will be kept to a minimum.
During the capture, every effort will be made to minimise stress to the deer. The deer will first be approached from behind whilst watching for eye, ear and head movements that can signal consciousness. First contact with the deer will be a light touch to the hind quarters so that the response can be safely observed, and a blindfold will be put on over the deer’s eyes to minimise external stimuli. To reduce likelihood of injury on releasing the deer, all persons will move away from the deer, allowing the deer an obvious escape route, clear from obstacles, and in the direction the deer is facing.
Monitoring using the VHF tracking beacon will be conducted during the period over which the animals are collared (because GPS data cannot be used for that purpose as they will be unavailable until the collar is recovered). Collars are purpose-designed to minimise impact on the animal (weight within recommended parameters and appropriate belt-thickness) and will be worn for no more than 12 months. At 12 months the collar will drop-off via a pre-programmed device and will be retrieved using a VHF tracking beacon for recovery of data and to prevent environmental contamination. Pre-programmed devices to allow collars to drop off without the need for recapture are commonly used in studies of this nature, and will be purchased from a specialist company. Failure rates are typically low for shorter durations (not greater than 12 months). Data from mountainous regions of Central Europe reveal a 98% recovery rate for collars that have dropped off Alpine chamois and ibex. In some studies of primates, individuals have worn collars for up to 6 years without evident problems (Klegarth et al. 2019 in "GPS and GIS for primatologists: applications of spatial analysis in primate behavioral Ecology".
Cambridge University Press). The use of automated drop-off mechanisms on the collars ensures that the collars can be collected using the VHF beacon, without the need for recapture of the study animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There is no published best practice for this type of work but two leading studies are those of the red deer on Rum (http://rumdeer.biology.ed.ac.uk; e.g., https://doi.org/10.1006/anbe.2003.2078) and the elk in Ya Ha Tinda (http://www.umt.edu/yahatinda/; e.g., https://doi.org/10.1111/oik.05304). One of the field team for the project we are proposing here has worked on both of these studies, and we have incorporated best practice from both by reference to their field protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

For more general issues around the 3Rs, we will keep up-to-date via peer-reviewed journals and contacts within relevant agencies, with which we have active collaborations. For information specifically relevant to deer, we are part of a small, informal network of deer researchers in the UK and we have communicated across this network regarding project design - both for our own and others' projects.

NON-TECHNICAL SUMMARY

158.Refining methods for rederiving and archiving genetically altered mice

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Cryopreservation, Mice, Embryos, Sperm, Superovulation

Animal types	Life stages
Mice	neonate, adult, embryo, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

My group's main focus is on the preservation/freezing and distribution of genetically altered mice generated around the world. We want to use the most refined animal procedures possible and minimise the number of mice used in our work. This project licence has been written to enable the development/refinement of assisted reproduction techniques (ART) such as *in vitro* fertilisation, superovulation, embryo/sperm freezing and embryo transfer. Access to robust cryopreservation techniques reduces the need for live animal movements around the world, as germplasm can be successfully sent instead. In addition, by increasing the efficiency of IVF, superovulation and embryo transfer we don't need as many mice to cryopreserve or recover individual mouse strains.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Any improvements in assisted reproductive techniques we develop will be shared with other groups in the scientific community which will help refine the procedures used on mice, as well as, reduce the number of animals used around the world.

What outputs do you think you will see at the end of this project?

This project will improve the techniques used to share unique mouse models of human disease throughout the scientific community, as well as, freezing down their embryos, sperm and oocytes for future generations of scientists. We will also develop assisted reproductive techniques that will be specifically applicable to a more diverse range of strains and species of mice, such as wild-derived mice i.e. Mus spretus and WSB. These wild-derived mice offer investigators access to greater genetic diversity than the inbred laboratory mouse and may better reflects the diversity in the human population. They are particularly useful for mapping, investigating complex traits/systems and studying evolution. Unfortunately, many of the assisted reproductive techniques that have been developed in laboratory adapted mice don’t translate well to wild-derived mouse strains. For example, the success of techniques like superovulation, IVF, embryo transfer and cryopreservation is poor which makes it difficult to rederive/exchange mice between research facilities and maximise their potential. This project licence aims to address some of these issues.

Working in conjunction with a service licence we will expand and maintain a large archive of mouse strains to safeguard the lines for the future. The sharing of gold standard mouse models should increase reproducibility of studies because the founder mouse stocks we distribute to all facilities will be identical.

Through this sharing process we will enable scientific collaborations to be established around the world in the pursuit of better understanding of gene function and the causes of human disease.

Progesterone analogues will be used to investigate the benefits of delaying parturition for a short period of time. The ability to control the time of parturition will have a considerable influence on the success of hysterectomy rederivation of germ-free mice. Under these conditions it is necessary to ensure that the donor females do not litter down before the scheduled hysterectomy is performed.

Better protocols for controlling this process have the potential of leading to an overall reduction in the number of animals needed for such rederivations.

Working on a previous licences, we have developed techniques that facilitate the exchange of unfrozen embryos and sperm, as well as, the exchange of frozen sperm on dry ice. Each of these techniques offers a practical alternative to exchanging live mice. In addition, we have improved IVF and sperm freezing procedures making these techniques more efficient and robust which has reduced the number of animals used in these procedures. We intend to continue to develop these areas during the course of this project licence. In particular, we will aim to improve our overall *in vitro* fertilisation rate using frozen sperm from 55% to over 66%. In addition, we will advance our understanding of *in vitro* embryo culture systems in an attempt to remove the need to perform surgical embryo transfers following IVF. A further long term goal for this project licence is to establish an improved superovulation technique that uses a non-animal alternative to the inhibin antisera which is currently used in conjunction with hCG and PMSG to boost ovulation rates.

All significant improvements to the protocols we use will be published in the scientific literature, presented on public websites and taught on training courses available to the wider community.

Who or what will benefit from these outputs, and how?

By improving assisted reproductive techniques and techniques for sharing unique mouse models we will reduce the need to recreate mouse strains carrying the same mutation. In doing so, we will eliminate the additional animal and laboratory costs associated with re-making genetically altered mice.

Systematic improvements to assisted reproductive techniques will enable researchers around the globe to have easier access to high quality mouse lines facilitating the study of diseases and/or furthering biological and medical knowledge.

By improving the methods used to freeze down a more diverse range of mouse lines, particularly those that are no longer part of ongoing research projects, we can reduce the number of mice being bred. By doing so, the need to reimport/recreate mice that can be quickly withdrawn from the archive will be eliminated

Technical advances will be disseminated throughout the mouse community (in the literature and at scientific meetings) so that others may also benefit from the techniques e.g. through the adoption of improved embryo culture techniques, non-surgical embryo transfer procedures, the use of improved superovulation techniques for wild derived mice and/or lab mouse strains or oocyte freezing to stream line their IVF programmes. These advances will help improve the efficiency and reproducibility of animal science in across the mouse community.

How will you look to maximise the outputs of this work?

To maximise the impact of what we do, all technical improvements will be widely published in the scientific literature, on our institutional website, during our bi-annual cryopreservation training courses and at scientific meetings. What is more, any technical improvements in assisted reproductive techniques or the techniques used to exchange mouse strains will be immediately incorporated into the procedures used on my service licence.

The technical improvements made under this technology development licence will be used to improve the services we offer to the scientific community under my service licence. The improved protocols will also be disseminated widely through presentations, training courses and websites etc. The mouse strains that we freeze down for the community under my service licence, whether funded by internally or not will be presented on our institutional website and other public websites . Where this is not appropriate for reasons of commercial and academic competitiveness, strains will be held in a private archive which will be reviewed at regular intervals with depositors being encouraged to make resources public. We also promote our services as widely as possible through information leaflets, workshops, presentations and conference proceedings. Other public websites are also used to present details of the techniques we use so the other institutions can take advantage of our leading practice.

Species and numbers of animals expected to be used

- Mice: 10,750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This is a technology development licence designed to improve the procedures used to freeze down and distribute genetically altered mice generated by the scientific community. As such it is not possible to use any other species than the mouse for this work. To preserve mouse strains for future generations of scientists it is necessary to harvest embryos and sperm from adult animals and freeze them down using well developed methods that ensure a higher proportion of embryos and sperm we obtain are able to survive the freezing process.

Typically, what will be done to an animal used in your project?

Some animals used in this project may be bred in order to establish the outcomes of the experimental work. Other mice will be injected with hormones to induced superovulation for egg (oocyte) or embryo harvesting. An additional group of other mice may undergo an operation to allow embryos to be transferred into foster mothers who will give birth.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals may be group housed or paired, mated and subject to such other non-painful procedures required for conventional breeding. Female mice may be examined for the presence of a copulation plug and culled at a specific time point in embryo development.

There are a variety of possible impacts due to the genetic modifications carried by the mice bred under this licence but the majority of animals will be from strains that do not carry any genetic modifications.

When tissue is required for DNA genetic analysis, the mildest appropriate method of sampling will be used for obtaining the tissue e.g. ear notching. Rarely due to a technical problem in analysis or the need to determine the presence or absence of additional genetic components, a second sample may be taken.

Complications due to surgery are rare although wounds may need re-closing. If this is required it will be done under general anaesthesia. The anaesthesia is brief and the mice recover quickly without undue effects on their health or weight. Pain post-surgery is controlled by administering pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity of the protocols used under this licence will vary between **Mild** and **Moderate**. It is expected that less than 24% (2,500) of the mice used on this licence will be recorded under a **Moderate** severity limit.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This is a technical development licence used to support the service work we do that it is specifically designed to cryopreserve the germ cells (embryos/sperm/ovaries) of genetically altered (GA) mouse strains generated by the scientific community so they are preserved for future generations or shared between laboratories without transporting live mice.

Which non-animal alternatives did you consider for use in this project?

Because this technology development licence is specifically designed to support the service work we do cryopreserving GA mouse strains generated by the scientific community there are no alternatives to the use of mice for this project.

Why were they not suitable?

Because this technology development licence is specifically designed to support the service work we do cryopreserving GA mouse strains generated by the scientific community there are no alternatives to the use of mice for this project.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This application is for a licence renewal and the numbers applied for in this licence reflect the number of mice we anticipate needing to complete the work described. These figures can only be estimates based on the expected opportunities for technical innovation and the potential for introducing new techniques developed by other groups that have yet to be published.

However, it is anticipated that up to 300 studies (averaging 15 mice/study) will be set up involving IVF techniques. The oocytes and embryos generated from these studies will be transferred (unfrozen or after a freeze/thaw cycle) into a total of 1,600 foster mothers to test the viability of the oocytes/embryos. In addition, a further 400 foster mothers will be used to test modifications to the methods used for culturing embryos for extended periods of time to make them suitable for non-surgical embryo transfers. The pups born from these embryo transfer studies will be recorded under Protocol 1 (3,000 mice).

On average, each ovary transfer study will involve the use of 4 ovary recipient females and I plan to conduct 60 studies under this project licence.

The hormone binding studies aimed at increasing superovulation rates will be based on comparisons between potential binding molecules e.g. the study would include 10 x candidate binding molecules, tested at 3 doses (with or without pregnant mares serum gonadotrophin supplementation), plus a no-treatment control. This study would be repeated 6 times. Total number of mice used 420

Where it is appropriate, statistical tools like 'Power Analysis' will be used to calculate the number of animals required to generate a statistically robust results from experimental work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Before starting any study in this project, data will be collected from any previous relevant studies and statistical analysis used to make accurate predictions of how many animals we will need to produce a decisive scientific result. In order to keep the number of animals to a minimum, only mice required for such studies will be bred. The efficiencies of all techniques used in this project will be subjected to

regular review to ensure consistently good results, whilst striving for technical improvements which in themselves will reduce the number of animals required to provide our services.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We ensure we use the minimum number of mice compatible with the work we are doing by ensuring all reagents are vigorously quality control tested and the laboratory staff are highly trained.

We also only use the most advanced techniques compatible with the work we do. The idea behind establishing a technology development project licence is to establish a pool of skilled people with expertise in the latest techniques so that they become/remain proficient in the latest procedures and can pass on their skills to the wider community. This will help keep animal usage to a minimum at all times.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This technology development project uses the mouse as an experimental model for every aspect it covers. The mouse is used exclusively because this project has been set up to develop/introduce improvements to the technologies used under a separate service licence when freezing down and storing sperm, oocytes and embryos taken from animals that carry unique variations in their genes. The mouse is used for this type of work because it is the lowest order of mammal that can have its genes manipulated with the precision and complexity available using modern molecular biology tools like CRISPR/Cas.

The basic methods used in this project are all well establish and well understood laboratory techniques, although we will be attempting to refine them. For example, we will inject mice with similar hormones to those used in human *in vitro* fertilisation (IVF) clinics to induce superovulation. The eggs we harvest will be used for IVF sessions that have been set up to generate fertile embryos for transfers into foster females or for freezing down. The embryo transfer techniques we use are again very similar to those found in human IVF clinics. Where surgery is performed, the operation will be conducted under general anaesthesia and pain relief will be given via injectable pain killers (analgesics). Sperm will also be frozen down for use by future generation of scientists.

Why can’t you use animals that are less sentient?

This licence has been prepared specifically to develop/introduce new technologies used under a separate service licence established to freeze down and recover genetically altered mouse strains for future generations of scientists. The mouse strains used under the service licence will have been generated as part of research into the function of genes or the causes of disease. Consequently there is no alternative to using mice for this project.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This project will aim to refine a number of well-established assisted reproduction procedures. Breeding is strictly controlled so we do not produce any more mice than is necessary for the work we want to perform.

The majority of mice used on this project will be wild type in origin i.e. not genetically modified, even so we will use known information to assess the potential welfare costs of the mice that we breed and the welfare of individual mice is followed on daily assessment sheets when it is appropriate i.e. sick animals.

Compounds are administered by injection which is considered to only cause momentary discomfort. To minimise discomfort during injections, we have a single use needle policy which means the needles will remain sharp. To minimise bruising, we also alternate the injection site when giving multiple injections.

We are hoping to develop a technique that will make the hormone preparations more efficient. This will lead to a reduction in the number of mice we need for our work.

We have developed an improved non-surgical embryo transfer technique that can entirely replace the need for abdominal surgery when handling late stage embryos. To complement this work, we are working towards improvements in the embryo culture environment to allow earlier stage embryos to be transferred using the same procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

To ensure our work is conducted to the highest standards and can be reproduced by other scientists we follow, and act on the PREPARE and ARRIVE guidelines. We also have access to statisticians who can advise on the appropriate experimental design and analysis techniques. The risk of infection or delayed healing is minimised by following the LASA guidelines on aseptic procedures (LASA 2017 - Guiding Principles for Preparing for and Undertaking Aseptic Surgery).

The risk of skin necrosis due to overtight clips or non-absorbable sutures will be minimised through training and competency assessment and checking wound margins prior to recovery.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed by reviewing the literature, attending scientific meetings and talking with colleagues in the field.

In previous years we have introduced several procedural changes that have been taken up by others in the field e.g. improved sperm freezing, IVF techniques and non-surgical embryo transfer procedures. As keen supporters of the 3Rs we have successfully submitted two grant proposals to the NC3Rs.

Home Office

NON-TECHNICAL SUMMARY

159. Regulation of blood and lymphatic vessel growth

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Endothelium, Cancer, Atherosclerosis, Transcription, Angiogenesis

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Zebra fish	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to identify novel pathways that regulate different types of blood and lymphatic vessel growth and behaviour, and to determine the role these pathways play in conditions such as tumour growth and cardiovascular disease. This knowledge will be used (by our group, by our collaborators and by others in our field and beyond) to develop and repurpose therapies to manipulate vessel growth in humans with vascular-related diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

The correct formation and function of the blood and lymphatic vessel system is essential for embryonic development and postnatal tissue repair. Conversely, incorrect vascular growth is associated with a wide range of pathological conditions in humans. The growth of new blood vessels is a necessary step in the development and spread of solid tumours, while the disorganised and aberrant structure of these vessels presents a significant barrier to effective therapy; abnormal and excessive blood vessel development in the retina of the eye is a major feature in the leading blinding diseases, and the transition of endothelial cells from a quiescent to an active phenotype is a key early event in the development of atherosclerosis (clogging of the arteries). Insufficient and incorrect blood vessel growth also contributes to many disease states, including heart disease and pre-eclampsia, whilst defects in lymphatic vessels are associated with lymphedema, hypertension and tumour metastasis, and errors in endocardial (the lining of the heart) formation and function can lead to defective cardiac valves, septa and conduction systems. Consequently, a clear understanding of the genetic programmes controlling vessel growth is key to strategies for intervention and regeneration in many human disease states.

What outputs do you think you will see at the end of this project?

Major outputs:

1) Identification and characterisation of the transcription factors and upstream regulatory pathways controlling different aspects of developmental vessel growth. Time-frame = short and mid-term.

2) Generation of novel GAA (genetically altered animal) models (zebrafish and mice). These animal models can be used as endogenous reporters for each regulatory pathways, providing powerful new tools to study how vascular regulation changes during adult stages, disease and regeneration. Timeframe = short and mid-term.

3) Identification of human diseases where re-activation of developmental vascular regulatory programmes may assist in tissue repair. Time-frame = mid to long-term.

4) Provide information leading to development of new drugs to inhibit, modulate or encourage vessel growth. Time-frame = mid to long-term.

4) High-quality high impact publications. Time-frame = short and mid-term.

5) Outreach to general public. Time-frame = ongoing throughout.

Who or what will benefit from these outputs, and how?

Those in the scientific research community working on better understanding how blood and lymphatic vessels specify and differentiate will be the first to benefit, both from the increased understanding of the different regulatory pathways, and from the new animal models created. These benefits can realistically be expected to

occur from mid-way through the PPL onwards (therefore short-term and after), as the results of our studies are published, made available as pre-prints and/or presented at meetings. Our laboratory always makes all zebrafish and mouse models freely available after publication.
Our animal models are already being used by both our own group, collaborators and others to understand blood and lymphatic vessel behaviour in disease states and during tissue regeneration. These benefits will be seen first in the short-term (primarily from models started in previous PPL) and will continue beyond this current PPL. Longer-term beneficiaries (from end of PPL onwards) will be the researchers and clinicians aiming to modulate vascular growth in a range of diseases, and the patients suffering from these conditions. These benefits will range from better models to investigate vessel growth and modulation techniques in these pathologies, increased knowledge allowing repurposing of existing drugs and treatments, and the development of novel therapeutic approaches to treatments.

How will you look to maximise the outputs of this work?

Beyond the pathological models covered by this license, we are, and will continue to, actively collaborating with other specialist groups to extend the use of our mouse and zebrafish models to pathological conditions for which we lack sufficient expertise, or time, to study ourselves. Additionally, we have and will continue to freely share these models with other groups for their own research, without any conditions.

It is anticipated that the key direct beneficiaries of the work in this proposal will be members of the academic research community and healthcare professionals. Our work may also lead in the longer term to benefits to patients in terms of treatments aimed at modulating vessel growth in conditions ranging from solid tumour growth, macular degeneration, limb ischemia and heart failure. I will liaise informally and frequently with clinical collaborators to identify results and aspects of our research with relevance to the clinic.
Our university provides an ideal environment to exploit the findings of our research. Intellectual assets and outputs are managed and protected with the help of the University's Research Services Department, which provides advice and support on all issues regarding the protection of intellectual property, including contracts, patenting and material transfers.
I constantly endeavour to increase the awareness of the vascular (and associated) community of our work, and the availability and utility of our animal models. This includes writing reviews, giving presentations at conferences and seminars at a wide range of locations and topics.
Species and numbers of animals expected to be used

- Mice: 26000
- Zebra fish: 7000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use two animal species in this project, mouse and zebrafish.
Mice
We are using mice because they are the closest model to humans that is relatively easy to genetically manipulate: mice breed quickly, and it is now simple to make genetically modified mice (for example, to generate a mouse expressing a specific gene in a specific cell type, or to generate a mouse in which a specific gene has

been deleted). This work will use both wild-type (genetically normal) and genetically modified mice. Genetic modifications will include:

- Transgenic mice expressing enhancer/promoter: reporter genes. Enhancers and promoters are two types of gene regulatory elements, which are responsible for switching genes on and off (they are often considered the "on/off" switches for genes). Reporter genes are genes that are easy to detect (e.g. the LacZ reporter gene makes a protein that gives off a blue colour when in a simple solution, the GFP reporter gene makes a protein that glows green). Enhancer: reporter and promoter: reporter transgenes contain a regulatory element (on/off switch) fused to a reporter gene so that it is easy to see where and when the regulatory element switches on and off. When these transgenes are inserted into the genome of a mouse, they generate a transgenic mouse in which the expression pattern of the reporter genes tell us where and when the regulatory element is active. This can be used to find regulatory elements, to assess their activity pattern (when and where are they off and on) and to determine how each regulatory element is controlled (e.g. which proteins bind them to turn on or off).

- Transgenic mice expressing Cre, CreERT2 or similar recombination-driving genes under ubiquitous or tissue-specific regulatory elements. They express recombinase proteins (such as Cre) which allow DNA modifications (such as deleting part of a gene) to be targeted to a specific cell type (for example, modifying a gene just in endothelial cells) or to be triggered by a specific external stimulus (for example, giving mice the drug tamoxifen turns CreERT2 from inactive to active and allows us to modify a gene at a specific time-point).

- Genetically modified mice in which one or more specific genes have been mutated or deleted. These can be mice which are engineered to have loxP sites (or similar) around specific bits of one gene (this allows recombinases such as Cre to work) or mice in which entire genes have been deleted.

- Various combinations of two or three of the above (for example, a mouse expressing Cre in endothelial cells with genetically modified loxP sites inserted into a gene).

We will use all life stages with the exception of aged mice (which are not needed for our research) because we are interested in how blood and lymphatic vessels initially form and differentiate (this occurs at embryonic, fetal and neonatal stages) and also how they respond to stimuli (such as blood flow, hypoxia or disease) during adult stages, including in pregnant mice

.

Zebrafish

Our research primarily uses zebrafish embryos prior to free feeding stages and therefore not regulated by the Home Office. These embryos are transparent and their blood vessels are easy to see during the early stages of development where much of the important specification and differentiation stages of vascular development occur. It is also very easy and quick to generate genetically modified zebrafish embryos, and treatments to modify different vascular pathways can often be simply added to the water the embryos swim in.
To generate the required zebrafish embryos for our research, we breed and maintain adult transgenic zebrafish expressing enhancer/promoter: reporter genes (see explanation in the mouse section above). **Typically, what will be done to an animal used in your project?**

The vast majority of mice (approximately 90%), the only procedures will be breeding and maintenance (protocols 1 and 2), in which we investigate blood and lymphatic development after death (e.g. postmortem analysis of reporter gene expression in a transgenic mouse line, post-mortem analysis of how blood vessel development is perturbed after gene deletion). The other 10% may be subject to an additional procedure. These may include administration of substances to induce gene deletion, interfere with vessel development or label the vasculature. In some of these mice, we will also induce vessel growth or vascular dysfunction in the adult. Techniques to do this include the insertion of a matrix (into which vessels will grow) or tumour (to stimulate tumour angiogenesis), the injection of a growth factor to mimic tumour angiogenesis without the tumour cells, or the induction of vascular injury by altering lipid composition, or the induction of vascular injury by surgical procedures which either ligation vessels or grafting vessels from one animal into another. We may also place mice (including

pregnant females) rapidly into a hypoxic (low oxygen) environment. This will be no lower than approximately 9.5% oxygen and will not last longer than 6 days. Analysis will again only occur after death and will include the same type of post-mortem analysis.
For all zebrafish on this licence, the only regulated procedure will be breeding and maintenance.

What are the expected impacts and/or adverse effects for the animals during your project?

Breeding and maintenance: The vast majority of mice covered by this licence (over 90%) will not be expected to experience any adverse effects because they will only be used for breeding and maintenance. A very small percentage of these mice may suffer some adverse effects as a consequence of having a compromised immune system (for example, immunocompromised mice do not have fur, and can sometimes suffer eye infections or skin infections due to this) or the consequences of gene modification (for example, if we modify a gene which plays an important role in adult vascular growth, if is possible that mice may show significant growth deficiencies). If these adverse effects occur the animals will be killed by a schedule 1 method to ensure the duration is as short as possible.
Administration of substances to alter gene expression, vascular pathways or to label or dye cells: Impacts and adverse effects from administration of substances are expected to be rare. However, potential adverse effects could include damage from administration method (for example, administering substances to mice via a gavage tube through the mouth into the oesophagus can very occasionally cause oesophageal rupture; injections into young pups can potentially damage the stomach or induce the mother to eat the pup), adverse effects due to alterations of gene expression caused by the substances given (for example, alterations of vascular pathways may cause significant growth deficiencies), or adverse effects in direct response to types of substances given (for example, a mouse may be given a drug that causes weight loss, bleeding or tremors as a side effect). Mice will be frequently observed for meeting defined humane end-points (for example, to ensure they are not losing too much weight or failing to eat and drink) and most are not expected to experience these adverse effects.
Matrix insertion and manipulation of blood vessel growth by adenovirus-VEGF: Adverse effects from matrix insertion (injecting a matrix into the mouse that blood vessels will grow into) and manipulation of blood vessel growth by adenovirus-VEGF administration (injecting adenovirus-VEGF into the mouse ear or flank region) are considered unlikely but could potentially include inflammation at the injection site. This is expected to be short-lived. If this persists then the animal would be killed by a schedule 1 method.
Tumour growth and metastasis: Adverse effects will include tumour growth, and may also include weight loss, breathing, neurological and liver and intestinal issues. To limit adverse effects to the mice, the tumours will not be permitted to grow beyond a total GMD of 1.2cm ((Length x width x height)1/3). Additionally, mice will not be permitted to suffer excessive weight loss or loss of body conditioning, respiratory distress (e.g. difficulty breathing), obvious neurological disorders, immobility, swelling of the abdomen or obvious signs of distress. Mice will be frequently observed for meeting defined humane end-points including those listed here, and if detected the animal would be killed by schedule 1 method.
Alterations of oxygen levels: Adverse effects may include mild distress when the oxygen levels are first lowered, but this should pass quickly. Additionally, some mice may lose weight at the beginning of the procedure due to reduced feeding. The mice will never be exposed to hypoxia for longer than 6 days but are not expected to show adverse effects for longer than 2-3 days. If loss of conditioning, weight loss, lower activity or mild distress are not improved after 2-3 days the animal will be killed by schedule 1 method.
Vascular damage and grafting: Adverse effects from inducing atherosclerotic lesions by feeding a higher fat diet may include oily skin resulting in skin sores, and mild obesity. The oily skin and obesity may occur for many weeks, although changes in bedding material will be made to lower risk of skin sores. Adverse effects from surgical procedures to induce vascular damage (partially tying off an artery to change the blood flow dynamics around it) and to graft vessels include the possibility that a small number of mice may suffer haemorrhage or infection from surgical wounds or death during surgery due to graft/ligation failure. If haemorrhage or wound infection are seen, the animal will immediately be killed by a schedule 1 method.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the mice on breeding and maintenance protocols (which make up 90% of all our mouse usage), we expect the majority (approximately 95%) to experience no adverse effects at all (resulting in a subthreshold level of severity rating). Of the rest, approximately 4% are expected to experience mild adverse effects such as minor scratches and malformed teeth that to not interfere with feeding (resulting in mild levels of severity rating) and less than 1% to suffer moderate adverse effects such as fight wounds and swollen or infected genitals (resulting in moderate severity rating).
For zebrafish on breeding and maintenance protocols (all zebrafish), we expect the majority (approximately 95%) to experience no adverse effects at all (resulting in a sub-threshold level of severity rating). Of the rest, approximately 4% are expected to experience mild adverse effects such as slight growth retardation or small lumps (resulting in mild levels of severity rating) and less than 1% to suffer moderate adverse effects such as more pronounced growth abnormalities, thinness or cataracts (resulting in moderate severity rating).
For mice in which we modify vascular-related genes and/or regulatory pathways by administration of substances, we expect the majority (approximately 90%) to experience only the mild adverse effects directly associated with the substance administration (resulting in mild levels of severity rating), such as the transient pain of injection or oral dosing. We expect less than 10% of mice on this protocol will suffer moderate adverse effects (resulting in moderate levels of severity rating) such as tremors and weight loss.
We do not anticipate adverse effects directly associated with severe blood vessel development defects, as we plan our experiments so that mice (including embryonic and fetal stages) are killed using a schedule 1 method before any vascular complications would compromise the health of the mouse.
For mice in which we inject a sterile matrix (so that new blood vessels can grow into the matrix), we expect the majority (approximately 98%) to experience only the mild adverse effects associated directly with the injection of the matrix (resulting in mild levels of severity rating). Less than 2% of mice are expected to suffer moderate adverse effects (resulting in moderate levels of severity rating), such as inflammation at the wound area.
For mice in which we induce tumour growth (primary tumours and metastasis), we expect 50% of mice to experience mild adverse effects and 50% to suffer moderate severity.

For mice experiencing induction of blood vessel growth after injection of adenoviral-VEGF, we expect the majority (approximately 95%) to experience only the mild adverse effects from experiencing an injection, resulting in mild levels of severity rating. We anticipate less than 5% will suffer any moderate adverse effects such as inflammation at injection site or consequences of using immunocompromised mice (which are nude and therefore more likely to suffer skin and eye infections).
For mice experiencing lowered oxygen levels, we expect the majority to experience only the mild adverse effects associated with changes in oxygen composition such as moderate weight loss due to reduced food intake and reduced physical activity (approximately 90%). We anticipate less than 10% of mice will experience adverse effects of moderate severity, such as more severe weight loss and loss of body conditioning.
For mice experiencing vascular damage and grafting, we expect around 50% of mice to experience mild severity (mice on lipid/diet alteration steps), and around 50% to suffer moderate severity (mice undergoing grafting or ligation).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vitro (non-animal) techniques can be used to test if potential enhancers and promoters are functional, and to examine which cell types they are active in. However, they are very unreliable and often do not agree with animal experiments when compared side-to-side. Further, this type of experiment cannot tell us the exact pattern of gene expression driven by each potential enhancer/promoter within the complex vasculature.
Part of the problem is that endothelial cells grown in culture (e.g. grown on a plate in an incubator) cannot adequately model the complexity and heterogeneity of the vascular network. The mature vasculature contains many different types of endothelial cells, something that is not well reflected by endothelial cells in culture, which tend to be very similar regardless of where they come from. Recent single cell analysis confirms this heterogeneity and show that endothelial cells from mice show a much higher difference from each other than they do when grown on a plate in culture in the lab.

Additionally, endothelial cells behave differently in their natural environment, where they are in tubular structures, surrounded by accessory cells and matrix and receiving intrinsic and extrinsic signals.

Pathological vascular growth (when vessel growth goes wrong or responds to a pathological situation, e.g. in response to lowered oxygen levels, in a tumour environment, in response to hyperlipidaemic or changes in blood flow) can also not be fully modelled *in vitro.*

Which non-animal alternatives did you consider for use in this project?

1. **Transfection of enhancer: reporter gene constructs into cell lines:** The ability of enhancer/promoters to drive any reporter gene activity can be measure by transfecting transgenes into cells in culture and determining reporter gene activity 1-3 days later.

2. **In vitro assays of endothelial behaviour:** Assays such as cell migration and tube formation are commonly used as in vitro proxies for angiogenesis.

3. **Perturbation of gene/pathway activity in endothelial cells in culture:** It is relatively easy to perturb gene expression and regulatory pathways in endothelial cells in tissue culture, and to determine the gene activity downstream of these perturbations.

4. **Organ-on-a-chip:** These can create 3D vascular networks and generate shear stress gradients.

Why were they not suitable?

1. **Transfection of enhancer:reporter gene constructs into cell lines:** This assays is known to not give reliable results with vascular enhancers: Many known vascular enhancers active in mouse transgenic models are inactive when transfected into endothelial cells in culture, whereas some regions that do not function as enhancers in vivo can activate reporter gene expression in vitro. Further, this assay also cannot give information

about where within the vasculature the enhancer/promoter is usually active. It can however sometimes be informative when used carefully in parallel with animal studies: where an enhancer is known to be active in both in vitro transfection studies and mouse/zebrafish transgenic models, information such as the determination of crucial cis-motifs within enhancers can be obtained from in vitro studies. This is particularly useful when studying the response to stimuli such altered flow and oxygen levels.

2. **In vitro assays of endothelial behaviour:** These assays are known to be poor mimics of events in vivo. Endothelial cells behave differently in their natural environment, where they are in tubular structures, surrounded by accessory cells and receiving intrinsic and extrinsic signals. Further, these assays do not provide reliable information about the heterogeneity of the endothelium: for example, it is impossible to mimic arteriovenous differentiation in these assays, nor to model the early specification of lymphatic endothelial cells from venous endothelium.

3. **Perturbation of gene/pathway activity in endothelial cells in culture:** It is challenging to precisely detect the effects that such perturbations have on proper vessel development, as in vitro models cannot mimic the three dimensional complex tissue of the mammalian vasculature. It is therefore impossible to use this type of analysis to understand the pattern of gene expression driven by a particular regulatory element functions within the complex vasculature: to determine the requirement of a protein or signalling pathway on a specific aspect of vascular development, it is necessary to look at the fully formed vascular network. Endothelial cells in culture also do not maintain their identity very well. Regardless of original source, they tend to adopt a constant proliferative, angiogenic-like mode, unlike the primarily quiescent human vasculature. Therefore, using a variety of different endothelial cell “types” in culture is unlikely to reflect how these different types of endothelial cells behave in vivo.

4. **Organ-on-a-chip:** These suffer from many of the same issues as transfection into general cells in culture, although the inclusion of shear stress may mean they can be used in parallel to some of our animal studies.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Zebrafish

Zebrafish numbers on this licence cover the required breeding population to provide genetically modified embryos for the following assays:

- Enhancer/promoter analysis. Examples of genetically modified zebrafish used in these assays include the lines expresses the mCherry reporter gene in all endothelial cells allowing us to see and follow the development of blood vessels in live embryos. Wild-type (normal, not genetically modified) embryos from wild-type zebrafish will also be used.

- Studies in which specific genes or regulatory pathways are modified to investigate their role in vascular development and endothelial behaviour. Examples of how this can be done include injecting morpholinos (small bits of DNA that bind and prevent specific proteins being made) into fertilised zebrafish eggs; or by adding chemical inhibitors to the water the fertilised eggs are kept in.

Gene/pathway disruption and analysis is restricted to 0-5 days post fertilisation (before zebrafish are free feeding and therefore before they are regulated) but requires adult fish to generate the embryos.
In each case, the analysis will be normally be qualitative in nature (e.g. looking at patterns of reporter gene expression activity, assessing pattern of mRNA expression in differentially treated conditions) and power calculations do not directly apply.
To assess likely numbers over the duration of the PPL we have considered that:

- Genetically modified lines used to visualise the vasculature (or other related cell types) will to limited to a single line for each transgene. Where suitable lines already exist, they will be obtained from the relevant supplier.

- For each different enhancer/promoter, we will usually maintain one-two independent enhancer/promoter:reporter gene transgenic zebrafish lines, which allows us to investigate activity at different genomic insertion locations.

- Established genetically modified lines are replenished approximately every two years.

- When establishing a novel genetically modified zebrafish line, zebrafish are bred more often as the enhancer: reporter gene expression is only stable after the F2 generation.

- For each specific project aim (e.g. establishing the regulation of lymphatic differentiation) we anticipate generating on average 2-6 novel transgenic lines.

Mice

Mouse numbers on this licence cover the required breeding population to provide genetically modified embryos, pups and adult mice in order to:

- Determine the activity of enhancer/promoter: reporter genes in blood and lymphatic vessels during normal vessel development and growth

- Investigate the consequences of gene, protein or pathway disruption on the vasculature and/or on enhancer/promoter activity

- Determine the behaviour of an enhancer/promoter, gene, protein or pathway during pathological vascular growth

To assess likely numbers over the duration of the PPL we have considered that:

- Mouse lines transgenic for novel enhancer/promoter: reporter gene transgenes will generally only be generated for enhancer/promoters that have already shown the ability to drive reporter gene expression in either transgenic zebrafish embryos or transgenic mouse embryos generated through external collaborators.

- We usually maintain one- two independent lines expressing each enhancer/promoter: reporter transgene, although a larger number of F0 (first generation, used when the founder is a male) and F1 (second generation, used when the founder is a female) lines may be initially studied in order to select the most representative lines for further maintenance

- Enhancer/promoter: reporter transgenic mice lines are usually maintained in colonies of 6-18 mice and replenished (new mice bred and used to replace older mice to prevent age-related adverse effects and reduced fertility) every 4-8 months, although numbers vary when multiple time points are required for a specific project.

We also study genetically modified mice where the gene of interest is either deleted or edited (for example, lox sites inserted in such a way that the gene/part of gene can be deleted by expression of Cre recombinase). Where suitable lines exist, they will be obtained from the relevant supplier. As the technology develops, we will also consider using genome editing technologies (e.g. Cas9/CRISPR) to generate transient gene deletions and

therefore reducing animal numbers. To determine the effects of gene modifications on the vasculature, sequential breeding is used to generate mice lines containing multiple modified alleles often requiring 3-4 generations.
Analysis of enhancer/promoter: reporter gene activity in wild-type (genetically normal) mice is purely qualitative (e.g. describing the pattern of reporter gene expression) and is not subject to power calculations. Previous publications from our laboratory have required a minimal of three replicates for each stage investigated, and journals often require the result to be replicated in two independent enhancer/promoter: reporter transgenic lines, to ensure that the site of transgene integration is not an issue.
Analysis of enhancer/promoter: reporter gene activity in genetically altered mice is usually also reported qualitatively with no statistical analysis but requires a higher n number to account for variability in the genetically altered mice (e.g. for Cre-ERT2-induced gene deletion, variability in levels of gene depletion must be anticipated because it is known that the reaction that activates this Cre recombinase is not always very efficient). This variability is Cre model-specific and can be monitored using common Cre reporter lines (in which the Cre recombinase activates a reporter gene) prior to the use of complex experimental models. In practice, we have needed between n=5 and n=20 samples for each genotype and have reported all data when publishing (e.g. all outcomes are reported with either multiple representative images, or with image for each data point).
To make a quantitative analysis of the effects of gene alterations on post-natal angiogenesis (blood vessel growth after birth), we will examine vessel growth in the retina. Angiogenesis occurs naturally in the retina in the first 10 days after birth, therefore this analysis reduces the need for invasive or artificially induced angiogenic assays. Vessel development in the retina occur at well defined, stereotypical points after birth, and therefore only limited time-points will be needed. The units of measurement are vascular density (how much total retina area is covered by vessels), number of branch points (how many branches each blood vessel has), and vascular outgrowth (how far from the middle of the retina does the new vessel network extend at a particular time point) within the retinal vasculature. Although power calculations are harder to define prior to pilot experiment of extent of phenotype, animal numbers are initially estimated assuming 10% standard deviation within control group, 25% standard deviation for each mutant, a difference in mean of 30% and p value of 0.05 using 1-way ANOVA or similar, requiring approximately 6 samples/group/time point.
When studying pathological vessel growth, most analysis will again be qualitative, but some measurements (e.g. tumour size and weight, vessel density and number) will be quantitative, and require statistical analysis. It is anticipated that all measurements can be taken from the same set of experiments. While the exact numbers of animal required for statistically significant results depend on the variation within and between groups, it is anticipated to need between 4-10 mice per experimental group (comparing the normal mice, known as wild-type, with the genetically modified mice). For example, with an anticipated 50% difference between groups (SD set at 25%), we need 5 mice/group to achieve 90% power, whereas for an anticipated 20% difference (SD at 15%), we need 10 mice/group for 90% power. Where possible multiple genetically modified lines will be compared to the same set of controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

- The analysis of putative enhancer/promoter activity and gene/pathway modification in F0 (transient) transgenic zebrafish (before 5 days post fertilisation) is used here as a partial replacement of mammals at more sentient, licensed stages. This therefore represents a reduction of our overall animal use.

- Where possible, mice will be bred as homozygotes to minimize excess waste.

- EDA analysis has contributed to the design of the analysis in gene perturbation experiments and pathological analysis. In these cases, local statisticians have also advised on power calculations, and the relevant statistical analysis required to provide meaningful results.

What measures, apart from good experimental design, will you use to optimise the number of animals

you plan to use in your project?

- I have attended a talk on efficient breeding and put the advice into practice. In general, breeding cages are separated after 4-5 litters and retired at six litters.

- For wild-type lines and those shared with other labs/outside suppliers, we assess whether it is more efficient to buy/import animals in than to generate them in-house

- Where possible, mouse lines are frozen down. In cases where we do not anticipate usage in the next 6 months, lines are not maintained.

- We perform breeding calculations before we plan our experiments and only produce the numbers of animals that we need.

- Animal numbers are recorded on computer databases in real time and are monitored regularly.

- Some pathological vascular analyses require that enhancer/promoter: reporter genes are investigated in immunocompromised mice (e.g. Foxn1 null). These lines are maintained as enhancer/promoter transgene positive, immunocompromised null backgrounds (e.g. Foxn1 -/-; enhancer:lacZ+/WT) to reduce animal numbers when breeding (as Foxn1 -/- females cannot lactate).

- We ensure any welfare or husbandry requirements of the strain have been identified. The cage card alerts people to any special welfare or husbandry requirements.

- Tissue samples are shared, or analysed for multiple different assays, where possible. For example, wild-type enhancer: reporter samples can be used as controls for multiple different assays, whereas analysis of tumour samples in enhancer: reporter lines can provide information about enhancer activity, and blood vessel behaviour (e.g. by immunohistochemistry prior to reporter gene staining).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Choice of species and models

Transgenic mice (e.g. expressing enhancer/promoter: reporter transgenes) are normally generated on a C57/Bl6; 129/J background and bred into a C57/Bl6 background. Genetically altered models imported from elsewhere are typically obtained and maintained onto the C57/Bl6 background, also sometimes strain-specific phenotypes will result in different genetic backgrounds being used. New breeding mice are introduced each year to prevent genetic drift of C57/Bl6 mice. Immunocompetent strains may include Foxn1nu mice and will be bred as heterozygotes where possible to reduce adverse effects. Where null mice have detrimental defects, efforts will be made to use tissue-specific and/or inducible models to reduce impact. As new technologies are generated to efficiently create multiple targeted alleles into one mouse line, these will be incorporated into our research to reduce wastage in breeding (e.g. where multiple alleles would typically be bred into a single mouse,

future technologies utilizing gene editing may be able to generate a F1 mouse with all desired alleles).

Matrix and tumour models to investigate angiogenesis

Aseptic precautions will be taken to reduce the risk of infection and care will be taken to ensure the animals are properly restrained during injections or incision. Injections will be used where practical to minimise distress of general anaesthesia. The matrix angiogenesis assay permits modelling of vascular growth in a healthy mouse after a minimally invasive procedure. Other models, such as wound healing and hindlimb ischemia, would cause a greater level of suffering in the mice. This model also allows for quantitative analysis of the resultant vessel growth. Occasionally slow release pellets containing tamoxifen or placebo will be used in conjunction with matrix or tumour models, or substances will be included before implantation, or injected after implantation, into the matrix (e.g. siRNA, growth factors), enabling us to alter gene expression specifically at the site of implantation. Administration of substances, including inhibitors (e.g. VEGF pathway antibodies) will permit the investigation of the role of these substances in these clear angiogenesis models.

Use of Ad-VEGF tumour surrogate models

The Ad-VEGF tumour surrogate model represents a refinement, as it simulates the tumour environment for blood vessel growth without subjecting the mouse to any tumour burden. For now, tumour passage will also be used for comparison, but as this model is developed in our lab, we anticipate moving to a position where most of our tumour angiogenesis modelling will utilize this technique with anticipated welfare benefits for the mice. The ear and flank will be used in order to match both published and unpublished data using this technique, reducing the total number of mice used as some experiments will not need to be repeated (e.g. the effects of VEGF inhibition, and time-points affected, have already been reported for Ad-VEGF injection in ear and flank, and we have access to extensive microarray data from flank regions after Ad-VEGF injection).

Models of vascular grafting and ligation

Models of vascular grafting and ligation provide valuable mechanistic data on the pathologies associated with these conditions that is hard to obtain from clinical samples due to the scarcity of this tissue and the lack of appropriate controls. The combination with our enhancer/promoter: reporter gene transgenic mice allows us to investigate the behaviour of different regulatory pathways in these models without further need for additional interventions. The pathology associated with these surgical models can be exacerbated by poor surgical technique and the length of surgery resulting in increased variability and decreased statistical power. We have worked hard to refine the surgical technique to increase consistence and decrease variability. Whenever possible we now carry out this graft surgery with two operators one to harvest the graft and one to construct the graft. This decreases total surgery time and graft ischemia resulting in reducing variability. Cohorts are designed to enable where possible all mice within one cage to undergo surgery on one day enabling mice can be maintained in a grouped housing environment.

Why can’t you use animals that are less sentient?

Much of our early validation and analysis of enhancer/promoters often occurs in transgenic zebrafish. This analysis is done before zebrafish are free feeding and are therefore not covered under ASPA. Live imaging allows study of the formation of the vessel system in the same fish, up to three different enhancer/promoter/reporter gene constructs can be examined in each transgenic embryo, and can easily be treated with chemical inhibitors, or used in morpholino or genome editing-based gene knockdown studies, enabling quick validation of putative regulatory pathways. However, studies of pathological vasculature often require a mammalian model: tumour growth and vascularization in zebrafish embryos is not a particularly good model for human disease, whilst human-relevant hypoxia is also challenging to model in zebrafish. Further, zebrafish are not an accepted model for atherosclerosis, and flow regulation in fish is widely agreed to utilize different pathways to that of mammalian flow regulation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- Animals will not be kept beyond 12 months of age to avoid unnecessary adverse effects associated with ageing.

- We currently use injectable anaesthetic in place of inhalation anaesthetic when injecting Ad-VEGF into mouse ears (Protocol 8) as our previous experience found it was impossible to give the inhalation anaesthetic and access the ears correctly for the intradermal injection. However, we will now trial using small moulded silicone inhalatory face masks, which would allow us to take advantage of the benefits of using inhalatory GA over injectable for this short procedure.

- Where practical (e.g. in studies of blood flow-related gene regulation) we will first screen putative enhancer/promoters in an in vitro system (e.g. parallel plate flow chamber) before producing new genetically modified lines.

- We will provide cage enrichment (e.g. sizzle nest and polycarbonate tunnels as standard, chew toys for single housed stud males, smart houses and nestlets for breeding pairs and pregnant females) to promote natural behaviours and improve general welfare.

- When possible, we will add companion female(s) to singly caged pregnant mice.

- Cryopreservation of new lines will occur early in the breeding programme.

- Bedding materials will be altered when needed, for example using Alpha Dry bedding to reduce/prevent the development of skin sores and reduce eye issues in nude mice and those feed with high fat diet.

- Mice at risk of tooth overgrowth due to high fat diet will be supplied with wooden chew blocks.

- We will trial the use of skin swabbing (for mucus) in place of fin biopsy when genotyping zebrafish.

- We will read and follow relevant LASA publications and guidelines, including those on undertaking aseptic surgery and transgenic models

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow advances publicised in the NC3R newsletter. This provides information on the most refined techniques, including new guidelines on non-aversive methods of picking up mice, single-use of needles and blood sampling. We will adhere to updated ARRIVE guidelines on reporting work with animals as now required by many journals. We will also follow publications from LASA on areas relevant to this work (e.g. guiding principles on aseptic techniques, position paper on transgenics).
Where new experiments are being set up, we will also use the online NC3Rs Experimental Design Assistant.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

- I, and all personal licence holders attached to this PPL, will be expected to attend all of our local Gold Standard meetings

- I subscribe to the NC3Rs newsletter, and discuss relevant points in our weekly lab meetings
- All PILs attached to this licence will be encouraged to attend symposia on the 3Rs (offered yearly by our University), which I will also attend.
- Periodic reviews of the literature will be held in weekly lab meetings to ensure recent advances are not overlooked

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project is to use frog embryo cells to understand how tissues and body structures are built with a view to applying this basic knowledge to create realistic test tissues for medical/pharmaceutical

research or to guide biologically informed techniques for repairing diseased or damaged tissues and structures in patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Repair or replacement of diseased or damaged tissues and organs created from cells in the laboratory is an achievable but currently distant objective for most tissues. One of the major challenges is to reconstruct the normal architecture of tissues. The basic biology of how normal tissue architecture is generated by cells during embryonic development is the major area of investigation of this project. In particular, how do tissue achieve organised shapes by directional growth? How do the cellular components we know of that control cell polarity organise polarised cells in intact tissues? How do these relate to the action of chemical signals that influence embryonic development in general?

What outputs do you think you will see at the end of this project?

We foresee two main outputs from this project. One is a paper or several publications on the ways that self-organisation can be cued or triggered to achieve specific tissue shapes. A second is a rigorous evaluation and potentially new guidelines for the community on the optimum use nd re-use of our animal species, Xenopus leavis, potentially reducing numbers in use by up to 50%.

Who or what will benefit from these outputs, and how?

In the short-to-medium term, the research will push the field forwards, providing a better understanding of the basic biology and potential practical application of cell self-organisation to make anatomical and tissue structures. In the long term, this project will contribute to the goal of extending our ability to general specific cell types in the lab to generating or repairing structures in the lab or in patients.

How will you look to maximise the outputs of this work?

All findings will be expeditiously published in appropriate peer-reviewed journals with the maximum visibility and impact. In addition, in collaboration with NC3Rs and the XenBase community pages and at domestic and international scientific meetings, improved protocols for 3Rs will be promulgated throughout the international community of Xenopus researchers.

Species and numbers of animals expected to be used

- Xenopus laevis: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Xenopus laevis frogs are a widely used experimental animal because they generate large numbers of eggs (frog spawn) that develop into tadpoles quickly (in about three days). The frog embryos are useful for scientific study because they are visible and accessible while they develop (unlike, for example, mice or other mammalian species) and yet their development has much in common with that of other vertebrates such as humans. Understanding embryonic development is the foundation of using cells, such as stem cells, for the repair and regeneration of diseased, injured or aging tissues.

Typically, what will be done to an animal used in your project?

Female Xenopus frogs will get a hormone injecting that triggers them to lay eggs. They will then be rested for three months before the procedure is repeated. Frogs that are used and re-used this way remain vigorous and healthy in many labs around the world for many years. Some frogs will be reinjected 7-10 days after an initial injection to induce a second round of egg laying. This is similar to the interval between mating events in the rainy season in the wild. We have been piloting this approach in the lab for the past few years and the frogs appear to be just as healthy after multiple cycles of this double-egg-laying procedure as the standard procedure while generating twice as many eggs per animal. Animals will be closely monitored for any stress or cumulative effects of this double-egg-laying procedure.

What are the expected impacts and/or adverse effects for the animals during your project?

No adverse impacts or effects on the animals subjected to these procedures are expected. Historically, animals subjected to repeated superovulation re-use remain healthy and continue to grow (slowly) over many years in our colony and similar Xenopus colonies around the world.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All of the animals will be subjected to the Mild level of protocol severity.

What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Trying to understand how cells in living tissues function and behave absolutely requires studying living tissues. These can only be obtained for this type of study from live animals.

Which non-animal alternatives did you consider for use in this project?

This project builds directly on a large body of knowledge and an experimental protocol that only exists for embryos of this animal species. Recently, some mammalian cell culture methods have begun to be used for related studies

Why were they not suitable?

The cell culture systems than are closest potential alternatives to the proposed project are too heterogenous in both composition and cell behaviour to provide the clear cut answers that this project will provide. They are also explicitly not an alternative for the development of the new ovulation procedure that this project aims to test.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have used pilot data from collaborators at the University of Chester to estimate how big the differences might be between different procedures we aim to test, and also how variable they will be. This enabled us to calculate how many tests, and therefore how many animals we need to use, to make sure that we can draw firm conclusions from the experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The re-use of animals is a major factor in reducing numbers being used and this is a central feature of this project and each of the protocols. We also used the calculations described above to determine the minimum number of animals we need to use to ensure that the scientific endpoints will be achieved with sufficient statistical power so that animals will not be wasted.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our main measures for optimising the numbers of animals to be used are the calculations described above plus the re-use of animals (which we know to be benign) so that none have to be killed.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Xenopus leavis females can produce large numbers of eggs throughout their long lives. They are well adapted to hormone-induced ovulation (our protocol) and are used routinely this way with no evident ill effects in research institutions throughout the world.

Why can’t you use animals that are less sentient?

The research is aimed at identifying methods and rules for the self-organisation of tissues relevant to humans. Xenopus laevis is the least sentient vertebrate species useable for this work.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Stress monitoring and improved methods are an explicit component of this project. Our routine animal care and veterinary supervision (involving NVS sign-off for every re-use as well as routine monitoring) are already of the highest standard.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow both NC3Rs and ARRIVE guidelines in experimental design and our protocols have been stringently peer-reviewed according to these criteria.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We are leaders in proposing and being funded (by NC3Rs) for 3Rs work and are in touch with the NC3Rs on a regular basis.

NON-TECHNICAL SUMMARY

161. Regulation of female fertility in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Ovarian function, Fertility preservation, Primary ovarian insufficiency, Cancer, Conservation

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to investigate how ovaries function by analysis of the interactions between the developing eggs and the cells of the follicle to develop treatments for human ovarian dysfunction and for conservation of endangered species.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Normal ovarian function and the generation of functional eggs underpins female fertility and the work in this project has numerous target groups. The number of children surviving cancer treatment is increasing but so too is the number of children who have undergone gonadotoxic chemotherapy or have had ovarian tissue frozen for fertility preservation. For these children, understanding how the ovarian tissue responds to different chemotherapy regimens and investigating molecules that may prevent damage is crucial. For patients with blood cancers that cannot have the tissue transplanted back, we need to develop methods to culture this tissue to grow eggs in vitro. For the 1% of women under 40 years of age with premature ovarian insufficiency (POI), 70% of the causes are unknown. We need to understand the mechanisms that cause the onset of POI and develop techniques to develop treatments. Finally, understanding how follicles develop and ovarian function is regulated will help our work into developing eggs in culture for endangered species.

What outputs do you think you will see at the end of this project?

At the end of this project, our aim is to have generated new publications revealing a deeper understanding of ovarian function in health and disease and progressed towards the development of new techniques for the clinical treatment of ovarian dysfunction including primary ovarian insufficiency (POI) and fertility preservation for ovarian cancer patients.

More specifically:

1 – Furthering our understanding about how follicle development and ovarian function are regulated throughout life, will further our understanding of ovarian function. Understanding the mechanisms that underlie follicle development, ovarian function and fertility regulation may reveal therapeutic targets for fertility treatments for women and for other species including endangered and agricultural species.

2 – By analysis of ovarian function in health and disease we will further our understanding of mechanisms that are involved in ovarian dysfunction and potentially identify mechanisms which will lead to new treatments.

3 - By developing novel methods of fertility preservation this will improve health and wellbeing for women who have fertility problems or have treatment that causes fertility problems. Since infertility causes emotional stress and can lead to mental health conditions as well as cardiovascular and skeletal issues, this will lead to improved health and wellbeing for women and girls with fertility issues.

4 – By investigating fertility preservation methods for cancer patients and how chemotherapies affect ovarian function and potential fertoprotect substances, we hope to generate data that will ultimately lead to improved methods of fertility preservation and new non-invasive treatments to preserve fertility for patients during cancer treatment.

5 – In exploring follicle development for non-domestic species including endangered species where little information exists, we will be furthering our understanding of how eggs are generated in endangered species which will support development of assisted reproductive technologies to generate eggs for endangered species.

Who or what will benefit from these outputs, and how?

These studies revealing more about ovarian function and disease will benefit scientists working in the fields of human, domestic animal and endangered species ovarian physiology whilst the work is ongoing as the data will be shared at conference presentation and by publication. The benefit to researchers is considerable and immediate upon sharing of results considering the fundamental mechanisms of ovarian function will be explored and thus will contribute to many areas of research.
In the long term, the output from this work will help women and girls with ovarian dysfunction, undergoing chemotherapy treatment, and undergoing fertility preservation for other conditions of ovarian dysfunction. The number of women and girls who survive cancer who would benefit would be considerable. The studies may lead to clinical treatments that preserve fertility for all prepubertal girls and reproductive age women who have to undergo chemotherapy. To restore or maintain fertility in women will lead to considerable economic benefits regarding their future medical requirements. The improvement to women's health by preventing early menopause caused by these diseases and cancer treatments will lead to savings for the NHS since hormone replacement therapy (HRT) treatment, treatment for osteoporosis, cardiac and metabolic conditions is reduced. Preserving fertility for female cancer survivors has huge potential for economic impact due to reduced costs for ovarian cryopreservation, future assisted reproductive techniques and IVF and treatments for side-effects that occur due to premature menopause.
The improvement and development of fertility preservation techniques to help patients with fertility will be realised after publication and the progress to developments and benefits will be pursued but will take some years for full development to clinical treatment.
Output from these studies into non-domestic species will benefit the survival of endangered species including rhino that have been pushed to the brink of extinction by poachers and thus require human intervention. Saving endangered species would lead to economic benefit for numerous counties where these species exist, there are also immeasurable conservation benefits to humankind and the planet as a whole.

How will you look to maximise the outputs of this work?

We will aim to maximise these outputs via the usual academic means including publication of results and dissemination at conferences. We will also publicise in the mainstream media and use social media to ensure the general public are aware of the advances generated by this work.
Where required to facilitate the translation of the techniques to clinical treatments, collaborations will be established.

Species and numbers of animals expected to be used

- Mice: 15,000
- Rats: 500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The regulation of ovarian follicle growth and development is complex and requires organization on multiple levels. To unravel the function of the oocyte requires the use of whole animals because the oocyte and follicle are mutually dependent and cell lines do not exist. Cell culture assays will be used wherever possible to characterise the function of molecules involved in oocyte-granulosa communication.
To investigate ovarian dysfunction and disease, models of such conditions are required, for example, to investigate primary ovarian insufficiency (POI), a mouse model of POI is used, and to develop fertility preservation therapies for ovarian cancer, a mouse model of ovarian cancer is used.
To examine follicle development in ovarian tissues, tissues will be transplanted into immuncompromised host animals; these animals have a dysfunctional immune system and this prevents tissue rejection after transplant.
Mice with labelled cells are used to trace cell lineages.

Typically, what will be done to an animal used in your project?

The vast majority of animals are born, maintained and humanely killed for tissue collection. To investigate follicles as they develop in the ovaries, imaging under general anaesthesia will be carried out on multiple occasions. A selection will be used as hosts for transplanted ovarian tissue from other species including human, sheep, rhino and mouse. Human ovarian tissue will not be transplanted in the ovarian bursa but into other locations for study; most often under the skin but occasionally into the omentum in the abdomen or under the kidney capsule. Transplanting up to 4 small pieces in the same animal via a limited number of surgical sites means we can carry out more meaningful experiments using less mice. Transplanting multiple pieces minimally extends surgery but does not result in any adverse effects. Some animals will undergo two surgeries far enough apart to ensure animals have fully recovered between. If follicles develop well, animals with transplants may also undergo multiple imaging sessions under general anaesthesia. The effect of drugs on ovarian function will be investigated. These will include chemotherapy drugs as well as drugs that can protect fertility during chemotherapy treatment (fertoprotect drugs).

What are the expected impacts and/or adverse effects for the animals during your project?

To study the effects of chemotherapy on ovarian function and to investigate molecules that may protect fertility during chemotherapy, we have to administer mice with chemotherapy. This will result in typical symptoms associated with chemotherapy treatments such as weight loss and ill health over the following 1-2 weeks.
To observe follicle development as it occurs normally, we will image the ovary using imaging technology such as MRI. To ensure the animals remain still and not stressed by the procedure, this will be done under general anaesthesia. To watch follicles as they develop, multiple anaesthesia's will be carried out which may accumulatively result in slower recovery from the anaesthesia.
To further our understanding of ovarian function in health and disease, we need to analyse ovaries and thus some experiments require surgery to transplant and modify ovaries under general anaesthesia. This can cause pain although this is alleviated through the use of pain killers. Typically animals recover well and behaving normally within an hour of surgery.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice:

Sub-threshold: 90% of all mice used.
Mild: 5% of all mice used.
Moderate - 5% of all mice used.
Rats:

Moderate: 100% as all animals used will have undergone surgery.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The regulation of ovarian follicle growth and development is complex and requires organisation of many different cells types on multiple levels. To unravel the function of the oocyte and the somatic cells that support its development requires the use of intact ovaries in whole animals because the oocyte and follicle are mutually dependent and cell lines do not exist.

Which non-animal alternatives did you consider for use in this project?

Cell culture assays and tissue culture will be used wherever possible to characterise the function of molecules involved in oocyte-granulosa communication. However, at present culture techniques do not fully replicate follicle development in vivo.

Why were they not suitable?

Although culture of ovarian tissues is being investigated, to date, culture of these tissue culture does not replicate oocyte and follicle development as it occurs in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers stated are based on my previous two Project Licenses.
The number of animals used for experiments will be around half of all animals bred since our work is the study of ovaries, and the only use we have for male mice (from lines with modification in ovarian function) is as breeders, and therefore, the majority of male mice are culled before weaning. Wildtype and immunocompromised males will be shared where possible.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Since the males have genetic modifications, there is no desire for them as they are not wildtype. If we breed immunocompromised SCID mice, the males will be made available to other groups. Animals required for each experiment will be carefully calculated and minimum numbers will be used to obtain statistical significance.
Bovine, ovine and equine ovaries are also used where possible since numerous ovaries can be obtained with no cost to animals from local slaughterhouses.
Ovaries collected are serially sectioned and thus many samples are available for analysis from the same animals.
We aim to reduce variation in the data by careful control of age and weight between groups. When possible the researcher is working blind to reduce measurement error.
Pilot studies will be performed when feasible followed by power tests to ascertain the number required to test for significant effects before larger experiments are carried out.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All animals used will be used as efficiently as possible by maximising the data collected per individual to ensure that the use of each animal is maximised. Transgenic mice will be maintained as individual colonies unless they are readily available commercially and it is more efficient to purchase them. Using breeding calculations, each mouse line maintained will produce only the mice needed for the specific designated experiments and for maintaining the colony minimising the number of animals used.

Recent amendments to our previous license have enabled us to graft multiple tissue pieces into one animal during one same surgery; this results in the use of fewer mice.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of our work uses ovarian tissue collected from dead animals and therefore, there is no lasting pain or harm.
The mouse models used are models of ovarian dysfunction and therefore have no adverse phenotype other than dysfunctional ovaries. Where models of ovarian cancer are used, the cancer is also targeted to the ovary, and since we are aiming to develop treatments for patients that have recovered from ovarian cancer, we will be using these models before the disease extends beyond the ovary.
To investigate the effect of chemotherapy drugs and fertoprotect drugs, these will be administered to mice. The dose and regimen will be used based on published studies with clinical relevance to human drug regimens. Mice will be carefully monitored and any side effects addressed where possible, e.g., mice with hair loss will be provided with additional bedding. Soft palatable food will be provided to all animals given drugs with some toxological side effects, as well as control animals.
To investigate the effect on human tissues, human ovarian tissues from patients that have consented to

research in animals will be used to examine the effect of these drugs and fertoprotect drugs on ovarian function.
To investigate follicle development in non-domestic species, tissues need to be transplanted into mice so that we can ascertain what 'is' normal development so that can aim to replicate it in cultured tissues.
Immunocompromised mice and rats will be used as the lack of an immune system is required to prevent graft rejection.
Transplantation of up to 4 pieces of ovarian tissues into a single animal in a single surgery with a max of two incisions means that less animals are used to obtain the same data.

Why can’t you use animals that are less sentient?

The regulation of ovarian follicle growth and development is complex and requires organization on multiple levels. To unravel the function of the oocyte in mammalian development requires the use of whole animals because the oocyte and follicle are mutually dependent and cell lines do not exist.
Mice have been chosen for these studies because they are the species of lowest neurophysiological sensitivity that will allow us to investigate these scientific questions. It is also relatively straightforward to manipulate genes in mice.
Since ovarian development changes with species of increasing complexity, to investigate mammalian development with the aim of developing treatments for patients, using fish or other less sentient models such as drosophila are not appropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Substance administration will be via the least invasive technique.
Chemotherapy regimens are based on published studies and pilot studies will be carried out where appropriate.
Numerous sites for transplantation of ovarian tissue have been included so that the most appropriate can be used for each study; for example, human, cow and sheep follicles can grow much larger than mouse and therefore transplanting human, cow or sheep ovarian tissue beneath the kidney capsule to develop mature follicles is not the most appropriate.
Human ovarian tissue will not be transplanted beneath the ovarian bursa.
Numerous refinements to surgery are carried out. Animals are regularly handled before surgery to ensure they are used to human manipulation and contact so that immediately prior and during post surgery monitoring, this aspect is stress-free. The dose of analgesia for managing pain is administered based on an individual animal's weight. To aid with post-operative recovery, more enrichments in the cage are provided.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The guidelines suggested by NC3R.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We participate in initiatives of the NC3R e.g. 3R research day, we are in contact with the 3R information officer of our institution and have subscribed to email alerts. We also have regular consultations with the NACWO and veterinarians

Home Office

NON-TECHNICAL SUMMARY

162. Regulation of thrombus formation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to investigate the cellular and molecular mechanisms involved in thrombus (blood clot) formation and ultimately to specifically block or modulate these mechanisms.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The formation of blood clots, although essential for normal haemostasis, can pose a significant risk to health. Thrombus formation is a contributory factor in heart attacks, stroke and atrial fibrillation. It is therefore extremely important that the underlying mechanisms of clot formation are better understood so that more effective therapies, and ultimately preventative therapies, can be designed. However, one of the main problems with agents used to prevent clotting is the increased risk of uncontrollable bleeding. This adds to the importance of understanding the intricacies of clot formation and lysis.

What outputs do you think you will see at the end of this project?

Through this Project Licence we will gain a greater understanding of the initiation, formation, structure and stability of thrombi and ways in which thrombus formation can be inhibited. The detail of mechanisms and molecules involved in specific mechanisms of thrombus formation and lysis can be used to develop small molecule inhibitors of these target molecules. The clinical benefits may be identification of novel pathways that can be targeted with therapeutics minimising risks associated (e.g. bleeding) with current therapies; this could be through the development of new treatments for thrombosis that are directed at modulating the developing fibrin clot rather than preventing its formation, as an alternative or complement to existing anticoagulant, antiplatelet and thrombolytic treatments. **Who or what will benefit from these outputs, and how?**

It is anticipated that the information gained through this programme of work will be of benefit to the scientific community through peer review publication. Findings gained from the in vivo work detailed in this project, together with in vitro data obtained will provide the research community with insight into the role of specific molecules in thrombus formation. They will also provide a greater understanding of alterations in function in clinically relevant mutations of these molecules.
Small molecules showing the greatest inhibition of thrombus formation in vivo will be sent for further testing with the aim of reaching human clinical trials.

How will you look to maximise the outputs of this work?

Our studies are conducted alongside other collaborators which has successfully established channels to share new knowledge to further develop and refine in vivo and in vitro systems to study thrombus formation at the cellular level. We have developed in vitro assays to examine potential test compounds on the basis of selectivity and efficacy.
Our research findings will be shared with the greater scientific community in the form of national and international conferences and workshops and also through peer-reviewed publication. **Species and numbers of animals expected to be used**

- Mice: 1900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice will be used as models of thrombus formation are well established in this species. Also, selective blocking antibodies and genetically modified or mutant mice relevant to these studies are available. We also know that human clotting factors and inhibitors have physiologically relevant actions in mice. In addition to this we intend to use genetically altered mice with specific clotting factor mutations to study their effects on clot development.

Typically, what will be done to an animal used in your project?

Under non-recovery anaesthesia, the carotid artery will be cannulated.
Test compounds and Fluorescent labels administered via the carotid artery.
Femoral vein or cremaster vessels will be exposed for microscopic visualisation.
Thrombosis will be initiated by causing injury to the surface of blood vessel(s) chemically or by laser injury.
Microscopic Images of the developing clot taken at regular intervals for up to 1 hour post injury.
At the end of imaging, whole blood will be taken for plasma samples.
Mouse killed.
A small proportion of mice will receive the test compound under investigation orally, intravenously or injected under the skin prior to being used under non-recovery anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Most of the animals used will undergo non-recovery anaesthesia to minimise suffering. If recovery is necessary, all procedures will be carried out by competent personal licence holders using appropriate procedures and experiments will be terminated should any sign of suffering be observed.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

90 % of mice will be used under non-recovery anaesthesia.
10% of mice undergo a surgical procedure under general anaesthesia and allowed to recover for a period of up to 7 days before being used under non-recovery experiments. This is to study the development of clots and the test compounds over longer periods of time. During the recovery period, the health and welfare of mice will be regularly monitored by experienced personnel.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although initial experiments will be carried out using ex vivo models of clot formation, the use of animals is required due to the complex nature of the clotting cascade; this requires multiple factors to be present simultaneously to evaluate the complete effect.

Which non-animal alternatives did you consider for use in this project?

Platelet aggregation assays and clot lysis assays are considered and are used as in vitro studies alongside this project.

Why were they not suitable?

In vitro studies, as mentioned, provide valuable information regarding the cellular components involved in the clotting cascade but do not replicate the interactions of these cellular components within a clinically relevant biological system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We calculate that 6 animals will be required for each experiment. These calculations will be constantly reviewed after initial experiments are performed to ensure they are accurate. If required, additional advice on study design and subsequent data analysis will be sought from our statistics service for more complex studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Internal controls will be used whenever possible. For example, in time course experiments progression of thrombus formation will be compared to fluorescence within the vessel recorded prior to injury. Where internal controls are not an option, test animals will be compared with inbred age-, weight- and sexmatched controls to minimize variation.
The online Experimental Design Assistant provided by NC3Rs will be used where applicable and advice from our statisticians will be sought to ensure correct number of animals are used to achieve statistical significance per study.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In vitro studies such as clot lysis assays and compound profiling studies (to analyse target specificity, potency and toxicity etc) are carried out to identify the best candidates for in vivo use. This reduced the number of compounds being put forward for in vivo analysis.
Small pilot studies are carried out for each family of compounds. Superior compounds are carried forward for

dose response studies. This ensures inferior compounds are not part of large scale investigations therefore reducing the number of animals used.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice will be used as models of thrombus formation as they are well established in this species. Also, selective blocking antibodies and genetically modified or mutant mice relevant to these studies are available. We also know that human clotting factors and inhibitors have physiologically relevant actions in mice.
Non-recovery anaesthesia is used throughout our studies to reduce pain and suffering to the animals.

Why can't you use animals that are less sentient?

Cellular components of blood and Clotting factors involved in the coagulation pathways in humans and mice are closely related. We have a well-established murine thrombosis model which utilises mutant mice as well as specific clotting cascade inhibitors which are not available or compatible in less sentient species. Scientific outcomes using mice in these studies will be of greater relevance with the aim of our findings leading to human clinical trials in the future.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Most experiments carried out under non-recovery anaesthesia therefore most refined.
Animals used in recovery experiments will receive the appropriate post-operative care (pain relief administered, kept incubated and softened food provided in necessary) to reduce pain and suffering and regular monitoring until fully recovered. Any animals failing to recover with 2-3 hours post op will be killed.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The principles in the LASA guidelines will be followed http://www.lasa.co.uk/wp-

content/uploads/2017/04/Aseptic-surgery-final.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs workshops/symposia are held regularly and provide an opportunity to discuss and learn about the latest developments and advances in experimental design.
Experimental design workshops are also held during our annual group meetings to keep up to date with latest advancements.

Home Office

NON-TECHNICAL SUMMARY

163. Regulatory RNA mechanisms in germ and stem cells.

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Germline, Developmental biology, epigenetics, RNA modifications, piRNA

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We are interested in reproductive cell (germ cell) development with a particular emphasis on the molecular mechanisms that underpin how chemical changes are made to gene DNA or chemical modification of the RNA produced from genes. We explore these topics predominantly in vivo and focus on RNA-based mechanisms that

regulate gene expression.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The objective here is to understand aspects of molecular biology that sustain reproductive cell (germ cell) development. The germ line is the lineage of cells that gives rise to the sperm and eggs cells that are responsible for the continuity of life and the genetic health for a given species. The germ line is passed from generation to generation and therefore merits special attention as it bears responsibility for the transmission of the genome and memory of modified gene expression patterns across generations. The understanding of how this lineage develops and how it is maintained throughout life bears importance to human health and socio-economic welfare given the dramatically increasing age of parenthood observed in Western societies and the associated age-related risks of infertility or birth defects.

What outputs do you think you will see at the end of this project?

We aim to identify the mechanism by which the small non-coding RNAs termed piRNAs recognize and silence jumping genes in male reproductive cells. We also aim to gain new insights into the function, mechanism and regulation of some of the RNA modification pathways in reproductive cells. These findings will give great insights into fundamental biological processes of gene regulation and reproductive cell development and will be published in high quality, peer-reviewed science journals and presented at international conferences. Furthermore, we hope to establish new collaborations based on our findings with experts in adjacent fields.

Who or what will benefit from these outputs, and how?

The benefits of understanding the mechanism by which the Piwi-interacting RNA (piRNA) pathway contributes to the establishment of epigenetic transposon silencing (Objective 1):

The function of germ line reprogramming is to reset genomic imprinting of the maternal and paternal chromosomes to that of the sex of the animal. Disrupted reprogramming results in sterility and defects in imprinting of specific parts of the chromosome have been associated with many human diseases exemplified by Prader-Willi or Angelman syndrome. Therefore, research on this topic offers benefits of understanding mechanisms that underpin mammalian development and genome stability.

The benefits of exploring the physiological importance and regulation of RNA modification in germ cell development (Objective 2):

RNA modifying pathways have been associated with human diseases or congenital disorders, such as cancer, obesity, infertility, underscoring the importance of these modifications for basic human development and physiology. Therefore, this aim delivers benefits that will advance knowledge on disease mechanisms as well as understanding of emerging facets of basic RNA molecular biology.

Given the majority of the work centres on basic germ cell and molecular biology, the work will be disseminated by two major routes. Firstly, the research will be presented to the respective communities at international scientific meetings. Secondly, the work will be published in peer-reviewed journals. Thus, the secondary benefits may therefore not only be developed in my own laboratory but also by the scientific community.

How will you look to maximise the outputs of this work?

The output of this work will primarily be published in open-access, peer-reviewed scientific journals as well as presented at international scientific conferences. After publication, data will be deposited in an open access digital repository. Published materials/reagents/mice will be available upon request to allow for collaboration and dissemination of new knowledge. Our data will also be safely stored to ensure their longevity and that they can easily be shared, uploaded or reanalysed by everyone.
Additionally, I aim to coordinate with our public relations team to make our results available to the wider public and understandable to the lay person.
Species and numbers of animals expected to be used

- Mice: 25,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

My laboratory is primarily interested in mammalian reproductive cell (germ cell) development and studies it from an RNA perspective. For this research, the use of animals is currently unavoidable as many facets of germ cell biology can only be studied in animals, such as mice, where these cells and developmental processes naturally occur. For example, the current knowledge does not allow us to properly culture mammalian germ cell cells in a dish – once plated into a dish they die or lose their potential, likely because of the missing tissue (micro-)environment present in vivo. Thus, current culture conditions do not allow us to test many key properties of germ cells. This necessitates the use of an animal model to study germ cell biology at the appropriate life stages.
Typically, what will be done to an animal used in your project?

Much of our work (greater than 90%) involves breeding, collection and analysis of tissues and a humane killing method only. In order to collect eggs for study, some animals need to be injected with hormones to induce superovulation which causes mild temporary discomfort but no lasting adverse effects. Animals primed with hormones for superovulation will be killed by a humane method of killing days after injection.
What are the expected impacts and/or adverse effects for the animals during your project?

We expect the observable characteristics (phenotypes) of mice used in this study to cause defective germ cell development or loss of germ cell. This renders mice infertile or sub-fertile and does not have other ill effects on mice that would cause suffering. Therefore, our work does not by default inflict suffering. Some animals need to be injected with hormones to induce superovulation, which cause mild transient discomfort and no lasting harm. Our work therefore causes minimal adverse effects to the animals.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Sub-threshold severity will apply to the majority of mice. Very few animals will suffer mild transient discomfort and no lasting harm due to injections required for superovulation.
What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The research of my laboratory focuses on the mammalian germ line, which makes the use of animals currently unavoidable as many facets of germ cell biology can only be studied in animals, such as mice, where these cells and developmental processes naturally occur. For example, the current knowledge does not allow us to properly culture mammalian reproductive cells in a dish – once plated into a dish they die or lose their potential, likely because of the missing tissue (micro-)environment present in vivo. Thus, current culture conditions do not allow us to test many key properties of reproductive cells. This necessitates the use of an animal model to study reproductive cell biology.

Which non-animal alternatives did you consider for use in this project?

We have considered and are making use of established cell lines as well as work on generating mammalian cell or tissue culture systems to study the RNA pathways and modifications. Furthermore, we have begun to investigate molecular and biochemical features of proteins of interest through in vitro analysis of purified proteins.

Why were they not suitable?

Unfortunately, in vitro mammalian tissue culture and germ cell systems that recapitulate reproductive cells development faithfully do not currently exist, nor do in vitro cultured foetal reproductive cells undergoing de novo DNA modification. None of the available systems provides the full complement of factors required for gene silencing or reproductive cells specific expression patterns of RNA modification pathways. Furthermore, the use of purified proteins only allows for the study of isolated biochemical functions that are independent of the larger, intricate complexes formed in vivo as the replication of complexes in vitro is currently impossible using recombinant purified proteins. This necessitates the use of an animal model to study RNA-based processes in germ cell development.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals used in each protocol is estimated based on my extensive previous experience and power calculations taking into account the number of experiments needed and number of mice per experiment required to obtain the appropriate statistical power.

The fact that the majority of experimentation is performed on either germ line, mice with the correct genotype but the opposite sex must be discarded, thus our project requires additional breeding over projects that analyse

mice independent of their sex. Additionally, some germ line observable traits are sensitive to the genetic background of the mouse line and thus newly generated mouse lines need to be crossed onto specific genetic backgrounds to make their analysis interpretable and scientifically sound.

According to our experience, we estimate for gene deletion and conditional genetics experiments that we require 100 experimental and 100 control animals per line per annum. Finally, for mice harbouring the correct genotype, we estimate that we would require 200 experimental mice required per year. Given we study several lines per year, we estimate that we would need to use 5,000 mice per year to obtain the necessary genotypes/sex which equates to 25,000 mice over the 5 years. These numbers include ca. 500 mice used on the superovulation protocol per year in order to collect sufficient amounts of oocytes for experimental use.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As key means of achieving reduction we have and will continue to carefully design our experiments and mindfully estimate the number of animals required in order for the results of our experiments to be statistically convincing. To minimise the number of animals used in each experiment while optimizing the output of scientific data, we will make use of online tools (such as the NC3R's Experimental Design Assistant) and power calculations, calculations that allow us to predict the minimal number of animals to test to gain statistically significant information on a given phenotype. For example, in preliminary studies where we are trying to determine the most effective number of cells, or drug dosage to use, no more than 3 animals per group will be used when possible.

Importantly, experiments will be carefully planned to maximise the information obtained per animal and thus limit the subsequent use of additional animals. All methods requiring cells or tissue from animals will be carefully optimised in order to minimise the number of animal cells required. For example, we managed to reduce the number of foetal testis required for interaction screens by a factor of 5 in the last two years and likewise optimized input material required for RNA sequencing techniques.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

An important means of achieving reduction is to apply the most efficient breeding strategies. My group has extensive expertise with mouse colony management (i.e. monitoring large cohorts of mice) and we will strive to employ the best breeding schemes. We will replace breeders before their reproductive performance declines, and non-productive breeders will be replaced.

My group is fully aware of the ARRIVE guidelines and experimental design tools provided from NC3Rs. As such, we employ the optimal experimental designs to implement the 3Rs and optimise the number of mice for each experiment.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The majority of our work involves the use of genetically modified mice to test gene function in the germ line, protein tags to probe their molecular function, isolate and characterize populations of reproductive cells using marking strategies. Some mouse lines show phenotypes of defective reproductive cell development or loss of reproductive cells, which renders mice infertile or sub-fertile but does not have other ill effects on mice that cause suffering. Some animals (less than 10%) need to be injected with hormones to induce superovulation using well established procedures for the collection of eggs, which causes mild transient discomfort and no lasting harm. Much of our work (greater than 90%) therefore involves breeding, collection and analysis of tissues following a humane method of killing only. Thus, our work does not by default inflict suffering.

Why can't you use animals that are less sentient?

The tools that modify gene expression and genomic protein function evolve rapidly. This means that these modification pathways are found in very few other model organisms where there is a clear homologue in mammals. Thus, we are dependent on using mouse foetal testes as the only system available to understand the mammalian pathway. Likewise, my group specializes in studying the in vivo regulatory role of RNA modifications in mammals and thus we require the usage of mice as our model system.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To ensure technical competence, all staff will be supervised by the project license holder. Animals exhibiting any unexpected pain or suffering will be humanely culled. All procedures involving injections of substances are based on the scientific literature as well as extensive in-house experience and constantly refined to use the lowest dosage and frequency as possible, both to achieve our scientific goals and to minimise suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our experimental designs are based on our long-term experience in this field (we have already refined many protocols and experimental designs) and peer-reviewed high-quality literature. We always seek to apply the most refined methods which are published in the field. We also base our knowledge on ample literature disseminated by NC3R and interactions with many expert colleagues and collaborators. We will always continue to refine our protocols based on the literature and knowledge exchanged with skilled collaborators and we are very proactive in this area.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Many advances in reproductive line research, including advances in mouse models, are disseminated during scientific conferences and seminars, which we frequently attend. Further, members of my group frequently attend 3Rs events organised by NC3R, and we continue to update our knowledge through the literature NC3R disseminates. We also have an extensive network of local and international collaborators who use similar state-of-the-art models, and by frequent exchange of information we will always stay informed about the best advances in the field. Given that our group is extremely committed to the implementation of the 3Rs, we will utilise any useful knowledge learned during these events and the literature to improve mouse procedures, apply cell culture models where possible, improve statistical methods, and minimise pain and suffering of our experimental mice.

Home Office

NON-TECHNICAL SUMMARY

164. Respiratory biology and pharmacology

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Respiratory, Therapeutics, Pharmacology, COPD, asthma

Animal types	Life stages
Mice	adult, aged
Rats	adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Understanding the biology of the respiratory system in experimental animal systems and using that knowledge to identify and develop novel treatments for human airway diseases

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Diseases of the respiratory system, such as asthma and chronic obstructive pulmonary disease (COPD), remain a significant cause of morbidity and mortality across the world. The World Health Organisation (WHO) estimates that 235 million children suffer from asthma and 6% of all deaths are caused by COPD. At the time of writing this application there is a global respiratory virus pandemic resulting in severe disease and high levels of suffering and loss of life. Understanding the mechanisms which result in respiratory disease enables us to design and develop new medicines which can increase the quality of life for patients.

What outputs do you think you will see at the end of this project?

We can reasonably expect that at the expiry of this licence we will have progressed at least three novel treatments for human airway diseases into early clinical testing. To get to this point we will have generated a great deal of novel information regarding the biology of the mechanisms involved and pharmacology of the novel treatments, and we would hope to have published where these data are not commercially sensitive.

Who or what will benefit from these outputs, and how?

We expect the new medicines we will discover and develop to have significant positive impacts on the lives of patients, their families and society as whole. These benefits may not be tangible until 10-15 years after initial discovery, so they are unlikely to be measurable during the lifetime of this licence. The new knowledge we will create and share will be of great use to other research groups in academia and in the pharmaceutical industry, and will enable other new medicines and treatments to be generated.

How will you look to maximise the outputs of this work?

We will share the new knowledge whenever we can through publications, conference posters and presentations. We have networks of academic collaborators with whom we share our findings and benefit from the discussion and validation of our findings. We are aware that there is a need to share negative findings as well as positive ones, and we will engage with others in the scientific community to understand if there may be ways to share non-commercially sensitive information that might reduce animal usage.

Species and numbers of animals expected to be used

- Mice: 4750
- Rats: 1750

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult and aged rats and mice are appropriate animals to study respiratory diseases as they have anatomically and physiologically relevant mammalian biology. Adult animals (>6 weeks old for mice, >8 weeks old for rats) are fully formed and can demonstrate representative tissue and immunological responses to inflammatory or other stimuli. Aged animals (>40 weeks in mice, >1 year in rats) may be used as we recognise that in some respiratory diseases (such as chronic obstructive pulmonary disease (COPD)) age itself may be a factor that limits the ability of the lung to repair or regenerate and we wish to understand mechanisms that could surmount this.

Typically, what will be done to an animal used in your project?

A typical study may involve 6 groups of 5 mice, which might be identified using a subcutaneous microchip after arrival, randomisation into cages and acclimation. At least 5 days after delivery animals they might receive a dose of a new treatment into the lungs in a very small volume of liquid (under anaesthesia) followed 1 hour later by a challenge to the lungs with a substance (again in a small volume) that will trigger inflammation (under anaesthesia). Animals would be returned to their home cage once recovered from anaesthesia, closely observed to ensure they are not exhibiting any unexpected side effects, checked again at the end of the working day and then left overnight. Animals are checked first thing in the morning and then at 24h after the lung challenge they would be anaesthetised before a final blood sample is taken. Animals are killed and their death confirmed before we rinse out the lung tissues to obtain a sample of cells.

What are the expected impacts and/or adverse effects for the animals during your project?

Inflammation of the airways is likely to be uncomfortable and animals may exhibit clinical signs of discomfort or illness such as loss of appetite, reduced grooming and reduced social interaction. Reduced food intake can lead to a body weight loss, and for this reason animals are weighed regularly (at least twice a week, daily of we see any changes in condition). Most of the studies we conduct are short (less than 3 days) although some experiments studying chronic airway remodelling or injury can last for 10 weeks or more.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mice and rats:

We expect approximately 50% of animals to be classified as Moderate, the remaining 50% being Mild. This will depend on the specific studies but in many cases we will have negative (non-diseased) controls, positive controls (disease but given a known treatment) and animals treated with new experimental materials which we expect to reduce the disease and thereby reduce suffering.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Respiratory diseases arise through complex interactions of multiple biological, genetic and environmental factors. The structural cells of the lung tissue, the underlying vascular and nervous system components, and the immune cell populations all interact in ways which cannot yet be modelled with sufficient predictive power to replace animal studies, especially when novel mechanisms which are not fully understood are involved.

Which non-animal alternatives did you consider for use in this project?

Non animal systems are a key part of our research programmes, and animal studies are only considered when sufficient data are available to justify their use or in certain circumstances where the biology is novel and not characterised sufficiently to enable in vitro emulation.

Why were they not suitable?

The in vitro systems we do use are not complete representations of the lung in health or disease. Cell culture systems, even when they have some structural homology (such as organoid culture) do not have the complex biology seen in living organisms where multiple types of cell and structure combine.
Human tissue, when available, is not a complete surrogate as it lacks exposure of the lung cells to air (in submerged culture), blood circulation, innervation, immune cell trafficking and many other components.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimates are based on anticipated throughput of studies and using numbers typically used in previous experiments. Over a 5 year period usage may vary across protocols as the demand from as yet unknown research projects emerges. Rather than defaulting to maximise the estimates across all protocols I have kept number within the range of recent experience so it is possible that future amendment may be required.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Study designs are reviewed as part of our internal statistical review system to ensure that studies are appropriately constructed to account for biases and are sized to enable robust conclusions to be drawn.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Much work is conducted in vitro on cells and human tissue prior to human work, which reduces animal usage for preliminary experiments. Breeding of rats and non-genetically modified mice is performed for us at a commercial supplier which enables the maximum efficiency of animal usage for these animals. Genetically modified mice are not bred under this licence but are supplied under continuous use authority. The breeding schemes for these lines are closely monitored and for established lines with straightforward genetics (e.g. a single knockout or manipulation of a single locus) homozygous breeding is used to reduce wastage significantly (as 100% animals have the correct genotype rather than 25% for heterozygous breeding).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and

methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mouse and rat models which enable us to study the mechanisms involved in human lung diseases such as asthma and chronic obstructive lung disease (COPD), as well as complications such as viral exacerbations which can lead to hospitalisation and death for severely affected patients. We need to induce airway inflammation and cause changes to the lung tissues which reflect these human diseases, so it is likely that animals will experience respiratory changes and discomfort that cannot be avoided. However, as we are seeking to find and develop new medicines, many animals would be likely to have this suffering ameliorated by our novel treatments. We have selected airway models that are well tolerated and are expected to result in a moderate level of severity, which includes some clinical signs such as reduced food intake and lack of grooming. Where possible we will carry out studies using anaesthetised animals that can be immediately killed without recovery, to minimise suffering.

Why can't you use animals that are less sentient?

We are seeking to identify and develop treatments for human use and therefore although there may be some analogous systems in lower species such as flies, worms or fish we would not expect therapeutic agents which have been selected in vitro to work against human receptors or mediators to have the necessary efficacy. These lower species also do not reflect the mammalian and human immune systems and respiratory structures. This licence application does include a protocol for purely nonrecovery studies where all steps are performed under terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are closely monitored and are kept in modern purpose built facility with highly trained and motivated technical staff. We implement many systems to improve animal welfare, including nonaversive handling (i.e. not picking up by the tail), environmental enrichments such as tunnels, nesting materials and chew sticks, as well as cage floor level access to food for animals displaying reduced activity or mobility.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Best practice, for example the use analgesics after surgical procedures will be employed to minimise suffering.

Publications such as the Handbook of Laboratory Animal Care and Welfare (Wolfenson and Lloyd), and the LASA best practice guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I am in regular contact with other in vivo scientists and teams of animal welfare specialists within and outside my organisation. I also convene regular 3Rs events where we meet with local and regional partners to share our best practices.

Home Office

NON-TECHNICAL SUMMARY

165. Responsiveness of adult neural stem cells to diet-induced obesity and exercise

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how diet and exercise regulate neural cell networks in the brain, which control feeding behaviour. Specifically, we will study cellular and molecular changes in adult neural stem cells and their cell progeny in the neurogenic niches of the adult brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In order to develop new procedures to combat the development of obesity, we need to elucidate how diet and exercise affects the regulatory centres of the brain. Most of the cellular and molecular components of these centres are understood, except for adult neural stem cells. These cells can generate newborn nerve cells in the brain, which contribute to critical functions such as memory or feeding control. We need to understand how the ability of stem cells to generate new nerve cells is affected by diet-induced obesity and if the negative effects of obesity can be rescued by exercise. If we can identify, which cell processes and what molecular factors in the stem cells are affected by the diet and exercise, we can develop new approaches on how to control hunger sensation and development of obesity.

What outputs do you think you will see at the end of this project?

Our goal is to understand how obesity-inducing diet and physical exercise influence the brain. Particularly, we aim to gain insights into how obesity affects the resident neural stem cells, which can generate new neurons in the adult mammalian brain. We will investigate how obesity affects the stem cells and new neurons and how these new neurons may regulate the sensation of hunger and appetite, which are the driving forces behind development of obesity. Also, we will determine how prenatal exposure to obesity-inducing diet may affect adult brain. Finally, we will be testing novel anti-obesity drugs, which may decrease the sensation of hunger by acting on the new neurons. Novel findings from the project will lead to better understanding of the relationship between obesity and brain and provide pre-clinical testing for anti-obesity therapies. The findings will lead to peer-reviewed publications and new grant funding.

Who or what will benefit from these outputs, and how?

In the short-term, outputs such as new information and experimental models will benefit the neural stem cell and neuroscience research communities. In the long term, the research findings will have impact on anti-obesity therapies and approaches in direct and indirect ways. The direct ways include better characterisation of novel anti-obesity compounds. The indirect impact consists of better understanding of genetic and cellular mechanisms in the brain that are regulating hunger sensation and are responsive to obesity.

How will you look to maximise the outputs of this work?

All knowledge generated during this project will be disseminated as peer-reviewed publications and presented at national/international scientific meetings. Data will be shared via open access journals and repositories. We will continue to actively engage with the general public via events for children or adults within the University or in local communities. Progress and successes in key milestones will be released via University research pages, newsletters and social media.

Species and numbers of animals expected to be used

- Mice: 9000 (both males and females)

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of

the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will study the effects of environmental interventions, such as diet-induced obesity or anti-obesity treatment, on resident neural stem cells in the brain. We will use mice as the most suitable experimental animal model for studying obesity for the following reasons: there is a large body of knowledge on the physiology, histology and molecular biology of the mouse's CNS; there are a wide range of existing genetically modified lines, a number of which are directly relevant and amenable to our studies; the relatively short life-cycle and high fecundity of mice is advantageous for genetic studies; and mice are generally regarded as being of lower sentience compared to other mammals such as the primates. In order to model the impact of obesity on brain, we induce obesity either in adult animals or expose pregnant females to obesity-inducing diets or anti-obesity compounds. This will allow us to study the effects of prenatal exposure to obesity-inducing diets and/or anti-obesity compounds on adult brain. Diet-induced obesity and actions of anti-obesity drugs act on the brain in a complex way, which cannot be simulated only in cell cultures.

Typically, what will be done to an animal used in your project?

Typically, we induce conditional gene expression in adult mice (e.g., 6-8 week old) using inducible-Cre recombinases and under the control of a tissue-specific genetic elements (called promoters), e.g., tamoxifen induced expression of the green fluorescent protein or removal of a specific gene in the adult neural stem cells. The animals will receive several injections of tamoxifen to induce transgene expression. Induced animals are aged to a defined end point (e.g., 14 or 28 days) before being killed by a Schedule I method or by transcardial perfusion under total anaesthesia to obtain tissue for further studies. Alternatively, we assign animals to a controlled feeding programme (e.g., high fat diet for 3 months), and/or to a voluntary physical exercise on running wheels. In addition, some animals will be administered previously tested anti-obesity compounds by repeated injections after the exposure to diet-induced obesity. Exposed animals are aged to a defined end point (e.g. 14 or 28 days) before
being killed by a Schedule I method by transcardial perfusion under total anaesthesia to obtain tissue for further studies.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect that obesity-inducing diets will generate obesity, which can be accompanied by increased tissue inflammation or reduced physical activity, however, without causing any painful experience. Animals may experience diet-induced obesity for several months. The genetically altered animals do not show any overall harmful phenotype in the general health of behaviour of the animals.
Administration of substances such as tamoxifen or anti-obesity compounds by injections will cause a brief discomfort without any lasting harm.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Typically, experimental animals will experience only mild severity. Rarely (<1/20), animals may develop more extreme forms of obesity, which may be classified in the moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complex regulatory mechanism of the brain and the interactions between diet and different organs cannot be replaced by in vitro models. There are reductionist cell-culture models, however, they can only mimic limited biological processes on the cell level but not on the tissue or organ levels. We will be using certain primary cell-culture models as a part of the reduction strategy; however, these are also derived from animals. The available *in vitro* models do not allow to model the complexity and interconnectivity of organs and tissues that occurs in animals. The very development of diet-induced obesity requires food intake and thus requires experimental animals. Diet-induced obesity in mice accurately model the development of obesity in humans. Mice represent a sensible compromise between mammalian model close to human physiology and more sentient mammalian species such as primates.

Which non-animal alternatives did you consider for use in this project?

We have considered in vitro brain organoids or cell cultures of neural stem cells.

Why were they not suitable?

In vitro models cannot recreate all the complex aspects of diet-induced obesity or exercise that occur in actual animals. Diet or exercise do not exclusively target discrete brain cells, or brain alone, but exert a very complex influence on the whole body, including cardiovascular and endocrine systems, whole body metabolism and immune system. All these complex effects, many of which are unpredictable, cannot be modelled in vitro, using only selected cell populations. Even the most sophisticated ex vivo brain organoid models do not robustly recapitulate healthy normal tissue and completely lack the feedback and regulatory mechanisms from the peripheral organs such as the intestine or the spleen.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

NC3Rs Experimental Design Assistant and Power Calculations. Effect size (m1-m2) and Variance (S.D.) were calculated using current data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All calculations were made using the NC3Rs Experimental Design Assistant and current data.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will breed heterozygous animals in trios to increase efficiency. On average, 50% of the offspring of genetically altered animals will have the desired phenotype. As a reduction strategy, we will be using primary cell-cultures derived from neural stem cells of the brain. These cell cultures can be propagated and utilized for parallel experiments such as testing different concentrations of drugs or studying simplified cell behaviours in

vitro. When possible, we will collaborate with other stem cell laboratories at the university or abroad to share animal-derived tissue. For example, we have arranged that animals from our experiments will be used for harvesting intestinal tissue by a collaborator lab, while we will be harvesting the brain. Vice versa, the collaborator's lab will provide their animals (used for isolation of intestines) for brain isolation. To reduce the overall number of used animals, we will use factorial experimental design as well as the power analysis. With anti-obesity compounds, we will use pilot studies to gauge efficacy (e.g., 2-4 animals).

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The basic paradigm in this project involves exposure of animals to obesity-inducing diets, exercise or anti-obesity compounds. The animals will have free access to high-fat diet, which they consume voluntarily. The diet induced mild to moderate obesity by increasing caloric intake in the animals. The health of the animals will be continuously monitored and in case of any severe health effect, the high-fat diet will be replaced by the regular, healthy diet. Selected animals will be exposed to voluntary exercise, which improves their welfare and health. A proportion of mice will be administered chemicals that allow tracing of specific cell populations. These drugs are well tolerated and are accompanied by sub-threshold symptoms. A proportion of mice will be administered exogenous substances (known as xenobiotics) that can contribute to the development of obesity. Only classes of substances that have been used previously in animal studies will be used. Pilot experiments will always be performed where a new genotype/drug combination is being studied, with a decreasing dose regime applied on single mice, starting below established maximum tolerated doses, to minimise mouse numbers. Some animals may be examined by behavioural tests. As a part of the refinement effort, we will use most modern alternatives of the behavioural tests, which reduce the stress of animals (e.g. using paddling maze instead of Morris water maze). Finally, some animals will be administered selected anti-obesity drugs, which improve the long-term animal health by reducing the weight gain. Injection of these drugs will cause very brief discomfort, however, without long-lasting harm.

We will use genetically altered mouse models and site-specific Cre-lox technology that allows temporal and inducible expression of reporter fluorescence proteins or deletion of genes in specific cell types. This refinement will minimize any possible detrimental impact of transgenes on the animals. All genetically altered lines will carry conditional alleles; therefore, only mice that carry site-specific recombinase and the conditional allele will express the reporter, but only after induction of genetic recombination by tamoxifen. We will only use genetically altered animals appropriate to our objectives (i.e., targeting specific, well-defined cell populations in a tissue-dependent manner) to ensure that the work carried out is accurate. After the experiment, the animals will be killed to collect their tissue for histological or physiological analyses.

Why can't you use animals that are less sentient?

Mice represent the most suitable experimental animal model of obesity and stem cells for the following reasons. First, there is a large body of knowledge on the physiology, dietology and stem cell biology of the mouse central nervous system. Second, there is a wide range of genetically modified lines, which allows technical flexibility and refinement. Third, mice are regarded as being of lower sentience compared to other mammals with digestive tracts closer to humans such as pigs or with nervous system like humans such as primates. Because we will study the effects of environmental interventions such as altered diets on adult brain, we cannot use more

immature or anaesthetised animals. Nevertheless, we will ensure that the best animal welfare possible is maintained. The experimental mice will experience only limited discomfort during the injections. The exposure to obesity-inducing diets is comparable to health and welfare risks that majority of people in the Western society undergo voluntarily. Selected mice will have access to running wheels as a component of the experimental design, which will bring about the positive effects of environmental enrichment to improve the animal welfare.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinements will include frequent monitoring of induced animals, post-operative or anaesthetised animals, or animals on altered diets. Exogenous substances/agents will be administered at the minimum dose, as determined using NC3Rs guidelines for best practice and dosing regimens and following consultation with our collaborators. All procedures will be carried out by trained and experienced staff with the support of experienced animal facility staff/NACWOs/NVS (e.g., application of anaesthesia, analgesics, surgical techniques). Assessment of severity of clinical signs will be based on Clinical Signs Health Check Score Sheet:

Parameter	Animal ID	Score	Date/Time	Date/Time
Appearance	Normal	0		
	General lack of groomin	1		
	Staring coat, ocular and nasal discharge	2		
	Piloerection, hunched u	3		
Food and water intake	Normal	0		
	5% - 15% weight los	1		
	15% - 20% weight los	2		
	Over 20% weight los	3		
Pregnant females (2nd half of pregnancy)	Normal	0		
	Reddening and swelling of vulv	1		
	> 5% weight los	2		
	Vulvar bleeding or > 10% weight los	3		
Natural behaviour	Normal	0		
	Minor changes e.g. lack of nes	1		
	Less mobile and alert, isolatec	2		
	Vocalisation, self-mutilation, restless	3		
Provoked behaviour	Normal	0		
	Minor depression or exaggerated respons	1		
	Moderate change in expected behaviou	2		
	Reacts violently or very weak and precomatos	3		
Movement	Normal	0		
	Partial paresis of any limbs	1		
	Paresis of any limbs	2		
	Paralysis or partial paralysis of any limbs	3		
	TOTAL:			

0-3 = Norma
4-8 = Monitor carefully, consider analgesic
9-12 = Provide relief, observe regularly. Seek advice of NACWO and/or NV
For mild protocols: score of 10 or greater = Kill by a Sch 1 metho
For moderate protocols: score of 12 or greater = Kill by a Sch 1 metho

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

This project will be carried out in collaboration with national and international researchers, who are experienced, have excellent track records and are world renowned leaders in stem cell biology, obesity and the use of

genetically altered mouse models.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Engage with NC3Rs representatives on a regular basis via local workshops/meetings, newsletters and social media.

Home Office

NON-TECHNICAL SUMMARY

166. Robustness of molecular programs driving cellular differentiation

Project duration

5 years 0 months
Project purpose

- (a) Basic research **Key**

words

cellular differentiation, embryogenesis, haematopoiesis, robustness, gene regulation

Animal types	Life stages
Zebra fish	embryo, adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to understand how individual gene regulators contribute to the robustness of cellular differentiation during zebrafish blood development.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our body consists of numerous different cell types that all fulfil specific functions. Cellular differentiation is the process by which these mature cells arise from immature precursor cells. While all precursor cells carry the same genetic information, each of them makes differential use of this information as it gives rise to a specific cell type. The gene regulatory network that is hard-wired in our genome determines the differentiation options of the precursor cells. It defines the target genes that a particular regulator can activate. Which part of the network is activated in a particular cell depends on prior gene expression (intrinsic factors) and on influences from outside the cells (extrinsic factors). As a cell differentiates it moves from one regulatory state to another. As it enters a new state, the cell not only activates a new set of genes, it also extinguishes the previous state and suppresses alternative options. Gene activators are needed to push the cell forward while gene repressors prevent cells from slipping back or taking alternative molecular trajectories. Together, they confer robustness to cellular differentiation and determine the pace of the process. Failure to establish or maintain robustness can lead to cellular deficiencies and cancer. Therefore, understanding how robustness is established and maintained is vitally important. In the short run, the project will provide a deeper understanding of the molecular programming of cellular differentiation. In the long run, patients may benefit from the basic knowledge generated during this project. It is reasonable to assume that the personalised medicine of the future will focus heavily on disease prevention. It will try to weigh the impact of genomic sequence variations
on the future health of the patient. It will also want to judge the suitability of donor cells used in regenerative medicine. This project will contribute to the development of a knowledge base that is needed to make such evaluations.

What outputs do you think you will see at the end of this project?

The idea of the project is to gain a better understanding of the molecular programme that drives differentiation in various cell types and the role that particular molecular players play in this process. We will learn more about the way that these players interact to ensure the robustness of the differentiation process. Because some of these molecular players are known to be involved in various types of cancers our data will also provide new insights into pathways that lead to cancer. The datasets that we will generate will be deposited in public databases. The conclusions drawn from the papers will be presented at scientific conferences and will be published in peer-reviewed journals. The reagents and genetically modified fish lines will be made available to other researchers in the field.

Who or what will benefit from these outputs, and how?

Our findings will be interesting to developmental biologists who want to gain a better understanding of cellular differentiation. Our work will focus mainly on blood cell development. Thus, scientists and clinicians working in haematology will benefit from our findings. Our data will also be interesting to scientists and clinicians in the field of oncology because many of the genes that we work on have been implicated in cancer. All beneficiaries will have access to the datasets that we will deposit in public databases. Reagents and genetically modified fish will be available on request. All publications on original data will be accessible through open access.

How will you look to maximise the outputs of this work?

Data from the study will be published in peer-reviewed, high profile, scientific journals and presented at local, national and international conferences. Data will also be publicised through the establishment's web page and in public engagement exercises. This study does not propose to develop new techniques. Thus, unsuccessful experimental approaches are not expected. It is, however, possible that the results reject our hypotheses. Such results will be discussed as part of a paper that supports a different interpretation.

Species and numbers of animals expected to be used

- Zebra fish: We estimate that we need to maintain about 19,600 adult fish in our breeding programme: 1,600 for the generation of new lines and 18,000 for the maintenance of old lines.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We want to study the differentiation of blood cells in their natural environment and shed light on the roles that molecular players, like the Gfi1/1b repressors, the epigenetic regulators Tet1-3 and two newly identified long-noncoding RNAs play in this process. We are using zebrafish embryos as our model system. Most experiments will be performed on embryos up to day 5, the point when they become freefeeding and fall under the regulations of ASPA.

Typically, what will be done to an animal used in your project?

To generate transgenic and genetically modified zebrafish, early stage embryos will be injected with DNA, RNA or proteins. Injected embryos may be anaesthetised to assess their phenotypes, i.e. to see whether they express the reporter transgene and whether they develop a normal swim bladder. Phenotypically normal zebrafish will be allowed to grow beyond the time point when they become freefeeding. This is when they become protected by Animal (Scientific Procedures) Act 1986 (ASPA). We expect to raise up to 1,600 fish over a period of 5 years to generate the genetically modified lines that we need for our experiments. Once the injected fish reach sexual maturity we will check whether they carry the transgene/genetic modification in cells of their germ line. For this purpose, we will cross the fish and collect embryos that we will examine for the presence of the transgene/genetic modification. Progeny that carry the genetic modification will be raised to adulthood. They will found a new line of genetically modified zebrafish. Newly generated and previously established lines are maintained on the breeding and maintenance programme. Fish on this programme may be anaesthetised and finclipped for genotyping purposes at embryonic or adult stages. They may also be anaesthetised at larval stages to assess their phenotypes, e.g. study the expression of a transgene or verify their normal phenotypes. Most fish will carry a single copy of the transgene or modified gene allele, i.e. will be heterozygous carriers. To study the impact of a particular genetic modification on cellular development, heterozygous carriers are incrossed to generate homozygous carriers, i.e. embryos with two copies of the modified allele. These embryos/larvae will be subject to experimentation up to day 5. Experience tells us that we need 18,000 fish on the breeding and maintenance programme to have enough breeding pairs of males and females for the lines that we need to keep over the 5 years of this licence. In cases, where homozygous larvae or larvae with new combinations of mutant alleles are phenotypically normal on day 5, homozygous larvae may enter the breeding and maintenance programme and be raised to adulthood.

What are the expected impacts and/or adverse effects for the animals during your project?

Injection of DNA, RNA and protein may cause embryos to show abnormal phenotypes. Likewise, homozygous carriers of mutant alleles and carriers of new combinations of mutant alleles may display abnormal phenotypes. Larvae that show abnormalities will not be allowed to develop beyond the freefeeding stage. Larvae that are normal on day 5 may be raised to adulthood. In rare cases, such larvae may develop persistent abnormalities later. These animals will then be killed by an S1 procedure. In very rare cases, fin clips used for genotyping may lead to persistent and/or significant infections. These animals will also be killed by an S1 procedure. Animals may also transiently experience deteriorating water quality when being kept in isolation and off the recirculating water system. To minimise negative effects, animals will be kept off the recirculating water system for a

maximum of 24 hours.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals (about 66%) will show sub-threshold symptoms. Experience tells us that up to a third of animals will be fin-clipped for genotyping. These will experience mild and transient symptoms (about 33%). Rarely (<1%), animals (like homozygous carriers of a modified gene allele or carriers of new combinations of modified gene alleles) that are phenotypically normal on day 5, may develop more severe, i.e. moderate, symptoms at a later time point. Persistent and/or significant infections cause symptoms of moderate severity. These are very rare (<1% each).

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

In vertebrates, cell fate specification and cell differentiation heavily rely on the cell's interactions with its neighbours in the embryo.

Which non-animal alternatives did you consider for use in this project?

One may argue that cellular differentiation could be studied in cell culture experiments.

Why were they not suitable?

However, faithful reproduction of in vivo cell-to-cell interactions is extremely difficult in cell cultures, if at all possible. Furthermore, the generation of cells with the correct experimental and control genotypes is not feasible.

By focussing our work on early stage zebrafish embryos, we are achieving what is considered to be a partial replacement of animal work. Juvenile and adult stage zebrafish will mainly be used for breeding purposes. Occasionally, they will also be used as tissue sources after terminal anaesthesia.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

On the breeding programme, we maintain existing genetically modified lines. We aim to maintain a good balance of males and females for each of the modifications to be able to derive homozygous embryos from incrosses of heterozygous male and female parents. Unfortunately, sex determination in domesticated zebrafish lines does not involve sex chromosomes. Instead, it is polygenic and complex, and can be subject to environmental influences, in particular temperature, food availability and stocking density (Kossack and Draper, 2019, Curr. Top. Dev. Biol., 134, 119-149). Thus, female/male ratios in offspring can vary widely from batch to batch, even if the parent fish involved are the same. This makes power calculations and statistical modelling impossible and forces us to rely on experience. On this licence, we want to maintain 60 different established lines of genetically altered fish over 5 years. To have enough breeding pairs of males and females, experience tells us that having 60 fish per line in our aquarium at any time is sufficient to achieve this goal. The overall number of fish required is therefore: 60 lines x 60 fish x 5 years = 18,000 fish.
Tol2 transgenesis and CRISPR/Cas9 targeting experiments are performed to achieve a particular goal, the generation of a genetically modified line. Success rates vary considerably in goal-directed experiments and can, therefore, not be modelled statistically using power calculations (Dell et al., 2002, ILAR J. 43 (4), 207-213). There are 2 sources of variability in our experiments. Firstly, the success rate varies with the type of genetic modification that we want to generate. For example, the generation of a simple small insertion/deletion (indel) mutation at a single CRISPR/Cas9 target site is easier to achieve than the deletion of a 10 kb DNA fragment between two target sites. Secondly, germline transmission can vary considerably. Successfully injected embryos are mosaic for the modification, and germline transmission is difficult to predict. Because we cannot use statistical modelling, we rely on previous experience to calculate animal numbers. Assuming that we will (a) generate 20 new transgenic or mutant lines over 5 years and (b) grow up an average of 80 injected larvae per experiment to find transgenic/mutant founders, we will need 1,600 animals overall.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs experimental design assistant is used. Furthermore, advice is taken from local statistics experts.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In transgenesis and genome editing experiments, we aim to minimise the number of injected animals that we grow beyond the free-feeding stage. We will achieve that by carefully assessing and optimising the success rate of transgene integration and genome targeting in the soma of injected siblings at embryonic stages. Whether the modification is also present in the germline cannot be judged at this stage.
We will use pilot studies to grow up animals with new combinations of genetic modifications that could reasonable be assumed to cause deficiencies. Initially, 5 experimental and 5 control embryos will be grown up in parallel.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

To be able to transfer insights gained in our experiments to the situation in humans we need to use a vertebrate model organism. Zebrafish is already the least sentient vertebrate model organism that is regularly used in project like ours.

Why can't you use animals that are less sentient?

Most of our experiments will be performed on the most immature life stages, i.e. up to 5 days post fertilisation. These stages are not covered by ASPA. Fish larvae that display obvious abnormal phenotypes on day 5 will not be raised beyond day 5. Adults may serve as source of tissues after terminal anaesthesia.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We previously optimised our fin clipping procedure. We carefully titrate up the anaesthetic until we are convinced that the correct anaesthetic depth is reached before the fish is removed from the water and fin-clipped.

We have considered to use low-dose lidocaine immersion to aid perioperative analgesia (Schroeder and Sneddon (2018) Applied Animal Behaviour Science 187 (2017) 93–102). Unfortunately, the data presented in this paper provide insufficient experimental evidence of its efficacy. On the basis of these data, we cannot justify the exposure of our fish to an additional treatment. We will keep an eye on further developments and reconsider the use of analgesia when better evidence becomes available.

We recently tried to use the published skin swabbing protocol (https://www.nc3rs.org.uk/quantifyingpotential-skin-swabbing-refinement-dna-sampling-laboratory-fish) in parallel to fin-clipping to collect genetic material from 10 animals after S1. Performing the experiment after S1 allowed us to swab extensively, giving us the best chance to get an optimal yield of cells. DNA was prepared and PCR amplified from the swab and fin-clip samples. While the fin-clip samples gave us unambiguous results for 10/10 samples, the swab experiment yielded clear data in only 5/10 cases. This result is not satisfactory. We are happy to keep reviewing alternative methods.

Earlier this year, we introduced two changes to reduce the time it takes to genotype the fish and, thus, the time that fin-clipped fish need to be kept in isolation. Firstly, we now keep fin-clipped fish in a fish grid tank rather than in individual tanks. This reduces the time we spend on labelling and handling tanks. It allows us to move to the DNA extraction more quickly. The fish may also appreciate seeing their siblings in neighbouring compartments. Secondly, we are in the process of speeding up our DNA extraction procedure by replacing an overnight incubation with a 30 min procedure. As this procedure yields lower quality DNA we are currently testing the extracted DNA in all of the different genotyping PCR experiments. We have seen that the DNA is good enough for our most reliable PCR assays. Others still need to be tested.

Larvae that carry a novel combination of gene alleles will initially be raised in small numbers (5 experimental and 5 control larvae) in pilot experiments. These will typically be monitored twice daily be the personal animal holder.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The most up-to-date guidance on zebrafish housing and husbandry was published in July last year. The paper by Aleström et al summarises recommendations from a working group that consisted of members of the European Society for Fish Models in Biology and Medicine [EUFishBioMed] and the Federation of European Laboratory Animal Science Association [FELASA]. Basic methods on zebrafish embryo handling are described in the Zebrafish book that is published online on the zfin.org web page (http://zfin.org/zf_info/zfbook/zfbk.html). We use the CRISPR-Scan track on the UCSC genome browser to identify suitable, high efficiency targets for CRISPR/Cas9 (Moreno-Mateos et al., 2015). CRISPR/Cas9 experiments follow the protocol published Hwang and colleagues (2013). We have replaced Cas9 mRNA with Cas9 protein injection to achieve gene editing at earlier stages to reduce mosaicism in the injected embryos and increase the chance of germline transmission. These embryo injections follow standard procedures. The fin-clips and DNA extractions are performed as published by Wilkinson and colleagues (2013).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Information and guidance published on nc3rs.org.uk, felasa.eu, zfin.org and eufishbiomed.eu are very useful. We also follow novel developments that are presented at national and international zebrafish meetings. The 3-minute-3Rs podcasts published on the NC3Rs web page are also a great source for new ideas, as is the information on the F1000 NC3Rs and the EURL ECVAM web pages.

Home Office

NON-TECHNICAL SUMMARY

167.Rodent models of heart failure progression

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cardiac hypertrophy, Heart failure, Trans-aortic constriction, Sumoylation

Animal types	Life stages
Mice	adult
Rats	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The purpose of this project is to generate rat and mouse models of heart wall thickening and heart failure using surgical techniques to constrict the major blood vessel that exits the heart (i.e. transverse aortic constriction (TAC) procedures). We aim to use these models to better understand the molecular processes underlying the progression of heart disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The incidence of chronic heart failure in the UK is increasing, however the underlying causes are not fully understood, and more effective treatments are necessary.

This project will allow us to better understand the molecular genetic processes underlying heart failure development and aid in the identification of novel therapeutic targets.

What outputs do you think you will see at the end of this project?

Outputs from this project will include increased knowledge in the field of heart disease and identification of novel therapeutic targets.

The results of the project will be presented at scientific conferences and will be written up and published in peer-reviewed scientific journals. The data generated will also be used to support future grant funding applications.

The unique KO rat model, and/or stored biological samples generated from these studies will be made available to other scientists in the field, on request.

Who or what will benefit from these outputs, and how?

The expected benefits arising from this project are multi-fold and will be in relation to both the advancement of scientific knowledge (short-medium term) and further to potential clinical translation of novel therapies (longer term).

Molecular investigations of the target genes and proteins identified in our studies will lead to a better understanding of the mechanisms responsible for development of changes in heart wall thickness (cardiac hypertrophy) and heart failure. This novel information will allow us to develop new therapeutic

strategies to prevent or reverse the underlying pathophysiological processes, which are suitable for clinical application.

Specifically, utilisation of the TAC procedure in our unique rat models will allow us to confirm the role of target genes in cardiac hypertrophy and heart failure progression and will provide a platform for investigating the underlying pathogenic processes and development of novel therapeutic interventions.

The TAC model in the mouse will be used to examine the impact of specific protein modifications (sumoylation)that are critical for normal heart function. It is hypothesised that the sumoylation process is a natural protection mechanism by which cardiac proteins can be stabilised during heart failure. Confirmation of this process would be of enormous benefit for future clinical applications e.g. therapeutic strategies and screening.

These outputs will be of benefit not only to my own research group and my clinical and basic science colleagues at my research institution, but also to my network of national and international collaborators and to other researchers in this field, through dissemination of the results in published papers and scientific conferences. Information from these pre-clinical studies will inform future clinical studies, where the ultimate beneficiaries will be heart disease patients who will receive improved diagnosis and treatment.

How will you look to maximise the outputs of this work?

The results from this project will be disseminated to the cardiovascular research scientific community through presentation at national and international scientific conferences, publication in peer reviewed scientific journals and through our local and international collaborative network.

Dissemination of data from studies with negative or neutral outcomes will still be possible since publication of neutral and negative studies is now being actively encouraged by some journal editors.

Species and numbers of animals expected to be used

- Mice: 200
- Rats: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

In this project we will use juvenile and adult rats and adult mice. These models have been carefully selected based on their unique genetic profiles. Some of the animals we use will have already established (spontaneous) hypertension. These animal models will allow us to determine the direct contribution of specific genes and proteins to the progression of heart disease and heart failure.

Previous studies with our rat model of hypertension have shown contrasting levels of expression of our gene of interest during early and adult stages, therefore we aim to study the impact of this differential gene expression on cardiac hypertrophy and heart failure development using both juvenile and adult rats.

Typically, what will be done to an animal used in your project?

During this project we will generate reproducible models of cardiac hypertrophy and heart failure in rats and mice in order to mimic the equivalent human disease. We will examine the mechanisms of heart disease progression in control animals and in animals which have been genetically modified to alter specific genes or proteins that may play an important role in the disease process.

The transverse aortic constriction (TAC) surgical procedure (i.e. permanent constriction of the major blood vessel from the heart) will initially cause an increase in blood pressure and heart size, which are not expected to result in any adverse clinical signs. However, over time the increased load on the heart, as a result of continued elevated blood pressure, will become detrimental and the heart will begin to lose its ability to function normally. We will monitor these structural and functional changes in the heart by echocardiography repeated at regular intervals during the pre- and post-surgery period. Echocardiography is a non-invasive method requiring brief anaesthesia for imaging purposes. Blood pressure will be monitored by non-invasive means on a weekly basis. Typically, animals will remain on procedure for up to 12 weeks (with a maximum limit of 16 weeks post-surgery). Any animal displaying signs of heart failure will be promptly and humanely killed.

During these TAC studies we may include optional steps where diet is modified, drugs are delivered, or expression of specific genes is altered in order to modify the heart disease processes. This will allow us to investigate potential therapeutic strategies. These studies may involve collection of blood and urine samples at regular interval during the pre- and post-surgery period.

What are the expected impacts and/or adverse effects for the animals during your project?

The TAC surgical procedure will initially cause an increase in blood pressure and heart size, which are not expected to result in any adverse clinical signs. However, over time the increased load on the heart, as a result of continued elevated blood pressure, will become detrimental and the heart will begin to lose its ability to function normally. All animals undergoing TAC surgery will be carefully monitored on a daily basis and any animal displaying signs of heart failure will be promptly and humanely killed.

Pain (100%). All animals will experience pain as a result of the surgical procedure. Analgesics will be given in consultation with the NVS for as long as necessary.

Anaesthetic death (1%).

Weight loss from repeated anaesthesia (1%).

Decreased palatability (1%) and weight loss (1%) as a result of dietary manipulation. Although the special diets are not expected to produce any major short-term weight loss or adverse clinical effects in rats or mice (other than the desired cardiovascular modification), palatability issues may result in gradual weight loss over longer intervention periods (e.g. 2 weeks or longer). Body weight will be

monitored at regular (typically twice weekly) intervals. Body condition scoring will be implemented if palatability issues are anticipated for specific diets.

We may use modified viruses to alter gene expression in our animal models. Acute toxicity to the maximum virus dose in our in-house colony of rats (5%). Sensitivity may be increased in rats from external sources (i.e. bought in from commercial suppliers). Acute toxicity is not anticipated in mice.

Sudden death due to stroke in the hypertensive stroke-prone rat model (6%)

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The TAC procedure is classed as moderate. 100% of animals will undergo either TAC or sham surgical procedure.

An improved (minimally invasive) method of transverse aortic constriction will be used in order to limit surgical complications.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The nature and complexity of the heart disease process makes finding alternatives to live animal models extremely difficult. Although in-vitro models are available to examine molecular mechanisms underlying heart cell size responses, there are limitations associated with interpretation of results from these models. These cells are mainly derived from new-born animals and therefore results may not be predictive of the cellular response in-vivo in the adult heart. Usually, a single cell type will be grown in isolation (e.g. cardiomyocytes, cardiofibroblasts), whereas in the in-vivo situation, different cell types develop together and function as units. Also, in-vitro systems have no blood supply, whereas in-vivo the circulation can contribute to the heart disease process by providing a pathway for disease causing molecules between the heart and the rest of the body. Therefore, it is important to understand the disease mechanisms in intact organisms, which show similar cardiovascular physiology to humans.

Which non-animal alternatives did you consider for use in this project?

Where possible we use non-sentient alternatives to live animals. For example, cell culture has replaced the use of animals in some of our functional analysis studies of candidate genes and gene networks and protein/protein interaction studies. Furthermore, we use cell culture to develop and optimise the virus gene delivery system in our gene transfer procedures before in-vivo testing is carried out.

To simulate some of the greater complexity of the whole heart, another consideration is the use of an organ-on-a-chip (OOC), which is a multi-channel 3-D microfluidic cell culture chip that can mimic the functions of human organs. This technology can provide a more detailed and more physiological approach than cell culture studies based on a single cell type. Whilst heart-on-a-chip systems are routinely used for drug efficacy screening, appropriate in-vitro model systems of human heart failure that fully recapitulate the essential changes and cardiac mechanisms seen in the disease are still in the developmental stage.

Human heart cells are difficult to obtain and can only be maintained in culture for a short period of time and are therefore not suitable as a robust testing model.

Why were they not suitable?

Although complementary cell-based assays can provide important detailed information on intracellular mechanisms and will be used alongside our rat and mouse studies, they cannot fully replace the use of live animals for investigation of heart disease progression where an intact cardiovascular system is necessary.

There are limitations associated with interpretation of results from in-vitro models. The heart cells used in these in-vitro models are mainly derived from new-born animals and therefore results may not be predictive of the cellular response in-vivo in the adult heart. Usually, a single cell type will be grown in isolation (e.g. cardiomyocytes, cardiofibroblasts), whereas in the in-vivo situation, different cell types develop together and function as units. Also, in-vitro systems have no blood supply, whereas in-vivo the circulation can contribute to heart disease process by providing a pathway for disease causing molecules between the heart and the rest of the body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Initial pilot studies have been conducted (under authority of a previous licence) to establish the lowest appropriate group sizes for investigation of cardiac function and hypertrophy in the rat and mouse TAC models. Estimated numbers of rats and mice have been based on these group sizes for the appropriate comparison of treatment and control groups using a randomised block design.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Expert statistical advice has been obtained from our Institute Statistics Department and online tools (e.g. NC3R's Experimental Design Assistant) have been utilised during the experimental design phase of this project. For all our studies we follow ARRIVE guidelines to ensure good laboratory practice and transparent scientific reporting.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The steps in the protocol have been chosen to provide the maximum detailed information necessary to address our research questions whilst at the same time ensuring that the animals under investigation experience the least pain, suffering, distress or lasting harm.

Use of methods that permit serial measurements in the same animal allows for optimisation of the number of animals we plan to use. For example, echocardiography permits a range of cardiac parameters to be determined at a number of different time-points, non-invasively in a single animal. The ability to carry out serial imaging allows the investigation of the evolution of heart disease and the potential influence of dietary, or drug or gene transfer interventions to be carried out in a single group of animals removing the need for multiple groups of animals to be humanely killed at each time point. This also increases the statistical power of the studies whereby the effect of an intervention can be assessed in the same animal over time. Also, since data for each time point come from the same group of animals, there is reduced variability in the data sets and consequently smaller group sizes are required when power calculations are carried out for study design.

Any tissues harvested when the animals are killed at the end of the study, that are not used for the purposes of this specific project, will be processed and stored for use in future studies by ourselves or will be made available to our collaborators.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and mice will be the only species used in the project.

The TAC procedure is classed as moderate and we will utilise improved (minimally invasive) transverse aortic constriction procedures to induce cardiac hypertrophy, which do not require surgical incision into the chest wall, intubation and mechanical respiration. All surgery will be carried out or supervised by highly skilled and experienced personnel. However, even with experienced hands, there is a risk of surgical complications and death during TAC surgery, especially in mice. We are committed to minimising these as much as possible and are exploring ways to reduce complications by exchanging

experience with other groups and by discussion with the NVS. Analgesics will be administered during all surgical procedures in consultation with the NVS, and for as long as necessary during the recovery phase.

Why can't you use animals that are less sentient?

Mice are the lowest vertebrate group in which the process of chronic pressure overload and hypertrophy in the heart can be fully interrogated. The TAC procedure is limited to adult mice or juvenile and adult rats due to the demanding surgical skill requirements. With current technology, it would not be possible to miniaturise the procedure to use in a more immature life stage. The procedure cannot be conducted in terminally anaesthetised animals because the process of cardiac hypertrophy and cardiac dysfunction develops over a period of weeks.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals that have undergone TAC surgery will be monitored on a daily basis for signs of pain, to check wound appearance and to monitor for clinical signs of heart failure. Any animal giving rise to concern will be scored according to a numerical scoring sheet for pain/discomfort/distress in mice & rats, and if necessary will be humanely culled.

Regular non-invasive monitoring by echocardiography will typically identify detrimental changes in heart function prior to the development of clinical signs.

To reduce stress, animals will be acclimatised for short periods in metabolic cages and will be familiarised with the blood pressure recording procedure prior to the actual measurement phase of the study.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice guidance published by the NC3Rs and the Laboratory Animal Science Association (LASA), as well as adhering to ARRIVE guidelines for appropriate transparent reporting of our research outputs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Project Licence holder and members of the research team will ensure continued professional development in the 3Rs area through regular attendance at meetings/workshops such the Animals in Science Regulation Unit (ASRU) annual meeting, 3Rs workshops/ symposiums held at local or national Research Institutes, and also attendance at local training workshops organised by the NTCO.

NON-TECHNICAL SUMMARY

168.Role of platelets in cardiovascular disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

heart, HIV, pollution, cardiovascular

Animal types	Life stages
Mice	adult, neonate, pregnant, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how substances produced naturally by the body or introduced to the body deliberately as medication or accidentally as pollution may increase or decrease the risk of heart diseases such as a heart attack.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Although much is known about heart disease, the causes are not fully understood and many therapies are not fully effective so that heart disease remains the biggest cause of death and ill-health in much of the world. In addition, because HIV is now treatable, people living with HIV grow old and develop heart disease. There is evidence that they are more susceptible to heart disease and this may be linked to side-effects of drugs used to treat HIV. Our work will also allow us to understand the side effects of drugs used to treat e.g. HIV so that these drugs can be made safer. In addition, we shall understand which components of pollution increase the risk of heart disease so that steps can be taken to reduce human exposure to these pollutants.

What outputs do you think you will see at the end of this project?

We will generate new information in the form of data sets that will be published in scientific journals and presented at scientific conferences that will provide better understanding of the processes of heart disease. We will produce data relating to which pollutants are most harmful to human health and which drugs used in the treatment of HIV are least likely to increase the risk of heart disease.

Who or what will benefit from these outputs, and how?

During the course of this project we shall increase understanding of the causes of heart disease in the general population as well as specific communities. Our work will open up new avenues of research and so will benefit the scientific research community, especially scientists and clinicians with an interest in heart disease and/or HIV. Our work in the field of pollution will benefit organisations such as the British Heart Foundation who are interested in raising public awareness of air pollution and it will be of benefit to vehicle and fuel manufacturers who wish to make their products less toxic. Our work in the HIV field will be of benefit to clinicians treating patients and those involved in setting clinical guidelines as well as patients themselves as we cause therapies to have fewer side-effects.

How will you look to maximise the outputs of this work?

We will continue to communicate our research via social media and through internal and external outreach events. We also publish and communicate our work through a range of scientific networks so that we reach a wide target audience. We also have established contacts in the pharmaceutical industry and HIV patient groups who will be updated on our research. We shall publish all of our data. Where data is not suitable for conventional journals, we shall use open access online platforms. We shall also disseminate our findings via charity networks such as the British Heart Foundation and HIV charities as well as environmental groups. This will in part be achieved by engaging with their social media channels.

Species and numbers of animals expected to be used

- Mice: 2000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using adult mice as we need to work with a mammalian species that can be genetically altered and which mimics the combined effects of the lungs, heart, immune system, liver, blood and blood vessels. We work with adult mice as we need these organs and systems to be mature and we need an animal that is physically large enough to monitor.

Typically, what will be done to an animal used in your project?

Animals that are genetically altered will be bred and then injected with experimental substances usually once but occasionally more often. Some animals may be anaesthetised once and have substances such a pollutants introduced into the lungs via a tube in the airways Animals will undergo procedures involving measurement of blood clot formation under general anaesthesia to determine the effects of experimental substances on this process. Animals will be killed at the end of the procedure without regaining consciousness.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals are expected to feel only brief discomfort due to injection.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity level is mild for all animals.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal studies are required because we need to assess the combined effects of substances upon the heart, blood vessels and immune system . This cannot be replicated artificially and so animal studies are required. In addition, we need to deliver substances to blood in a manner that replicates human exposure. This sometimes requires delivery of substances to the lungs of living animals to replicate inhalation and, at other times, the administration of drugs that need to pass through the liver before becoming active.

Which non-animal alternatives did you consider for use in this project?

We have considered analysis of human cells from donated blood and clinical studies using human volunteers. We will use these models in some of our studies but they are not always suitable.

Why were they not suitable?

Studies with human blood do not mimic inhalation and drugs may not be processed to their active form as they are by animals and humans. It is not always possible to administer drugs to human volunteers for ethical reasons and in the field of HIV it is not possible to stop drug treatment in patients as they will become ill as HIV reactivates in the body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have estimated mice based on the anticipated numbers of experiments, the numbers of experimental groups and the numbers of mice in each group. The estimates are based on similar studies we have conducted in the past using similar protocols.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We use the NC3Rs Experimental Design Assistant and consult with the college Statistical Service to design experiments with the fewest animals. We also collect tissues and measure cardiovascular function in the same animals to reduce animal numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Where possible, we induce responses that are entirely reversible. This allows us to assess multiple responses in an individual mouse (e.g. before and after administration of test reagents reduces mouse use by 50%). In some experiments, we are also able to obtain several responses in individual animals which reduces mouse use by greater that 50%.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Animal suffering is minimised by conducting protocols under terminal anaesthesia. This is a refinement of the original methodology which involved death as an endpoint and inflicted considerable pain and suffering. We regularly test for effective anaesthesia during procedures by assessing the toe pinch reflex and administering additional anaesthesia if necessary. There is the potential for suffering when substances are administered to conscious animals or temporally anaesthetised animals prior to terminal procedures. Suffering is minimised by careful aseptic technique and administration of substances by skilled scientists.

Why can’t you use animals that are less sentient?

Most procedures are conducted under terminal anaesthesia. When substances are administered before the main experimental procedures, it is usually less painful to do so in conscious animals rather than giving an anaesthetic from which the animal recovers. We need to work with mice because we need to work with mammals since they have lungs, immune systems and liver function that are similar to humans. We also need to work with adult animals as we need a fully developed cardiovascular system and we need to work with animals that are fully grown from a practical perspective.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

When animals are recovering from anaesthesia they will be monitored continuously for signs of distress and will be kept warm using a recovery box. Animals receiving injections will be monitored daily by the PIL holder. Where problems arise, we shall consult the NACWO and veterinary surgeon and offer pain relief, treatment or cull animals as appropriate.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

LASA guidelines and ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The license holder is very experienced in 3Rs research and regularly attends NC3Rs organised events. He makes efforts to keep up to date on 3Rs best practice and advances.

Home Office

NON-TECHNICAL SUMMARY

169. Small animal models for investigating SARSCoV-2 pathogenesis and for evaluating antiviral compounds

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Coronavirus, SARS-CoV-2, Pathogenesis, Antivirals, Therapy

Animal types	Life stages
Mice	juvenile, adult
Hamsters	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

1. To study SARS-CoV-2-associated pathogenesis in hamster and mouse models.

2. To evaluate the efficacy of known and experimental antiviral drugs and antibodies in these models

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) is responsible for the coronavirus disease-2019 (COVID-19). This virus emerged in late 2019 in China and spread rapidly across the world causing a pandemic. The virus has caused over 600,000 deaths so far world-wide. The most important clinical features of COVID-19 are pneumonia with fever, cough and difficulty with breathing. The virus infects cells in the lung and triggers an adverse immune response (cytokine storm). Severe disease can also affect multiple organs of the body. To date there is no vaccine or antivirus treatment available, and they represent a priority area of research for the global control of the pandemic.
The virus can infect human or animal cells in culture, and such infection systems are proving useful in advancing our knowledge on the basic processes related to the molecular biology of the virus. On the other hand, the availability of (and accessibility to) animal models is limited. Animal models that mimic human disease are crucial in studies on the processes and factors that lead to the occurrence of the disease, and in the assessment of the potency of antiviral compounds which is an essential step in a drug development pipeline.
Here, our aim is to establish hamster and mouse models to investigate SARS-CoV-2 pathogenesis and to evaluate in them the efficacy of antiviral compounds that are under development both at our Institution and elsewhere.

What outputs do you think you will see at the end of this project?

Objectives 1 and 2: We hope to gain new insights into the biological mechanisms of virus infection and spread in the host organism. It is not clear how the virus spreads in the host and what cell types are affected by the infection. We also hope to gain enhanced understanding of the basic pathology in tissues, of how viral and host factors modulate host immune and inflammatory responses, and how the complex interplay between them contribute to COVID-19 disease.
Objective 3: There is an urgent need for an effective therapy for COVID-19. Animal models are essential for pre-clinical assessment of promising new therapeutics. The drug/antibody efficacy assessment studies planned herein will allow us to identify lead compounds that can be taken forward for clinical end-use. Our studies will identify potential drug-and antibody-resistant viruses and assess them in our efficacy model. This will inform future treatment options (e.g. use of drug or antibody combinations) that would mitigate the effect of resistance-associated mutations.
The results of our study will be disseminated in the form of publications, presentations at meetings, and through

press releases and other social media platforms.

Who or what will benefit from these outputs, and how?

These research outputs will be published in leading interdisciplinary journals so that they can be used by a variety of research and health professionals. The short-term benefits will primarily be specific to scientific researchers investigating the COVID-19 disease. Medium to longer term beneficiaries will include drug developers and clinical teams who will be able to use these new insights to further develop novel and more rational therapeutic and patient management strategies to reduce disease burden.
The insights gained will eventually be translated to the human context in collaboration with our local clinical colleagues. In addition, through interactions with colleagues in pharmaceutical companies, we will actively seek opportunities to use the knowledge gained to further develop novel therapeutic approaches.

How will you look to maximise the outputs of this work?

We will have extensive collaborations with medicinal chemists, virologists, and pharmaceutical partners. We will disseminate new knowledge in the form of publications, presentations at meetings, and through press releases and other social media platforms.

Species and numbers of animals expected to be used

- Mice: 1000
- Hamsters: 1000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Small animals such as mouse and hamster have been reported to be suitable for studies with SARSCoV-2. Standard golden Syrian hamsters are susceptible to infection with the virus and present clinical features resembling those found in human patients, including contact transmissibility. While standard laboratory mice are resistant to infection by a natural isolate of SARS-CoV-2, they can be infected with a mouse-adapted mutant virus. Furthermore, mice that express human angiotensin-converting enzyme 2 (hACE2) protein, a host receptor essential for virus entry into target cells, can be infected with a natural isolate of the virus.
The choice of juvenile and adult life stages is based on published reports describing their suitability for this type of study.

Typically, what will be done to an animal used in your project?

Animals will be infected via intranasal route with SARS-CoV-2 virus. In some cases, normal mice will first be given a dose of a harmless adenovirus that express the human ACE2 protein prior to infection with SARS-CoV-2.
In protocols 3 and 4, animals will be administered with drugs or antibodies prior to, and after, infection with SARS-CoV-2.
Animals will be on procedure typically up to 10 days (in some cases this period could be extended up to 30 days).

At the end of all procedures the animals will be euthanised and tissue and organs will be harvested for analysis as described below.

What are the expected impacts and/or adverse effects for the animals during your project?

Most procedures to be carried out are associated with moderate severity rating. Infected animals are expected to experience weight loss, possibly abnormal breathing, and lung abnormalities that could subsequently progress to more severe form (consistent with severe pneumonia found in human with COVID-19 disease). We do not expect any animal to exceed moderate rating. Any animals showing 3 moderate signs or any single severe sign will be humanely killed. Mice undergoing all procedures will be monitored carefully and regularly by the NVS to minimise distress and suffering.
All substances will be administered at doses known to be non-toxic, based on the availability (in the literature or otherwise) of their toxicity profile, and also based on their *in vitro* cytotoxicity profile.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most procedures to be carried out are associated with moderate severity rating. For both hamsters and mice, we estimate overall approximately 50% of animals experiencing Mild severity and 50% Moderate. We do not expect any animal to exceed moderate rating. Any animals showing 3 moderate or any severe signs will be humanely killed.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Only living animals can exhibit the complex interactions between cells in tissues, the immune system and the virus, which together, help determine how the virus can spread in different tissues and organs, and how it causes the disease Therefore, animal models that mimic human disease are crucial in studies designed to understand the disease process and to test compounds for their ability to inhibit virus infection. Those showing strong inhibition can then be considered for treatment.

Which non-animal alternatives did you consider for use in this project?

SARS-CoV-2 can infect human or animal cells (such as the human epithelial cells A549 or CALU-3 or the monkey kidney cells VERO) in culture. We use such cell culture systems to perform the biological analyses of the virus in the context of infection. We also such systems to perform studies to identify and evaluate potential compounds that can be developed for therapy.

Why were they not suitable?

While these cell-based systems are useful in advancing our knowledge on the basic processes related to the

molecular biology of the virus, they do not mimic many aspects of the complex multicellular environment of tissues and organs of living animals. Only living animals exhibit this.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We propose to restrict the number of animals to a minimum required to provide statistically significant analysis. From previous publications and upon expert advice from bio-statisticians, we will use 3 animals per cage and each cage will represent therefore n=1 experimental unit. Each condition (e.g. dose 1 of drug/antibody “x”) will be tested in n=4 experimental units, referred collectively as a “group”. Hence a group is formed by 4 experimental units (12 animals placed in 4 different cages). Each group will be split in two distinct experiments. The condition is therefore tested initially on 2 experimental units (2 cages, 6 animals) and then repeated independently once in another 2 experimental units giving n=4.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Sought advice from bio-statisticians to determine animal group size. Data from our cell culture work also helped inform experimental design – e.g. the type viruses (WT or mutant) and/or the type and doses of drugs or antibodies to be used. Thus, results collected prior cell culture studies mean a reduced number of animals can be used to resolve questions of pathogenesis using information obtained from in vitro studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have factored in sharing of tissues where appropriate with our collaborators to minimise the number of animals in the study.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use hamster and mouse models in our studies, as they have been reported to be suitable for studies with SARS-CoV-2.
Animals will be infected via intranasal route with SARS-CoV-2 virus. In some cases, normal mice will first be given a dose of a harmless adenovirus that express the human ACE2 protein prior to infection with SARS-CoV-

2.
In protocols 3 and 4, animals will be administered with drugs or antibodies prior to, and after, infection with SARS-CoV-2.
Animals will be on procedure typically up to 10 days (in some cases this period could be extended up to 30 days).
At the end of all procedures the animals will be euthanised and tissue and organs will be harvested for analysis as described below.
The proposed protocols are designed to cause least pain and suffering.

Why can't you use animals that are less sentient?

The animals chosen are the least sentient animals that are suitable for our studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals will be monitored daily and will be humanely killed if necessary, following veterinary advice. We will use local AWERB and other guidelines for dosing and for blood sampling, establishing clear humane endpoints, monitoring animals frequently, not allowing infections to develop into severe illness.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow Home Office and NC3R guidelines and those published such as:
Carbone and Austin (2016) Pain and Laboratory Animals: Publication Practices for Better Data Reproducibility and Better Animal Welfare. *PLoS ONE* **11(5)**: e0155001. doi:10.1371/journal. pone.0155001.
Percie du Sert *et al.* (2020) The ARRIVE guidelines 2.0: Updated guidelines for reporting animal research. *PLoS Biol* **18(7)**: e3000410. https://doi.org/10.1371/journal. pbio.3000410.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Keeping abreast with any new information and guidelines through the NC3R website and through our animal facility. We will constantly liaise with the animal facility staff and attend relevant presentations from them to ensure that we are up to date with the information and that they are implemented.

Home Office

NON-TECHNICAL SUMMARY

170. Somatosensory processing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

somatosensation, spinal cord, brain, nerve

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant
Rats	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project seeks to find ways to further our understanding of painful conditions in order to improve pain relief by studying how injury alters the way in which sensory information is processed in the nervous system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Current pain relief options are only partially effective or patients may not respond at all to treatment and many of the available medications have adverse side effects and/or abuse potential. This poorly managed pain is extremely debilitating and significantly reduces patient quality of life. To develop urgently needed novel therapies we need to better understand the aberrant processing of sensory signals within peripheral nerves, spinal cord and brain. This need is well illustrated by the neuropathic pain that results from damage to nerves by chemotherapy treatment in cancer patients. These conditions can be so debilitating and poorly managed by current therapies that they can result in cessation of life-prolonging chemotherapy treatment.

What outputs do you think you will see at the end of this project?

Sex influences our sensitivity to pain and how we respond to injury. Women are more sensitive to pain and are more likely to develop persistent pain following injury, experiencing more severe symptoms. There is gradually accumulating evidence for sex differences in underlying pain neurobiology but this is poorly understood. Therefore, the proposed research which aims to further our understanding of pain neurobiology, in both sexes, should provide new information that will be required in the longer term to develop and improve pain management for both sexes. It is anticipated that this work will yield exciting data, that will have a significant impact in the field and will be published in high quality Neuroscience or Physiology journals.

Who or what will benefit from these outputs, and how?

Less than 50% of chronic pain patients achieve pain relief but this is often only partial and is accompanied by adverse side effects. For these individuals pain literally dominates their daily existence, drastically reduces their quality of life and markedly impairs their capacity to be independent of family and friends, contribute to the workforce and be an active functioning member of society. Therefore, the proposed research that should provide new information should have a broad impact: i) the scientific community – pain researchers; neuroscientists; ii) health professionals and ultimately their patients iii) the Pharmaceutical Industry iv) Government and policy makers and v) the wider community.

How will you look to maximise the outputs of this work?

Collaboration: I have previously collaborated on translational pain research projects to produce high impact publications that have led to significant publicity (online and print newspapers, medical forums and on television) and current funding applications for an early phase clinical trial. I will similarly exploit findings from the projects proposed over the course of this project licence.

Dissemination of knowledge:

The scientific community – pain researchers; neuroscientists: Publication of results, including negative findings, in high quality Neuroscience or Physiology journals ensuring free Open Access. I will present and organise workshops at national and international meetings.

Health professionals and ultimately their patients: In addition to presentation at national and international meetings where there is significant healthcare professional participation, I will also further this through my active membership of a National Pain and Research Community one of whose founding objectives is to disseminate new, relevant research to clinicians and patients through its annual meeting and community website. The overarching aim of this grouping is to ensure that clinical practice in managing chronic pain is informed by research and that current research in chronic pain is relevant to clinical practice.

The Pharmaceutical Industry: Intellectual property management, licensing and technology and knowledge transfer is supported by a dedicated team within my Institution. It has extensive expertise in the protection of intellectual property arising from research. Regular meetings will be scheduled to discuss developments on this research programme and to ensure that potential outputs are maximised.

Government and policy makers.

I will also continue to the National Pain Research Community, as one of its key functions is to ‘disseminate relevant research findings to health service policy makers, highlighting relevance to future and current policy’. To ensure a direct impact, I have been a member of a Service Improvement Group that reports back to a Government National Chronic Pain Steering Group whose remit is to ensure that clinical practice in managing chronic pain benefits from current pain research that is clinically relevant.

v) The wider community.

The Institution’s Press Office has a strong record of communicating research to the public (both directly and through the media). They have promoted prior work from my lab. It received significant press interest and was covered widely in online and print newspapers, medical forums and on television. Furthermore, I have previously and will continue to contribute to outreach activities such as hosting school pupil laboratory visits.

Species and numbers of animals expected to be used

- Mice: 6000
- Rats: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We study mice and rats because their nervous system and development are very similar to that of humans. Moreover, scientists have created many genetically altered mouse and rat lines that allow us to dissect in fine detail how the nervous system processes sensory information. This will help us to identify how this changes, and leads to debilitating conditions, following tissue injury or nerve damage. We study neonatal, juvenile and adult stages because we wish to understand how this system develops and how it may be altered by injury at these different life stages.

Typically, what will be done to an animal used in your project?

Typically an animal will receive a local tissue injury or injection of a chemotherapy agent which results in nerve damage. To study the changes that this tissue/nerve injury induces within the nervous system, following cessation of the animal - skin, peripheral nerve, spinal and brain tissue will be isolated for anatomical or functional analysis. In some studies, the symptoms that these injuries produce such as hypersensitivity to touch or cold will be assessed by monitoring the animals' behaviour and the ability of pharmacological agents to reduce these symptoms will be assessed. Some studies will be carried out in genetically modified animals to enable in depth analysis of the changes within the nervous system that cause hypersensitivity symptoms that is needed to identify new therapeutic targets.

What are the expected impacts and/or adverse effects for the animals during your project?

Tissue injury will be conducted under general anaesthesia. Following tissue injury and chemotherapy–induced nerve injury animals become hypersensitive to stimuli such as touch and cold. However, these animals feed and drink normally, put on weight normally and do not modify their general behaviour. The duration of these symptoms depend on the type of injury and can range from hours to weeks. However, in all injury models there will be a defined period when symptoms peak and in most studies we will limit investigation to the shortest period feasible. Notably any genetically modified animals used do not have adverse impacts.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Just under a half of animals will be used for establishment, maintenance and production of genetically altered animals of which 1/4 will simply be used for harvesting tissues and will fall will into a subthreshold or mild limit of severity. Generally, most experimental studies will be conducted on mice (~3/4) with a smaller proportion carried out on rats (~1/4). Most experimental animals will be used to study tissue injury with 2/3 experiencing tissue injury (moderate severity) and 1/3 acting as control comparisons (mild severity). A small proportion of experimental animals will be used to study chemotherapy-induced neuropathy with ½ receiving chemotherapy (moderate severity) and ½ receiving a control treatment (mild severity). Animals killed under terminal anaesthesia for extraction of blood but not experiencing any other procedure while alive will be classed as non-recovery but will be relatively few in number.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this work is to further understanding of pain conditions by working out how injury alters the processing of sensory information by peripheral nerves, spinal cord and brain. We aim to identify the connections within this system that malfunction in these conditions with the aim of improving the development of pain relieving medications. We therefore need to conduct these studies in a species that develops these symptoms and has a comparable sensory nervous system with similar complexity.

Which non-animal alternatives did you consider for use in this project?

In vitro cell culture or theoretical modelling

Why were they not suitable?

The normal functioning and wiring of this system is not as yet fully understood and so these pathways cannot be modelled in vitro or theoretically, so there is no feasible alternative that would entirely replace the use of a living animal

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals has been estimated based on experience gained under my previous Home Office license. In this regard, the work plan and nature of experiments covered by this project are similar in design to those covered under my previous license. Hence, I have based estimates on successfully obtaining funding for x3 3-yr post-doctoral positions and X3 3-4yr PhD studentships and completion of x2 current studentships to execute the work detailed in this license, and the average yearly animal use per group member returned under my current license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The following points specifically address experimental design that reduces animal numbers. In functional studies, up to 4 preparations can be obtained from any one animal, greatly increasing successful data acquisition from an individual animal and thereby reducing the total number of animals required. In proposed functional studies, recordings will be made from neurons processing specific symptoms using genetically modified animals. In this way, data will be directly obtained from the key neuronal populations involved. This reduces usage as the alternative approach of recording data from random neurons would vastly increase the numbers of animals required to obtain relevant information.

All studies will be conducted in both sexes and analysed by sex. Although somewhat counter-intuitive studying these basic questions in both sexes will lead to a reduction in the numbers of animals used. From our own experience, pooling data from both sexes can lead to a diluting of effect size or worse a misinterpretation of findings that can lead to additional experimentation that may be eliminated by addressing these questions independently in both sexes at the outset.

Importantly, the numbers of animals required for a given study is worked out using statistical analysis of pre-existing data or if this is not possible in preliminary data collected from a very small group of animals to ensure that subsequently only the minimum numbers that are required for the study are used. Our experiments are also designed to reduce the number of variables to as few as possible and thereby reduce the number of control groups required. In this respect, we will always consider carefully whether it is important to include ‘naïve’ as well as ‘vehicle’ control groups in experiments, or if the latter alone is sufficient for interpretation of results. In some cases, the uninjured side can be used as a control.

To ensure best practice in statistical analysis and experimental design all new staff members working under this license will attend the in-house ‘Experimental Design Course’. Planned experiments are discussed regularly within group meetings to ensure all are correctly controlled and to facilitate sharing of tissues/data for the most effective use of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

My group routinely perform pilot experiments or use pre-existing data from the lab where possible to determine sample sizes required by power calculations. We standardly base power calculations on the ability to detect at least a 20% difference using online tools. We also seek advice when required from a

local experimental design expert and NC3Rs Experimental Design Assistant as appropriate. Planned experiments are discussed regularly within group meetings to ensure all are correctly controlled and to facilitate sharing of tissues/data for the most effective use of animals.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats and mice are chosen for this work given that much of the current understanding of this topic has been carried out in these species, knowledge that is an essential foundation for the studies proposed here. Moreover, the mechanisms and neural connections established in these species are comparable, to the extent that this can be addressed, to that in humans, underscoring the relevance of this work for humans. The models to be employed should not modify general behaviour (grooming, eating, sleeping, social interactions) although a localised tenderness of one limb may be present which is required in order to investigate biological mechanisms in order to guide future pain relief strategies. In all studies we will seek to limit the timeframe of the tenderness and the majority of studies will be conducted on isolated tissue preparations.

Why can’t you use animals that are less sentient?

A mammalian model is required to study a nervous system with a high degree of functional, anatomical and developmental similarity and complexity. This is required to generate relevant findings on which to base future therapeutic strategies. The duration of the pathophysiological processes to be studied prevent using mice or rats under terminal anaesthetic.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In line with institution policy, we will adopt the latest techniques in animal handling (e.g. cupping) to significantly reduce the stress associated with procedures. For behavioural testing, all animals are well habituated to the test scenario and returned as quickly as possible to their home cage.

Furthermore, where possible, the least invasive methods for dosing and sampling will be applied. Anaesthesia and analgesia will be provided where suitable (e.g. for humane restraint, during and recovery from surgery). To reduce infection risk, the best aseptic technique will be used during surgery (e.g. sterilization of instruments between animals, full surgical drapes). When possible early endpoints will be used in the models.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our institute employs a dedicated team of veterinarians that are continually seeking to improve animal welfare and refine animal use. My group consults closely with this team and takes full advantage of the extensive resources provided on their website to ensure we are following current best practices. These resources include comprehensive guidelines and standard operating procedures for most common rodent procedures. We have also consulted the NC3Rs research strategy paper by Prescott MJ, Lidster K (2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute employs a team of dedicated veterinarians that are continually seeking to improve animal welfare and refine animal use. My group consult closely with this team and take full advantage of the extensive resources provided on their website to ensure we are following current best practices. These resources include comprehensive guidelines and standard operating procedures for most common rodent procedures that are continually being updated. Our university is also in the process of adopting the improved rodent handling methods that reduce animal stress (detailed by Hurst et al. Nat Methods 2010) and our animal facilities now provide environment enrichment as standard. My group will adopt these methods alongside the staff in our animal facilities. We will also take full advantage of the annual 3R’s seminar day organized by the University’s Animal Welfare Committee to find out about pioneering developments in best practice.

Home Office

NON-TECHNICAL SUMMARY

171. State-dependent neural information processing and brain function in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b) **Key words**

brain, neuron, sleep, ageing, hearing

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, aged, embryo
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to better understand how the brain processes information at the level of neural circuits and how it changes in brain disorders or ageing. In addition, this project aims to develop novel technologies to realise them.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our brain is one of the most important organs in our body. Abnormalities in the brain cause brain disorders that often lead to life-long disability.
This work will investigate how internal states of the brain are regulated and how internal states of the brain affect various brain functions in health and disease.
An internal state of the brain, called "brain state", can be defined by ongoing electrical activity in the brain. While the brain is never at rest, brain states dynamically change over multiple timescales. A typical example is the sleep-wake cycle where brain states changes in a range of seconds to hours. Our sensory percepts can be also changed depending on those brain states. For example, our hearing ability can vary across the sleep-wake cycle. Moreover, ageing is also associated with changes in brain states. For example, brain activity typically becomes slower in the aged brain. This is particularly acute in hearing: even when hearing threshold is held, the ability to comprehend speech sounds in noisy environment decreases as age.
A better understanding of the neural basis of brain states is a fundamental issue in modern neuroscience.
In addition to brain states in health, abnormalities in brain activity are associated with brain disorders including neurodegenerative diseases (such as Alzheimer's disease) and neurodevelopmental disorders (such as autism).
A better understanding of brain states in disease can make a huge impact on our society.
For example, in 2010 alone, there were approximately 45 million cases of brain disorders in the UK. The economic cost of brain disorders was over £120 billion. For example, Alzheimer's disease (AD) is the most common cause of dementia, which affects around 850 thousand people in the UK, with a cost of £13.9 billion.
Despite this enormous societal and economic burden, our knowledge about how brain disorders are caused and even how the healthy brain works is still limited. Because of this, no effective treatments are available for most brain disorders.
To tackle this challenge, not just clinical research, but also pre-clinical animal research is essential. Because the brain consists of complex networks of neurons and non-neuronal cells, it is important to gain an access of individual cells in living animals by taking and developing advanced technologies.
Thus, this work will help (1) understand principles of how neuronal circuits operate in the healthy brain and (2)

gain insights into the mechanisms of brain disorders and the ageing process. In addition, because existing tools to investigate brain functions have their limited ability to monitor and control brain activity in vivo, this work will also help develop and validate novel devices to monitor and control brain activity in an unprecedented manner.

What outputs do you think you will see at the end of this project?

The main outputs will be

- Conference presentations
- Publications in peer-reviewed journals
- Publicly available data files for reproducibility and reduction
- Novel neural implants and interfaces, some of which will become commercial products

Who or what will benefit from these outputs, and how?

Because this study is still basic science, primarily beneficiaries from the output of this study will be academia. As we will publish our findings, this impact will be realised.
Because we believe that a better understanding of brain state is a fundamental issue, long-term (>10 years) impacts can be vast, from advancing human knowledge to clinical applications for brain disorders, such as Alzheimer's disease, and the development of novel artificial intelligence to help human activities in multiple domains.

How will you look to maximise the outputs of this work?

Wherever possible, we will disseminate the project by presenting it at national and international conferences and by publishing a paper with an open-access option.
Along with publications, we will make data publicly available to facilitate reproducibility and reduction.

Species and numbers of animals expected to be used

- Mice: 9700
- Rats: 100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

There is no feasible alternative that would entirely replace the use of these types of animals at the life stages in order to investigate state-dependent brain functions in health and disease. Constitutive GAAs are necessary to model genetic defects of human disorders/diseases, such as Alzheimer's disease. Conditional GAAs are necessary to modify gene expression in a spatially and temporally restricted fashion. Aged animals are necessary to better understand age-related changes in neural information processing at the level of neural circuits.

Typically, what will be done to an animal used in your project?

A large proportion of animals will be used for breeding. Some animals will undergo surgical procedures under general anaesthesia in order to prepare them for physiological and behavioural assessments later. The surgical procedures will allow placement of recording and stimulation devices on the skull and head/neck muscles. After a 1-week recovery period, the animals will be habituated with an experimental environment. Then behavioural and physiological assessments will be carried out. After completing all procedures, the animals will be killed by a schedule 1 or non-schedule 1 procedures. A typical duration of procedures will be between two and six months. A small number of animals will also undergo procedures during their development as a model of neurodevelopmental disorders. The animals will be also examined for their behavioural and physiological characteristics once they mature. Another group of animals may be allowed to reach older ages (up to 2 years) in order to study age-related changes in brain activity. The procedures are similar to those for young animals while a longer recovery period will be allowed.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals undergoing surgical procedures may suffer from post-surgical pain/discomfort for several days. A few animals may also lose moderate amounts of weight compared to control animals during longer procedures that also involve steps such as water-restriction for behavioural training, even though they will receive a limited amount of water and an unlimited amount of food every day.
Regarding aged animals, all C57BL/6 mice will develop age-related hearing loss (presbycusis). Although this strain has a low susceptibility to tumours, this strain shows a susceptibility to diet-induced obesity and hair loss associated with overgrooming.
CBA or CBA/Ca mice were originally developed for longevity. However, it is known that ageing CBA mice can develop spontaneous hepatomas. Male CBA/Ca strain develops a mild adult onset diabetes obesity. Because most GAA mice used under this protocol will have a genetic background of either strain and because only “knock-in” animals will be used for this purpose (i.e., ageing), the effect of ageing will be similar to the one expected for the background strain and hence well-established. Nevertheless, other age-related conditions may appear

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severities can be categorised as either Mild or Moderate.
Mild severity is expected for a very small number of animals that are subject to an unconventional genotyping method (e.g., blood sampling), rather than ear notching.
Moderate severity is expected for animals that are subject to surgical procedures, pharmacological or non-pharmacological interventions, and ageing.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The quantitative assessment of sensory-evoked neural activity and behaviours (including sleep states) requires in vivo studies. There is no alternative that would entirely replace the use of a living animal that would allow the objectives to be met.
In some of behavioural experiments (such as classical conditioning), aversive stimuli (such as air puff) may be more suitable than positive reinforcement in order to reduce their training periods and the number of animals used.

Measuring neural responses in conscious animals is necessary to investigate the neural mechanisms of sensory perception and other brain functions because neural activity in conscious animals significantly differs from that in unconscious ones.
Monitoring electrical activities of the brain (EEG) and muscle (EMG) is commonly used to objectively assess brain/behavioural states because of its less invasive nature. EMG measuring is essential to distinguish wakefulness and rapid-eye-movement (REM) sleep states. Currently there is no alternative approach to the best of my knowledge.

Which non-animal alternatives did you consider for use in this project?

The following alternatives were considered:

- human subjects in
- vitro systems

Why were they not suitable?

It is not ethical to conduct experiments on human subjects, especially because this project requires invasive procedures.
In vitro systems do not allow us to assess sensory-evoked responses and does not produce behavioural outputs.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers of animals have been estimated based on:

- statistics from pilot experiments
- statistics from my own published works and similar works experience from
- the previous PPL

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I took the following steps:

- Designed each study to determine control groups and experimental units (e.g., a single animal, a single cell)
- Considered outcome measures to achieve the goal of the study together with experimental procedures
- Considered a range of inclusion and exclusion criteria
  Considered whether randomisation and/or blinding can be taken
- Estimated sample size
  Considered potential statistical methods to assess the results
-
-

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

I will use the following measures where possible:

- efficient and well-planned breeding
  performing a pilot study before starting a large-scale study to ensure the estimate of sample size and
- no toxicity adopting advanced data analytical approaches to maximise the outcome sharing non-used
- tissue with other scientists and storing brain samples for future studies
-

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use rats and mice. Rats are suitable for experiments that require to accommodate a certain methodology/technology, whereas mice are more suitable to utilise genetic technologies and some behavioural experiments. To complement both advantages, we will use both species depending on the objective: when any experiments require genetic approaches, we will use only mice. However, rats will be used when certain experiments (such as validating a novel device) cannot be applied to mice. GAAs are required to express exogenous genes to monitor and control brain activity at refined spatio-temporal resolution or to model brain

disorders, such as Alzheimer's disease to develop novel pharmacological or non-pharmacological intervention strategies.

Why can’t you use animals that are less sentient?

To investigate state-dependent brain functions, such as the sleep-wake cycle, non-mammalian species exhibit different patterns of state changes from mammals. Out of mammals, rodents may be recognised as less sentient species. Given available and proven methodologies and technologies, rodents are believed to be most appropriate for this project. In non-recovery conditions, less frequent state changes are expected and brain states differ from those in un-anaesthetised conditions. Thus, experiments in un-anaesthetised conditions are required. Patterns of state shifts (e.g., sleep duration) also change as a function of age. Thus, animals at a more immature life stage will provide a very limited aspect of state dependent brain functions.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All animals in recovery experiments may experience some post-operative pain or discomfort because of surgery. We will use post-operative analgesia to reduce surgical post-operative discomfort. Health condition including body weight, spontaneous movement, head/face swelling, and appearance will be monitored and scored in first several days after surgery.
All animals involved in behavioural assessment under head restraint conditions may experience some discomfort and stress. To minimise stress, animals will be trained to willingly accept the restraint by positive reinforcement and the duration of training will be gradually extended from several minutes over weeks. During training animals will be video-monitored online. If animals show discomfort, experiments will be immediately terminated. Procedures involved implanting a device will be terminated in 6 months. If animals show any deviation from normal health (e.g., weight loss), behavioural training will be suspended to allow them to recover or they will be killed humanely.
To reduce the mortality rate of aged animals during and after surgery, the amount of anaesthesia will be reduced and the duration of surgery will be minimised. Depending on the animal’s condition, we will take a longer recovery period by monitoring health conditions on a daily basis.
Although some of age-related changes (e.g., age-related hearing loss) can be observed only from a certain age, an option to use younger animals will be sought to minimise age-related adverse effects.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the guidelines on the NC3Rs website (https://nc3rs.org.uk/3rs-advice-project-licenceapplicants-refinement).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly check the websites of ARRIVE (https://arriveguidelines.org/) and the NC3Rs (https://www.nc3rs.org.uk/)

NON-TECHNICAL SUMMARY

172. Studies on vascular diseases and repair mechanisms

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Cardiovascular, AMPK, Breeding, Wire Injury, Blood Pressure

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile, aged
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project seeks to understand more about how some very serious and common cardiovascular diseases affect the structure and function of our blood vessels and how drugs or other interventions may improve the health of the vascular system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular diseases, or diseases which indirectly affect the cardiovascular system have a huge impact on our health, cause many people to die prematurely and have a high cost to the National Health Service. The project will increase our understanding of how blood vessels change when subjected to adverse situations such as hypoxia (a low level of oxygen), high fat in the blood or mechanical injury and how this causes changes in their normal function. This will include studying the natural processes which occur over time. This can sometimes help to identify how and why the function changes and maybe identify ways in which new drugs can be developed to target these processes.

What outputs do you think you will see at the end of this project?

We will generate significant new data on blood vessel regulation and how this changes in disease and when vessels repair after injury. We intend to publish this data to share our findings and help advance the field. We may use our animal models to study the effect of novel drugs- for example drugs which inhibit the enzyme AMPK or SK. We may also study the effect of novel ways of delivering drugs to an injured blood vessel to study if this improves the action of the drug or how effective it is in improving the outcome of the treatment.

Who or what will benefit from these outputs, and how?

In the long-term, human health will benefit as data from this project can inform future directions of research in humans using novel drugs or novel surgical techniques with improved results. This may be achievable if we understand more about blood vessel function and repair after injury.
As basic scientists we will benefit by learning more about blood vessel function and, more importantly, how they stop functioning properly when they become diseased. We will find out more about how the fat which surrounds our blood vessels can change during diseases such that it becomes damaging rather than protective. We will also learn more about how blood vessels repair themselves after injury and the effect low levels of oxygen (called hypoxia) can have on a family of lipids which can affect the function of blood vessels.
Students (PhD and Masters) working on this project will benefit by being trained in good experimental design and *in vivo* techniques. Publication of the work we have performed and dissemination in the wider scientific community will more the field forwards.
In the mid- and longer-term these outputs may assist in identification of drug targets which the pharmaceutical industry can use to develop new or improved drugs to treat human disease. Such improved therapies will have a

beneficial impact on human health in the long-term.

How will you look to maximise the outputs of this work?

We aim to publish our research in scientific journals so that our findings can be shared with other researchers working in this area. We also aim to present our findings at national and international meetings so that ideas and novel techniques can be shared and the best approach to investigating our area of research adopted. We collaborate with others in the area so that new skills can be learnt and supporting skills can be used to optimise the programme of research and maximise the outcomes. **Species and numbers of animals expected to be used**

- Mice: 5700
- Rats: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

For the types of experiments we are performing we need to use adult animals as their cardiovascular systems are fully developed. For experiments where we cause damage to the vessel or to the endothelium (the cells which line the inside of blood vessels), the vessel has to be of a sufficient size to allow access with the fine wire we use for the procedure.
We choose to use mostly mice as this allows us to breed and use mice which are genetically modified (GM), this allows the genome of the animal to be manipulated so that the protein product of a particular gene is not produced (or in some cases the manipulation can be so that more of the protein is produced). This allows us to use animals which are deficient in proteins we are interested in studying- such as an enzyme known as AMPK.

Typically, what will be done to an animal used in your project?

The vast majority will simply be used for breeding, their genotype being determined by a small sample removed from their earlobe at the time of identification.
Some animals will be used to measure blood pressure non-invasively and they will be treated acutely or chronically with experimental compounds given either orally or by injection, up to twice daily for up to one month (depending on route) before they are killed humanely. In some cases, their diet may be modified so that they are fed a high-fat diet for up to 30 weeks- this does not have any overt adverse effects on the mice.
A small subset of mice (or rats) may undergo a surgical procedure under general anaesthetic that will result in damage to the wall of a blood vessel and in some cases and implantable stent will be delivered, after which they are allowed to recover. These animals may receive therapeutic doses of novel drugs that help remodel the induced vessel defect for up to one month after induction of the lesion. This is to study the effects of vascular injury on the structure and function of blood vessels and how they heal after an injury.

What are the expected impacts and/or adverse effects for the animals during your project?

Breeding of mice and modifying their diet should not cause any ill-effects.

Administering drugs to animals can sometimes have unpredictable effects but we try to minimise this by testing the drug in experiments which do not use live animals and we try to use doses which have been used by other researchers or from the manufacturer of the drug where this information is available. When we study pharmacological agents *in vivo* we commence with small pilot studies to minimise numbers of animals exposed initially to establish a safe dose.
Injuring animal blood vessels and then recovering the animals can sometimes produce some adverse effects such as:
An animal not recovering from the anaesthetic- perhaps 1 animal in 100 (1%)
The animal dying during the procedure- this can often be because the blood vessel which is being injured breaks or bursts. This may happen in up to 10% of animals but the animal never regains consciousness.
After the surgery sometimes the stitches or wound can become infected or open up again if the stitches fail (maybe 2% of animals)
Pain – we expect all animals may experience some discomfort during recovery but we minimise this by using pain-killing drugs given before the surgery starts and after it, and also drugs which reduce inflammation.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1 of this licence is mild (100% of mice will experience this due to ear notching for genotype analysis, while protocols 2 and 3 are moderate. In protocol 2 some animals may experience discomfort or adverse effects due to repeated injection of pharmacological agents. In protocol 3 we estimate that 100% of animals will experience some post-operative discomfort.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A blood vessel is a complex tube consisting of multiple layers of different cell types and in a living creature, has a constant, pulsatile flow of blood through it. How these cells interact when the blood vessel is injured or when the amount of oxygen is reduced is crucial to our understanding of vascular diseases. The only real way to understand this in detail is to examine the changes in a live animal, comparing an injured blood vessel to a non-injured vessel and how the structure and function changes over time. Although alternatives can give us some information, they often fail to mimic the complex environment in a live animal, with blood, immune cells and circulating hormones and mediators.

Which non-animal alternatives did you consider for use in this project?

We derive much of our preliminary data from experiments which do not use live animals (for example the use of cells grown in culture) and this helps us to decide on doses of drugs and other conditions for studies which do

use animals. It also helps to cut down the risks of unforeseen problems when we do use live animals. For example, cultured cells can be purchased commercially and may be either human or animal cells. We also maintain other relevant cell lines such as fat cells called 3T3 adipocytes, which we use extensively. From these experiments we can derive a huge amount of data which reduces animal numbers and informs the experimental conditions when we do need to use animals. We also make extensive use of historical samples of preserved tissue and tissue fluids/blood which originally came from animals but can be used in multiple experiments.

Why were they not suitable?

They are suitable for certain experiments which form the bulk of our research. However, in certain experiments- such as measuring blood pressure, blood vessel healing responses or testing the effect of a drug on the cardiovascular system, we need to use a live animal. A live animal has many features which cannot be replicated using cultured cells or tissues removed from the animal for *in vitro* experiments. For example, blood pressure can only be measured in a live animal and the healing response of a blood vessel after injury cannot be studied *in vitro* because other cells and systems which are only active in a live animal (for example blood cells and immune cells, circulating hormones and growth factors) will be involved.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers are based on past experience of running breeding colonies of mice which are used to produce animals for experimental projects. In the proposed research over the 5 years of this licence, the vast majority of these mice will be used for breeding and not for any other licenced procedures. Rats are used on occasion for some experiments where they represent the best means of obtaining reliable scientific data- for example where mice are too small and consequently the size of the blood vessels is too small.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where licenced procedures other than breeding are carried out, experiments are designed carefully in line with best practice to minimise numbers but still obtain statistically valid data. This is normally via tests which use the expected difference between experimental groups and the chances or probability of finding a significant difference- this can inform us of how many animals are required in each group.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our breeding programme is tightly controlled so that the colony size is monitored and is of a sufficient size to produce the number of animals needed without significant excess. When a member of my research group uses an animal, tissues are shared between multiple users and across research groups so that maximum use is made of that animal.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project involves breeding mice with specific genetic modifications which are of interest to us. Such modification- removing the ability of the animal's genome to produce a specific protein or enzyme allows us to investigate what effect that has on the animal in terms of its cardiovascular system and how its blood vessels function. When required for use these mice are usually killed via a humane method and their tissue and cardiovascular system investigated. On occasion we use anaesthetised animals to study the effects of injecting drugs and the effects of injuring their blood vessels and then studying how the vessel repairs itself over a period of time. In this case, pain, suffering and distress are minimised by good handling techniques, experienced and trained people performing the surgery, use of analgesic drugs and good post-operative care; following all current guidelines.

Why can’t you use animals that are less sentient?

We are investigating the cardiovascular system and so the best models of cardiovascular disease are in mammals and this is why we use mice and rats. It is important that our basic scientific research has what is called "transferability"- where the results have relevance to the disease or condition in humans. This is difficult to argue when using some less sentient species in the type of research we do.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The experimental models we use are accepted by the scientific community and we have published a great deal of peer-reviewed data reported our findings with them over the last 10-12 years. Through this period we have refined our techniques to make each of the proposed procedures have a high success rate.
In all experiments, suffering to the animals is minimised by careful experimental technique and judicious use of analgesics and anti-inflammatory agents at dosages recommended by the veterinary surgeon. Close supervision of the animal during recovery also ensures that any complications can quickly be identified and dealt with to minimise suffering.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We design and report all our studies according to the ARRIVE guidelines which are widely accepted and endorsed by the scientific community: https://www.nc3rs.org.uk/arrive-guidelines

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

There are several sources of information available including the NC3Rs website: https://www.nc3rs.org.uk/
I also regularly correspond with the NACWOs (animal house staff) regarding the best way to maintain our colony of breeding mice and consult with the NVS where any problems arise and to get the most up-to-date information on best use of anaesthetic agents, analgesics and post-operative care of animals under procedure. My employer is committed to a culture of care and respect for research animals and organises an annual 3Rs day.

Home Office

173. Studying macrophage plasticity in inflammatory disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research **Key**

words

inflammatory disease, macrophages, cell therapy

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant
Rats	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how cells of the immune system called macrophages cause damage during inflammatory disease. Macrophages are versatile cells and depending on the tissue, they can have beneficiary or harmful effects. Through an ambitious and vast research programme, we ultimately aim to identify drugs that can modulate their activity and treat inflammatory disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is pivotal to undertake this research because the animal models we have are reproducible and mimic perfectly the human disease. For instance, we can model the different disease states (i.e. early inflammatory state and late scarring phase) and understand the transition from one to the other. This is crucial in designing small molecules that can be potentially be effective in a specific disease-context.

There is a gap in understanding and targeting inflammatory disease and current therapies involve drugs that silence the entire immune system (immuno-suppressors). These 'non-specific' drugs cause also harm to the human body as they damage the immune system that we rely on to fight against microbes and viruses. This application aims to find more specific drugs that will target one type of immune cell (i.e. the macrophage) while keeping the immune system intact. This strategy can be applied in many unmet clinical needs such as treatment of chronic conditions (chronic kidney disease). The studies we propose will aim to change the activity of the macrophage and 're-program' such that it could help tissue regeneration and repair. These approaches are still challenging to undertake in humans. Although our understanding of human inflammatory conditions are growing every day, any cell therapy aiming to re-program immune cells require the use of animal models. Animal models of inflammatory conditions help us in (i) understanding the disease progression in a controlled environment (ii) targeting specific cell types that worsen the inflammatory reaction.

What outputs do you think you will see at the end of this project?

The project will increase knowledge in understanding and treating human inflammatory disease. The information gained from the project will be translated into human disease where applicable. As we have shown in our previous project, it is highly likely that the new findings will be peer-reviewed and published, contributing to the current scientific knowledge in complex diseases such as chronic kidney disease and skin inflammation. Some findings may also lead to new products that could have potential industrial value.

The ability to understand the role of macrophages in human inflammatory disease is important. It can indeed help designing better treatments. Because these cells change their activity during the inflammatory process (e.g. inflammatory at early stages and 'repair' like at later stages), one can take advantage from this temporal changes to target kidney inflammation. Practically, instead of the convential anti-inflammatory treatments, we can now think of treatments that will support repair - a novel line of research that this project would like to implement.

Who or what will benefit from these outputs, and how?

The short-term beneficiaries will be academic partners and the undergraduate and postgraduate education . The impact of our outputs will also be communicated, where appropriate, as part of lay reports in Press Releases. Other outputs' impact may be realised in the long term. For instance, the translation of the findings through innovation procedures or patent applications is likely to be prolonged in the long-term.

The potential medium term non-academic beneficiaries also include pharmaceutical companies and longer term patient benefits. For instance, we are working with a small pharma company to develop potential drugs that can have an effect on transforming macrophages into 'repair-type' cells. We are excited about these outputs, which can have a clear patient benefit in the long-term.

How will you look to maximise the outputs of this work?

We actively collaborate with researchers around the world in order the optimally disseminate new knowledge. Publication but also press release and/or social media releases are part of the different ways to disseminate research findings. The recently established public databases encourage scientists to disseminate their results in a timely way (e.g. BioRxiv). Furthermore, the increased number of journals publishing negative results show that the scientific community has made knowledge dissemination as one of its primary goals.

Species and numbers of animals expected to be used

- Mice: 700
- Rats: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Studying the immune system in rats and mice is an important step in understanding and treating inflammatory conditions. Inflammatory conditions comprise a broad range of diseases where current therapies lack specificity. For instance, when the filtering unit of the kidney (i.e. the glomerulus) becomes chronically inflamed and there is a risk of kidney failure, current therapies are mainly based on corticosteroids, which are non-specific anti-inflammatory agents that affect many tissues within the body causing adverse effects such as weight gain, bone thinning, diabetes and high blood pressure. There is a scientific need to understand how the inflammation is caused (what are the different steps, mediators and their relative importance) in organs/tissues such as the kidney and the skin. By using mostly adult mice and rats, we aim to understand how inflammation occurs and how we can treat it. Mice and rats' immune system resemble closely the one described in humans. For instance, the steps of wound closure in mice and rats' skin is very similar to those observed in humans. Furthermore, the rat model of kidney inflammation in adult animals mimics perfectly the human disease - an important consideration for using these types of animals for biomedical research.

Typically, what will be done to an animal used in your project?

Typically, we will induce kidney or skin or more general inflammation in rats and mice. The procedures described in the protocol 2 are designed to identify the immune mechanisms involved in initiating and/or resolution of the tissue damage and to explore therapeutic targets. A typical protocol will involve the administration of a treatment (e.g. a drug with protective effects) followed by the induction of a brief and transient inflammatory reaction. We are only interested in the biology of early inflammation. We will therefore study the immune cells involved in earl inflammation and seek for protective effects against inflammation. The duration of these experiments will not exceed a period of 7 days following the induction of the inflammatory reaction.

The kidney inflammation (Protocol 3) requires an injection while skin wounds (Protocol 4) will be induced after surgery. The duration of both experiments will be typically between 10-14 days after causing the initial injury. The number of procedures will be kept to minimum. Typically, this will involve a treatment (e.g. a drug that will reduce inflammation).

Both techniques are extremely well-established in our laboratory where our proven track-record identified multiple ways of treating inflammation by targeting the immune system. This work will help in the development of therapeutic approaches to human kidney and skin inflammation.

A typical kidney inflammation protocol will be carried out as follows and will last 10 days after inducing the initial injury

- Injection of nephrotoxic serum (NTS) to induce an inflammatory response and progressive renal scarring.
- Collection of samples (metabolic cages which separates faeces and urine into tubes and blood sampling).
- Tissue harvesting (Schedule 1).

A typical wound healing protocol will be carried out as follows and will last 14 days after inducing the initial injury

- Induction of a skin wound to induce the healing
- Testing a treatment that generally aims to increase the healing process
- Tissue harvesting (Schedule 1)

What are the expected impacts and/or adverse effects for the animals during your project?

Generally, the expected adverse effects are minimal for all protocols and this is because we are interested in early inflammatory reaction characterised by the infiltration of immune cells called macrophages. The duration of the experiment following induction of injury (general inflammation in protocol 2; kidney inflammation in protocol 3; skin healing in protocol 4) is relatively short (7-18 days), which in our hands do not cause any significant adverse effects to the animals other than transient discomfort.

Specifically, for the kidney inflammation protocol (Protocol 3), the animals are usually killed by Schedule 1 before they develop any renal failure. There is no pain nor discomfort associated with this protocol through the total duration (7 days generally). Similarly, the incidence of wound infection (protocol 4) is minimised by the use of appropriate aseptic surgical techniques and we have not observed any pain nor discomfort in the animals throughout the healing process (14-18 days).

Most importantly, in all protocols, treatments are applied to seek from protection from inflammation (protocol 2 and 3) and to accelerate the healing process following wounds (protocol 4). This strategy has an overall beneficial impact for the animals reducing further the transient discomfort they may experience.

Our protocols have been designed to reach a moderate level of severity at the maximum. Every animal undergoing recovery surgery will receive adequate and timely painkillers to reduce pain or discomfort after the procedure. Signs for infections will be dealt by applying the appropriate treatments and immune-compromised animals will be held in designated facilities. Animals will be humanely killed using approved methods at the end of the protocol. Any animal in which pain is uncontrolled, or which has significant surgical complications, or whose general health deteriorates significantly will be humanely killed.. All the procedures will be carried out while working closely with experienced animal care staff. All the protocols proposed in this licence underwent considerable refinement and some protocol (e.g. kidney inflammation in rats) have been used for >20 years, where there is cumulative expertise in all the procedures involved. There are no new (or previously not tested) protocols proposed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The protocol 1 refers to the breeding and maintenance of genetically modified animals. In this protocol the expected severity is mild and less than 5 percent of the animals are expected to experience this severity. Protocol 2 aims to measure immune and inflammatory responses in rats and mice. Half of the animals will experience moderate and the other half mild severity. Protocol 3 is set to induce kidney inflammation and all animals are expected to experience moderate severity. Finally, Protocol 4 is proposed to study wound healing in the skin and all animals are expected to experience moderate severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of animals is essential for our work, since it is only by study of the intact animal that we will be able to work out how inflammatory disease is caused and what therapeutic approaches might be of benefit. We also use cell culture experiments, where possible, to address specific questions about cellular mechanisms of disease, but this cannot reproduce the complexity of the whole animal **Which non-animal alternatives did you consider for use in this project?**

We also use cell culture experiments, where possible, to address specific questions about cellular mechanisms of disease, but this cannot reproduce the complexity of whole animal tissues and organs. We have parallel projects that use human tissue material where possible. These projects identify targets (genes, gene products, soluble factors) that we ultimately target using animal models. We take advantage of integrative approaches in human tissues (multiple and diverse technologies) to prioritize biological targets.

Why were they not suitable?

Although some human tissues can be accessed during surgery, animal models are valuable in offering a 'treatment' component - the key reason for using refined models of inflammatory disease. Our research is very much focussed on generating robust and reliable hypotheses that can only be tested in animal model as the final confirmation of a potential therapeutic approach.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The applicant's previous licence included the same protocols that are proposed in this replacement application. Experiments conducted under the previous licence for a period of 5 years, allowed us to estimate the number of animals that are required in each experimental protocol. Briefly, their number is determined by:

- good knowledge of the protocol that can provide a conclusive result that will be sufficient for data sharing (e.g. publication or submission for funding applications)

- the existence knowledge on previously published worked by us and other scientists (publications, publicly available databases).

- in vitro models (those that do not use any living system) that may complement the in vivo (involving living organisms) usage (where applicable).

- robust experimental design refined efficiently to provide the most comprehensive information

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

1. The Experimental Design Assistant (EDA) from the The National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs) for appropriate statistical analysis and visualization of the project.

2. Peer-review of experimental design and statistical analysis by the Medical Research Council. The MRC has an online tool that includes the Reduction as part of the Research Project applications - the power calculations (statistical analysis that are made prior to undertaking research - this determines the number of animals required for the proposed experiments) are submitted by a collaborative effort with a medical statistician and the Reduction plan of the Research Project gets peer-reviewed with feedback provided to the main applicant.

3. Collaboration with biomedical statisticians and data scientists.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding. Only the necessary animal numbers provided by power calculations will be considered through an efficient and reductive breeding strategy.

Pilot studies will provide preliminary data on future experiments. For instance, we have determined that the usage of 3 rats as control and 3 as 'treated' animals gives enough statistical power to determine whether a potential treatment is effective. This minimal and highly informative approach will be applied where necessary.

Sharing of tissue. Tissues are shared between collaborators in the UK using similar protocols. Where necessary, we will use these tissues to further reduce the animal numbers required in our own protocols.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This application includes both rat and mouse models of inflammatory diseases, since each species has advantages for certain studies. One advantage of mouse models has been the availability of a wide range of genetically modified mice which can be used to determine the effect of specific genes on the disease model being studied. However, there have been major advances in rat genetics over the last

few years, and several genes involved in macrophage-dependent inflammatory disease in the rat have been shown to be relevant in the related human disease. Also, recent advances in techniques mean that specific genes can be deleted in rats in order to study their relevance in particular disease models. We therefore wish to generate and breed genetically modified rats in order to investigate the more accurate models of human disease that can be produced in the rat as compared with the mouse.

Because of their reproducibility, rapid onset, the mice and rats models studied in this licence cause no lasting harm to the animals. For instance, the model of kidney injury in the rat is obtained by using a method that causes the least pain, suffering or distress. This is because of the genetic background of the animals which make them susceptible to disease. Hence, we use this method preferentially in susceptible animals and cause kidney injury in an efficient, rapid and reproducible manner.

Because of the application of Replacement, Reduction and Refinement (3Rs) in all of our studies involving inflammatory disease in experimental animals, we assess the outcome of the experiments by using laboratory techniques, at a relatively early stage of disease such that no animals suffer from the clinical effects of prolonged inflammation (i.e. kidney or lung failure). Any animal which becomes unwell during the course of the experiments, for any reason, will be humanely killed.

Another aspect of refinement is the usage of recently available data-rich techniques such as next generation sequencing methods. In recent years, we have collected and analysed these kinds of data from multiple tissues from single animals in various models of inflammatory disease. We have established a data analysis pipeline which allows identification of molecular targets using computer-based methods. This minimises experimental approaches. It also makes any experimental approach focussed and with a clear hypothesis.

Why can’t you use animals that are less sentient?

Rats, and in particular the certain strains, are genetically susceptible to inflammatory disease. Similarly, mice have been widely used in immunology and biomedical research because of the possibility to mimic human conditions and modelling similar pathologies. Because of their unique susceptibility to disease and 3R principles that can be implemented, these species are the most appropriate ones for the proposed protocols.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Because of the application of 3 Rs in all of our studies involving inflammatory disease in experimental animals, we assess the outcome of the experiments by studying tissue samples under a microscope, at a relatively early stage of disease such that no animals suffer from the clinical effects of prolonged inflammation (i.e. kidney failure or skin inflammation). Any animal which becomes unwell during the course of the experiments, for any reason, will be humanely killed. We will increase monitoring, post-operative care and pain management in all protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE guidelines (Animal Research: Reporting of In Vivo Experiments) are a checklist of recommendations to improve the reporting of research involving animals – maximising the quality and reliability of published research, and enabling others to better scrutinise, evaluate and reproduce it. The new ARRIVE 2.0 guidelines have been recently published in a scientific journal so that they are now accessible to the wider public. These build on previous guidelines published by the NC3Rs in 2010 and set out to address comprehensive improvements in reporting.

The “ARRIVE Essential 10” that are the basic minimum to include in a manuscript to enable readers and reviewers to assess the reliability of the findings, and the complementary “Recommended Set” that provides context to the study. The aim is for the scientific community to focus initial efforts on the Essential 10, with the recommended set subsequently adopted as best reporting practice.

Another aspect of refinement is the usage of recently available data-rich techniques such as the fast growing advances in sequencing methods. In recent years, we have collected and analysed these kinds of data from multiple tissues from single animals in various models of inflammatory disease. We have established a data analysis pipeline which allows identification of molecular targets in silico, using exclusively computational methods. This minimises experimental approaches by offering a hypothesis-driven approach.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs) is an independent scientific organization in the United Kingdom (UK) that was set up by the government

to lead the discovery and application of new technologies and approaches that minimize the use of animals in research . They help the research community use the latest science and technology to replace animal studies, providing new approaches for biomedical research . Where the use of animals is still required, they support researchers to design the best experiments so that their methods and findings are robust and reproducible. They provide information and guidance on the latest knowledge to improve laboratory animal welfare.

Home Office

NON-TECHNICAL SUMMARY

174. Studying microbial pathogenesis to cure infections

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

Infectious diseases, Microbial metabolism and virulence, Host response, IVIS, mouse infection models

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This study aims to define bacterial and host factors active during infection to develop and test therapeutic and prophylactic compounds.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Microbial diseases pose a large threat to public health and they continue to be an important cause of death and suffering around the world. Antimicrobial resistance continues to be a major problem, and some of the existing vaccines are not very effective. Therefore, we urgently need effective vaccines and new therapeutic strategies. One of the well-established ways to identify new anti-infective targets and strategies is to study the 'behaviour' of microbes during infection. We hypothesis that by using different metabolic pathways in different host tissues, bacteria acquire distinct phenotypes. Once the critical microbial metabolic pathways for *in vivo* survival are identified, we can target them pharmaceutically to produce much-needed anti-infectives.

There is a severe lack of knowledge on how microbes survive in different host tissues for example for bacteria that are going to be used commonly in this study such as *Streptococcus pneumoniae, Klebsiella pneumoniae,* and *Pseudomonas aeruginosa*. Unless we have a detailed understanding of microbial survival strategies in host, the efforts to combat infectious agents will be a much harder task. So far in-host survival mechanisms have been studied using a small number of strains of individual microbial species but there is a significant variation in the ability of different strains of same species to cause disease due to the differences in their genetic background. Moreover, so far there has been little attention to the microbial response to the *in vivo* environments or how external environments effect the *in vivo* behaviour of microorganisms. In host tissues, individual species of microorganisms do not exist in isolation but rather interact with the existing microbiota. However, there is incomplete understanding of the *in vivo* interactions of different microbial populations. Infections do not occur solely due to the microbial factors. Host response is an important factor for the occurrence and progression of infectious diseases. Despite this there is an incomplete understanding of the host's response to infections and how microbial metabolism shapes host response during infection.

The study of microbial metabolism *in vitro* and *in vivo*, will allow the identification of essential microbial metabolic pathways as well as the impact of microbial products in formation of host response during acute and chronic infection. Consequently, the data generated in this study can then be used for developing effective anti-infectives, and enable a detailed understanding of pathophysiology of infectious diseases affecting human health.

What outputs do you think you will see at the end of this project?

Main outcomes of this project will be a detailed understanding of pathogen biology, host response to infection, and identifying and validating anti-infective targets. In this study, we will test hypotheses relating to how various microbial species of medical importance cause disease, and identify the host factors important in response to microbial agents. By using the models of pneumonia, meningitis, septicaemia, and colonisation, we will generate complementary data for a holistic understanding of microbial and host factors important for colonisation and virulence. This study will generate new information on infectious disease biology and can potentially reveal commercially exploitable data by testing anti-infective compounds. In the projects after this, such anti-infective compounds can be developed into drugs and/or vaccines.

Who or what will benefit from these outputs, and how?

In the short term, users and beneficiaries of the data will include the academic community, particularly those interested in microbiology, genetics, and infectious diseases. Dissemination of results to the wider scientific community will occur throughout the project in the form of conference presentations, and publications after IP considerations. We envisage that 18 months after the start of the project, publishable data will be generated, and these data will be shared with the scientific community by publications in high impact journals. In addition, the data generated during this project will be disseminated via presentations at local, national and international conferences. As well as the scientific community, notable outcomes of the project also will be communicated to the general public. Public awareness of the research will be promoted through the institutional press office. The potential commercial development of our discoveries will no doubt require additional resources. We do not anticipate that antimicrobials will be generated within the lifetime of this project. However, this project will reveal viable candidates for anti-infective development which can be further developed in future studies. Any commercial potential of our findings will be exploited. Anti-infectives developed by data generated in this study will be beneficial both for human and animal health.

How will you look to maximise the outputs of this work?

I will maximise the outputs from this work by using my extensive network of collaborators. I collaborate with overseas and UK colleagues. My collaborations have been productive and led to publications in high impact journals and research grant awards. Combining my efforts with their expertise will surely increase the quantity and quality of my data.

Species and numbers of animals expected to be used

- Mice: 5040

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will be using adult mouse in this study. It is by far the most widely chosen animal for the study of infection and host responses, providing very reproducible models of infection. The genetics of the mouse is the subject of a global research effort, meaning that the data generated in this study can be interpreted in detail. Furthermore, there are many in-bred mouse strains available as well as strains with defined mutations for the study of disease processes. Additionally, the extensive background of existing experimental murine data is a very valuable resource.

Typically, what will be done to an animal used in your project?

We will use four protocols in this study. With the first two protocols, we will initiate either the models of acute- (Protocol 1) or chronic infection (Protocol 2) using the microbes that make us sick. These models will be an extremely valuable tool in understanding the mechanisms by which the microbes cause disease in humans. With Protocol 3, we will test the safe doses of selected compounds that can treat infectious disease or those with an

impact on our immune system (Protocol 3). This step will allow us to determine the non-toxic dose of study compounds against the infectious agents, and prevent unnecessary suffering of animals. Protocol 4 will be used to produce antibody. This protocol will provide the required tool to understand how our immune system functions during infectious disease.
Each protocol has several mandatory and optional steps. The optional steps are required, for example, either to establish certain infection models or to assess the impact of selected compounds. Depending on the objective of each experiment, these optional steps increase the data output per animal reducing potentially the number of animals and/or refining our protocols. It should be noted that animals will not go through each step in these protocols.
In Protocol 1, 2, 3, and 4, the maximum number of steps including the mandatory euthanasia step, the animals will go through 5, 5, 4, and 3 steps, respectively. At the end of each protocol, mice will be killed humanely by schedule 1 or non-schedule 1 method. Typically, we will administer infectious agent to follow the clinical signs, and evaluate host immune response (Protocol 1 and 2), or administer antiinfective agent to determine the toxicity or efficacy of compounds under study (Protocol 3 and 4). We will obtain tissue samples such as blood or peritoneal fluid to assess the progress of infection and evaluate host response (Protocol 1-4). These processes will inevitably inflict pain and discomfort to the mice. However, we will do every effort to reduce the pain and suffering by closely monitoring animals and setting up humane endpoints using our robust scoring system, through use of anaesthetic and analgesics, and continuous application of good practice in the field.
Protocol 3 and 4 are designed to evaluate the dose for therapeutic and immune-modulatory compounds and antibody production, respectively, and these animals will not be infected. Data generated in Protocol 3 and 4 will be very useful for Protocol 1 and 2, where we plan to administer the non-toxic concentrations of compounds under study or evaluate the protective ability of selected compounds. Protocol 1 and 2 aim to initiate acute or chronic infection, respectively. They evaluate the role of selected microbial products and compounds on the outcome of infection or enable us to study the pathophysiology of the infectious disease process. This understanding can lead to the development of drugs and vaccines in future.
The duration of each protocol will vary. For example, Protocol 1 will be up to 7 days, while Protocol 2 to create chronic infection can be up to 90 days. Protocol 4 can be up to 90 days. The therapeutic dose setting experiments can be as short as 24 hours or extended over several weeks to evaluate the longterm toxicity (Protocol 3).

What are the expected impacts and/or adverse effects for the animals during your project?

In the project experiments, the animals may experience pain and discomfort due to (i.) the administered compounds, (ii.) infectious agent, and (iii.) procedures that will be applied.
(i.) Adverse effects due to the administered compounds:

Administration of immunising agents and adjuvants can drive moderate inflammatory responses in the tissue, which could be prolonged. Animals may manifest their discomfort by changing their routine eating and drinking habits or by altering their interactions with other mice.
X-irradiation of mice can leave them susceptible to infection as the bone marrow reconstitutes their immune system. Radiation renders mice susceptible to opportunistic infections, leading to clinical signs such as diarrhoea. Particularly, *Pseudomonas aeruginosa*, can translocate through the gut in irradiated animals and this can lead to bacteraemia and sepsis. Animals may develop dry skin due to radiation. The animals may rarely experience post-irradiation lethargy.
Mice receiving inducing, labelling, antibiotic or immunomodulatory active agents have the potential to respond negatively although most treatments will be based on previous successful delivery (literature or documented historical data sets), any mouse undergoing these treatments will be monitored.
(ii.) Adverse effects due to infectious agents:

For example, after infection with respiratory pathogen *Streptococcus pneumoniae*, which will be frequently used in this study, mice move progressively through piloerection, hunched, lethargic and moribund before death. The end-point in this study will be when the animals become lethargic, being immobile unless prompted when they

will be humanely killed by a Schedule 1 method or immediately placed under terminal anaesthesia to obtain cardiac blood. In order to minimise their suffering, animals will be infected at a time of day and week when they will be able to be inspected at their most critical times, and treatments will be administered to animals not later than the early lethargic stage.
In chronic infection, mice can lose weight and when the weight loss reaches 20% relative to the weight of age-matched controls, the mice will be culled by the Schedule 1 or non-schedule 1 method.
(iii.)Adverse effects due to the procedures: During multiple dosing, administration of agents may cause discomfort (e.g. local injection site reaction) but the likelihood of such an event is low (<10%).

Venepuncture can lead to excessive bleeding. Animals may feel pain and discomfort during tissue sampling.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Up to 96% of animals may experience moderate severity limit
.
Up to 4% of animals may experience mild severity limit
.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

To achieve the project aims and objectives we will employ a comprehensive set of in vitro and ex vivo assays. However, to be able to assign a role to different microbial metabolic pathways in vivo, and to study the impact of these pathways in interaction with host molecules, the use of animals is essential for complete understanding. While in vitro and ex vivo experiments are useful, they cannot mimic the complexity of in vivo environment, and only through the inclusion of animal models, we can fully understand the key microbial metabolic pathways at different stages of infection.

Which non-animal alternatives did you consider for use in this project?

We considered replacement alternatives but the total replacement of animal models for this project is not possible. Whenever possible, we will use replacement alternatives. For example, when we do not see the impact of the efficacy of a tested chemical in in vitro and ex vivo models, we will not test them in vivo. The number of anti-

infective compounds to be tested in animal models will be reduced based on the structure-function studies. If the compounds have the same mechanism of predicted activity, only a few representative compounds will be tested. Similarly, we will use initially ex vivo and in vitro assays before in vivo models. This so-called “stepwise testing strategy” is recognised by FRAME as a way of reducing animal numbers and suffering. Where appropriate, we will also use the *Galleria mellonella* model of infection and ex vivo models, e.g. respiratory and brain ciliated epithelial tissue models instead of rodents.

Why were they not suitable?

As discussed above, the full complexity of bacterial metabolism and its impact on host-pathogen interaction cannot be understood fully using in vitro and ex vivo models. Bacteria are versatile entities and can manifest distinct phenotypes under different environmental conditions. We cannot assume that the relative importance of metabolic pathways will be the same in vitro and in vivo. Bacteria encounter very complex and fluctuating environment in host tissue than in vitro and creating this environment in vitro is currently not possible.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of mice needed for each experiment has been calculated in collaboration with statisticians and by using the NC3R’s Experimental Design Assistant tool. The number of mice that will be required in our proposed experiments will be the minimum number needed to achieve the project objectives. Information from previous studies has been useful in predicting the number of mice in each experiment required to determine the answer to the important scientific questions using as few mice as possible. We will continuously monitor group sizes in the light of data generated throughout the course of the project and will introduce the required adjustments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

To reduce the number of animals being used in this project, we sought advice from local statistician and also made use of NC3Rs' Experimental Design Assistant. In addition, I sought advice from colleagues who have long term experience in the use of animal models of infectious diseases.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To prevent the wastage of a large number of animals, before doing large scale experiments, we will do small scale pilot studies to decide how best to conduct a large-scale experiment. Moreover, if the gender is not a variable in the hypotheses we test, this study will use both male and female rodents. In addition, we will store tissues for future use and will share tissue samples with other colleagues who have similar research interest.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse models of infection will be used. It is the most frequently used animal for the study of infectious disease biology. There are many in-bred mouse strains, as well as strains with defined mutations for the study of disease processes. Furthermore, the genetics of the mouse is the subject of a global research effort, including making knock-out strains covering every mouse gene. Additionally, the extensive existing experimental data with the mouse is a very valuable resource.
Our experience in working with animal models of infectious diseases show that as the disease develops animals gradually move through piloerection, hunched, lethargic and moribund before death. Each stage can be finely rated as 1+ or 2+. This scoring scheme has proved remarkably reliable and only on very rare cases is an endpoint missed, which allowed us to predict the stage of infection and prevent the suffering at the right time during the course of infection without significantly compromising the quality of scientific data. The suffering will be minimised by evaluating the disease sign scores regularly. In addition, we will refine our models through the use of in vivo imaging technologies.

Why can't you use animals that are less sentient?

Wherever possible we will use *Galleria molenella* (greater wax moth) model for pre-screening anti-infective compounds and our bacterial strains. This model has been a highly informative tool for the study of infectious disease biology. Although it is useful, it cannot mimic the complexity of mammalian tissue. Infection process in this model is initiated by injecting the inoculum into the haemocoel of *G. mellonella* larvae. This means that common natural infection routes that can be created in a mammalian host, such as inhalation or oral routes, cannot be generated in this model. Moreover, unlike rodents, *G. mollonella* does not have adaptive immunity, which hampers studies of host-pathogen interaction.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In our models, we know the approximate timing of disease sign development. Once the disease signs set, generally 24 h post-infection, we will increase the periodicity of monitoring. When appropriate, to alleviate pain, we will administer pain killers after consultation with the named veterinary officer. The usual procedure under this licence is to kill any animal as soon as it becomes very lethargic stage when they are immobile unless prompted to prevent suffering.
Throughout this project, we will refine our methodology based on our results, based on relevant publications of other scientists, and the guidelines issued by the Home Office and NC3Rs. Animals will be infected at a time of day and week when they will be able to be inspected at their most critical times in order to minimise their suffering. Recently, I developed efficient microbial bioluminescent strains, which will be used during the course of this project. These strains will help me refine my models and reduce the number of animals used in this study. For example, by relating the number of bacteria to the light intensity, we may be able to stop the course of infection at an earlier stage. Although these techniques involve additional procedures, the quantity and quality of data can be markedly increased to allow more detailed analysis of disease progression and timing of termination of experiments. The irradiation administered in a single dose can compromise intestinal mucosa and so half doses administered 2 hours apart reduces potential adverse effects and improves outcome.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow NC3Rs guidelines to ensure experiments are conducted in the most refined way. We will subscribe to the electronic version of the monthly newsletter of NC3Rs. Also, the Nuffield Council on Bioethics has relevant published work concerning animal welfare and refinement of animal experiments. We will seek advice from the experts on 3Rs based in NC3Rs and will regularly attend and present our work at scientific meetings.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow the guidance issued by the NC3Rs, attend relevant symposia and conferences organised by Microbiology Society and Laboratory Animal Science Association, and through relevant published data in the field. At NC3Rs web site valuable guidance on various 3Rs topics is available including on animal welfare, experimental design for animal experiments, and good animal housing and husbandry practices. We will seek advice from the experts on 3Rs based in NC3Rs, and will regularly attend and present our work in scientific meetings. The advances in 3Rs will be implemented in collaboration with my colleagues.

Home Office

NON-TECHNICAL SUMMARY

175. Targeting Fibroblast Heterogeneity, Plasticity and Functions in Pancreatic Cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Pancreatic cancer, Tumour microenvironment, Fibroblasts, Cancer therapies, Cellular cross-talks

Animal types	Life stages
Mice	embryo, pregnant, adult, juvenile, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We aim to understand how different populations of non-cancerous cells, called fibroblasts, support pancreatic cancer progression to identify new combinations of treatments that block the tumour promoting cross-talks of cancer cells and fibroblasts.
A retrospective assessment of these aims will be due by 24 January 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve it's aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Pancreatic cancer is highly lethal. Drug resistance is one of the main reasons of pancreatic cancer lethality and is largely caused by non-cancerous components, called stroma, that comprise up to 90% of the tumour mass. Within the stroma, fibroblasts are the most abundant cell population and promote drug resistance and cancer growth. No current therapy effectively targets these cells. Although previous studies provide insights into the wide range of fibroblast cells (i.e. fibroblast heterogeneity) in pancreatic ductal adenocarcinoma (PDAC), the extent of this heterogeneity, the roles of distinct fibroblast subtypes and how to selectively target them remain unclear.
The role of cancer-associated fibroblasts (CAFs) in modulating tumour progression is emerging as a strong player in therapy resistance, metastasis formation and poor prognosis. However, whereas the biology of pancreatic cancer cells have been extensively investigated, the roles of pancreatic CAFs are largely unknown. Evidence suggests that distinct fibroblast groups (i.e. subtypes) play different roles in the progression of pancreatic cancer, and that targeting them individually may lead to disparate outcomes. We propose that strategies using combinations of drugs that target tumour-promoting fibroblast populations could be used in the future for pancreatic cancer treatment.
It is therefore important to deeply characterise different fibroblast subtypes to understand how to target them. The strategies proposed herein will directly address knowledge gaps that could have significant therapeutic implications. Notably, the emerging understanding that fibroblast heterogeneity is not restricted to pancreatic cancer indicates that our findings could be applied to other tumours.

What outputs do you think you will see at the end of this project?

The completion of this project will significantly expand the knowledge about fibroblasts and the tumour microenvironment (i.e. the arrangement and characteristics of the different cells in the tumour) in pancreatic cancer and will potentially identify new ways to better group patients for different treatments. Overall, the investigation of fibroblast biology may lead to new strategies to treat and detect pancreatic cancer. Additionally, the publications originating from our studies could inspire future work in various laboratories across the world. As it is emerging that fibroblast heterogeneity is present in other malignancies and inflammatory conditions, our findings could provide useful insights to other cancer fields and be of interest to the broader scientific community.

Similarly, we will generate and make available to the scientific community new mouse models that could allow to investigate fibroblast functions in other malignancies, diseased states and normal tissues, and could thus be important for the scientific advancement in other fields.

Who or what will benefit from these outputs, and how?

In the short term (2-3 years), the scientific community will benefit from our discoveries through peer reviewed (i.e. assessed by other academic experts in our field) open-access (i.e. available to everyone without a journal subscription/fee) publications and open-access, not yet peer-reviewed pre-prints originating from our work. This will promote further research and rapidly advance our and others field. Papers published on both of these platforms will also be available to the non-scientific community, so that everyone could be informed, if interested, about our scientific progress. Additionally, we will present our work at conferences and workshops. We will also engage the non-scientific community in public events. We will also host college students over the summer, to train and inspire the next generation showing them our research progress and models.
Our main long-term goal is to deeply understand the mechanisms regulating tumour heterogeneity to develop strategies that would benefit patients. Although this output will not be rapidly evident following our work, as it will need to be evaluated in clinical trials, our studies will be a first step towards that direction.
Eventually, pancreatic cancer patients could benefit from the design of selective combinations of drug treatments resulting from our research and specific for their particular tumour.

How will you look to maximise the outputs of this work?

We aim at publishing at least one article per objective. When possible, we will also submit these works before peer-review, as pre-prints, so that the findings of these studies will more rapidly advance research and will also limit potential duplications and unnecessary mouse work in other laboratories. Publications of unsuccessful or non-high impact approaches that would spare unnecessary duplications could also be deposited as pre-prints.
As similarities between fibroblasts in pancreatic cancer and fibroblasts in other cancer types are emerging, we also aim at establishing collaborations with other laboratories.
We are also planning to share with other laboratories the new mouse models that we will generate. Of note, these new mouse models could be used in the future to study the roles of distinct fibroblast subtypes in other cancer types, inflammatory conditions, and normal tissues.

Species and numbers of animals expected to be used

- Mice: 18300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We aim to deeply investigate the biology of fibroblasts in pancreatic ductal adenocarcinoma (PDAC), while keeping in sight a potential clinical output. Using the best models of PDAC is, therefore, a priority. We will use mice for the proposed study. Mice are commonly used as an animal model of PDAC as, more than any other model, they recapitulate the progression of the human disease, the crosstalk between cancer cells and stromal cells, such as fibroblasts, and the response to therapies. Finally, mice are required to test the efficacy of potential anti-cancer therapeutics prior to their testing in clinical trials. For example, the KPC mouse model remains the gold-standard for studying PDAC biology, progression and therapeutic response, as numerous parallels can be made between KPC tumours and the human disease.
This is possible because the KPC mouse model has been genetically altered to express in its pancreas the key genetic mutations that occur most frequently in human pancreatic cancer, hence it develops pancreatic tumours which accurately reproduce the characteristics of the tumours that develop in humans.

Our protocols for 1) breeding and maintenance of genetically altered mice, 2) breeding and administration of substances to genetically altered mice, and 3) production/maintenance of genetically altered mice that develop autochthonous (i.e. spontaneously arising) pancreatic tumours (e.g. KPC mice) will include various life stages. For other protocols, e.g. drug studies with genetically altered mice bearing autochthonous pancreatic tumours and transplantation of pancreatic organoids (i.e. three-dimensional cultures of pancreatic cancer cells) into the pancreas (i.e. orthotopically), we will only use adult (and aged) mice, as we aim to investigate tumour biology and tumour response to treatments.

Typically, what will be done to an animal used in your project?

Some mice will be administered drugs in the food or water while pregnant or before and after birth, for up to 6 months.
Some mice will develop pancreatic tumours, either spontaneously if genetically engineered mouse models (GEMMs) or following transplantation of organoids into the pancreas, in some cases after having aged. Some of these mice may be imaged (for example by ultrasound) to detect the presence of a tumour in the pancreas and humanely killed, prior to analysis of tissues.
Some mice will develop tumours and will be imaged by ultrasound and will be administered drugs (i.e. enrolled in drug studies). Mice enrolled in drug studies will be typically alone in the cage to decrease the experimental variability, which will overall decrease the number of mice needed. Mice will be then humanely killed, prior to analysis of tissues.
For genetically altered KPC mice, spontaneous pancreatic tumours develop at 3-6 months of age. Following tumour formation, the mice can survive approximately for up to 1-2 months. For transplantation models, pancreatic cells will be typically injected into the pancreas at 6-8 weeks of age, unless performed in aged mice around 16-18 months of age. Depending on the cell line and number of cells transplanted, tumour presentation typically occurs between 1 (more common) and 12 (rare) months from surgery. Following tumour formation, the mice can survive approximately for up to 2-3 months.

What are the expected impacts and/or adverse effects for the animals during your project?

Both genetically altered KPC mice and transplantation models bearing pancreatic tumours recapitulate clinical signs observed in pancreatic cancer patients, including loss of appetite, weight loss, inactivity and ill health. Additionally, KPC mice can develop other clinical signs typical of advanced pancreatic cancer in patients, including ascites (i.e. accumulation of fluids in the abdominal cavity) and bowel obstruction (when the presence of the tumour is blocking a part of the intestine). These symptoms usually occur at a late stage of tumour development in the mice and will normally only be present for 12 weeks prior to reaching a humane endpoint. During their life time, KPC mice also often develop facial and anal papillomas (i.e. benign epithelial tumour growths) that do not cause discomfort, if not infected, unless they obstruct vital functions, such as eating, drinking or defecation.

Administration of substances via injection or oral gavage (i.e. with a feeding tube that reaches the animal stomach) will cause recurrent (daily or weekly), transient (10-15 minutes) discomfort and distress, due to the restraint and procedure required. Administration of substances to the food may also cause discomfort and loss of appetite due to poor palatability, leading to transient weight loss.

Ultrasound imaging could cause transient distress and discomfort normally associated with the anaesthesia. Ageing mice may exhibit phenotypes associated with ageing. Common age-related clinical presentations, which are not expected to cause adverse suffering and can be managed are: i) skin lesions, such as loss of hair; ii) ocular lesions, such as conjunctivitis; iii) hearing loss; iv) reduced mobility; and v) body weight changes. Additionally, adverse age-related clinical presentations may be: i) visible or palpable masses, including tumours; and ii) prolonged body weight loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Overall, <2.5% of genetically altered KP mice (i.e. parental mice of the KPC mice), <2.5% transplantation models (i.e. models in which pancreatic cancer cells are injected in the pancreas of mice), <5% genetically altered KPC mice may be in a severe (in terms of level of pain, suffering and distress) category. The majority of mice will experience a moderate severity, and the remaining will be in mild or sub-threshold (i.e. even lower than mild in terms of level of pain, suffering and distress) categories.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 24 January 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although recent improvements have occurred in the development of novel laboratory platforms for the study of the tumour microenvironment, animals remain the most informative model to recapitulate the cross-talks of cancer cells and fibroblasts observed in patients, because only a tumour in a living animal, such as a mouse, can exhibit all the complex features of a human tumour. To carry out impactful and meaningful research that could lead to the development of new therapies, it is therefore essential to use animals for the investigation of cancer/fibroblast cross-talks.

Which non-animal alternatives did you consider for use in this project?

As an additional approach, we will employ research alternatives that do not involve the use of animals. In particular, for some of the biological questions we aim to address, we will employ three-dimensional pancreatic organoid/fibroblast co-cultures.
Although the use of these co-cultures will reduce the number of mice employed in this project, it cannot completely substitute for it as, to date, no system can accurately recapitulate the fibroblast cross-talk with pancreatic cancer cells and the surrounding microenvironment as well as mouse models.
However, we are also actively working on optimising our current co-cultures by including additional cell types, such as immune cells, with the hope to develop more meaningful laboratory models for the study of pancreatic cancer biology.

Why were they not suitable?

Although our co-cultures will allow to reduce the use of animals, they cannot entirely replace the use of these models as they do not fully recapitulate the tumour microenvironment of pancreatic cancer.
Additionally, prior to testing our findings in clinical trials, the relevance of our findings will have to be evaluated in mouse models of pancreatic cancer that have been shown to largely recapitulate the human disease (e.g.

transplantation mouse models and genetically altered KPC mice).
A retrospective assessment of replacement will be due by 24 January 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are an approximation as the effective size will depend on the results obtained from the pancreatic cancer organoid/fibroblast co-cultures and initial smaller-scale (i.e. pilot) studies, when relevant. Indeed, animal usage may be reduced by performing pilot studies (with 4-5 animals) prior to the full studies with a larger number of mice. If biological and statistical significance is reached in a pilot study, a full study may not be required and this will reduce the number of animals used.
Additionally, the results gathered from experiments performed in the co-cultures will inform the design of the animal studies.
For transplantation models of pancreatic cancer, the cohort sizes have been initially determined based on our previous studies. Previously, n=5-10 per group has been sufficient to reach biological and statistical significance.
Similarly, for therapeutic studies in genetically altered mouse models (e.g. KPC mice), we have performed pilot studies to characterise growth rate and variability of tumours to inform subsequent studies. Previously, n=5-10 per group has been sufficient for monitoring the anti-tumour effect of drugs. Finally, based on our experience, for survival studies (i.e. studies in which animals are humanely killed only when they show severe clinical signs at humane enpoints), 10-12 mice per cohort have been sufficient to reach biological and statistical significance. Moving forward, we will re-assess these numbers when more information will become available with our future studies. To do this, we will work closely with our Bioinformatics core facility who will provide advice on the study design and statistical analysis to determine the number of animals needed.
Additionally, our Bioinformatics core facility uses a variety of statistical methods to analyse different types of datasets.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

At all times, we attempt to reduce, replace and refine our animal models. We are committed to limit the use of animals in our research. To this end, when scientifically meaningful, instead of using genetically engineered mouse models (GEMMs), we will establish pancreatic transplantation mouse models in which pancreatic cells or organoids are injected into the mouse pancreas. These models will reduce the number of mice needed to address our experimental questions, as they do not need the breeding required to generate the GEMMs. Although useful, these transplantation models cannot entirely replace GEMMs, such as KPC mice, as they bypass the early stages of tumour formation. The combination of both mouse models will be necessary for deeply understanding pancreatic cancer fibroblast biology and for evaluating new therapeutic strategies.
To further reduce the number of animals in our research, whenever possible and scientifically meaningful, we will use co-cultures of previously established murine and human pancreatic cancer organoids and fibroblasts.
These analyses will help indicate how and whether an animal study should take place.

Additionally, each therapeutic study will include all necessary controls, thus increasing the reproducibility and robustness of the study, and decreasing the variability and, therefore, the number of mice per group.
Additionally, we will employ ultrasound imaging to reduce the number of mice used in drug studies. Indeed, this technique allows to identify, and exclude, mice without pancreatic cancer or mice with other pathologies. Additionally, as the time needed for the development of a tumour is quite variable across animals (between 3-6 months), the use of imaging allows to start treating mice with similar tumour sizes (6-8 mm in diameter), reducing the variability during studies and therefore, reducing the number of mice needed.
Finally, imaging techniques allow to follow tumour growth at different time points, reducing the number of animals required to observe tumour growth at various stages.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies (with 4-5 animals) will be performed to characterise tumour growth rate and experimental variability to inform the design of subsequent studies and also to potentially reduce the number of animals used. Indeed, if biological and statistical significance is reached in a pilot study, a full study may not be required.
For genetically altered mouse models, whenever possible, we will maintain parents already with the required phenotype to reduce the overall number of mice needed, as all mice born from such breeding strategies will have the required genotype. Whenever this will not be possible, mice carrying inappropriate alleles will be humanely killed.
Although we do not expect surplus animals produced from our breeding strategy, if more mice than what we can use are born, the surplus may be transferred to other project licences to limit wastage. We will also share with other laboratories the tissues and organoid/fibroblast lines we will generate, to limit the use of additional mice elsewhere.
A retrospective assessment of reduction will be due by 24 January 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For our research, we will use mice. In particular, we will use genetically engineered mouse models (GEMMs), such as KPC mice, and, when scientifically meaningful, mouse models with organoids/cells transplanted in the pancreas. These transplantation mouse models appear healthier than KPC mice (i.e. develop less clinical signs during tumour progression) and likely experience less distress and pain during tumour formation compared to GEMMs, as evident by reduced signs of ill health. Subcutaneous transplantation models of pancreatic cancer, which would further decrease the occurrence of clinical signs in the animals, and the associated pain, do not faithfully recapitulate the cancer/fibroblast interactions that are at the centre of our research, and we therefore cannot consider them as relevant and scientifically meaningful substitutes.

We will minimise suffering by adhering to best practice guidance, in accordance with the “Guidelines for the

welfare and use of animals in cancer research" by Workman et al. 2010, BR J Cancer and the National Centre for the 3Rs. Every procedure proposed has been refined in order to cause the minimum distress, pain and discomfort to the animals.

Why can't you use animals that are less sentient?

The mouse remains the most relevant species with the least sentience that we can use to predict the biology and therapy response of pancreatic cancer. In particular, KPC mice are the gold-standard for pancreatic cancer research, as they recapitulate many aspects of the human disease. Not only they recapitulate the characteristics of human pancreatic tumours, but they also recapitulate many cancer associated clinical signs typical of pancreatic cancer patients with advanced disease, including weight loss, jaundice (i.e. yellow skin colour), and ascites (i.e. accumulation of fluids in the abdomen).
KPC mice develop pancreatic tumours at 3-6 months of age and their analysis over the following few weeks is pivotal for the understanding of tumour progression and testing of novel therapeutic approaches.
Transplantation models of organoids or cancer cells in the mouse pancreas also largely recapitulate the human disease and associated clinical signs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Environmental enrichment (i.e. material that is added in the cage to improve the psychological and physical well-being of animals, such as small tunnels) will be provided to improve animal welfare and promote the expression of species-appropriate behaviour and mental activities. More material that can be used to make a nest will be provided to mice that have been housed alone, for example, during a therapeutic study. Animals will be housed on an appropriate light/dark cycle with control of room temperature and humidity. Animals purchased and transferred to our facility will be allowed at least 7 days to adapt to their new environment and will be handled prior to any procedure or surgery to minimise their distress.

All mice will be monitored at least once a day by qualified, competent and trained staff. Post-operative care will occur following every pancreatic surgery (e.g. transplantation of tumour cells/organoids into the pancreas) and imaging procedure. Mice that show any clinical sign will be more closely monitored and, at all times, we will attempt to reduce any sign of discomfort, distress or pain (e.g. providing gel cups and food at the bottom of the cage, if possible). If long-lasting pain is experienced and no sign of improvement is observed from any measure that we will undertake, mice will be humanely killed.
We will use anaesthetics and analgesics during procedures that require physical restraint (e.g. ultrasound imaging), and during invasive procedures, such as pancreatic surgeries to minimize the animal distress and/or pain.
When mice are to be given certain agents in the diet, it is well documented that mice refuse to eat the diet for a few days due to its unpleasant taste. This results in a transient weight loss, which is typically recovered after a few days, when the animal starts eating again. However, if possible, to try limiting the weight loss by making the food more appealing, Nesquik or condensed milk may be added to the regular mashed diet. If this were to be the route of administration, mice would be exposed to Nesquik or condensed milk mashed food prior to treatment to acclimatise them to the diet. During the course of this licence, we will regularly monitor and try to reduce the percentage of mice that experience transient weight losses associated with this type of drug administration.
All protocols will be annually reviewed based upon records of severity kept under the Animals Scientific Procedures Act (ASPA) requirements to ensure that any new advances that can minimize the severity (in terms of pain, distress and discomfort) will be incorporated.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We are committed to following the LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery in our surgical protocols. We will also follow guidelines in accordance with Workman et al 2010, Br J Cancer and the National Centre for the 3Rs, which are considered the best current practice. We will also regularly review and implement any updated guidance from the National Centre for the 3Rs.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We currently follow any update provided by the National Centre for the 3Rs and, whenever possible, we will implement any new advance identified in term of replacement, reduction and refinement. We will also attend conferences and keep up-to-date with the current publications on themes related to the animal work carried out in our laboratory (e.g. conferences on animal models). These approaches will allow us to be exposed to the newest advances in the field which, whenever scientifically meaningful, we will start implementing in our research.

A retrospective assessment of refinement will be due by 24 January 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

176. Targeting signalling pathways driving chronic inflammation and tissue damage in osteoarthritis and related musculoskeletal diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, adult, neonate, juvenile
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overarching aim of this project is to identify the key cellular mechanism mediating tissue injury/damage in musculoskeletal diseases particularly osteoarthritis. This will facilitate identifying druggable targets for targeted therapy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In this Project, we aim to identify the upstream ubiquitination machinery mediating tissue injury inflammatory response. This is crucial for understanding the role of injury in initiating repair, and promoting pathological tissue damage. Knowledge of this new mechanism will define a pathway that could be targeted to reduce pathological injury responses in musculoskeletal diseases such as osteoarthritis which is crucial for understanding the disease behaviour and for designing new drugs for targeted therapy in osteoarthritis- a disease with no available disease modifying therapy.

As this early injury response may initiate wound healing, identification of this new mechanism may suggest new therapeutic approaches to delayed healing of wounds and fractures. Furthermore, investigating a new mechanism initiating inflammation may also give insights into inflammatory diseases of unknown aetiology such as rheumatoid arthritis, other rheumatological diseases, inflammatory bowel disease and many other diseases caused by chronic inflammation.

What outputs do you think you will see at the end of this project?

We envisage that our programme of work will lead to improved understanding of the genetic and cellular processes involved in tissue damage in response to mechanical injury. In so doing we hope to identify treatments that could be used to promote joint healing and repair in diseases like osteoarthritis.

Some of the outputs we expect during and at the end or the project include:

- New data that will be made discoverable via peer-reviewed publications, presentations at key meetings, deposited proteomics data in PRIDE, and through the publication of our datasets.
- New zebrafish transgenic lines: these will be available for zebrafish research community.
  Data that may be of use to the pharmaceutical industry for potential new therapies for musculoskeletal
- diseases [long-term]

Who or what will benefit from these outputs, and how?

Key groups that will benefit from findings from the outlined project include:

Scientists working on the project

Immediate beneficiaries of this project will be the scientists working on the project (PI, RA and PhD students). With the opportunity to apply new approaches and techniques with Zebrafish models there will be career

development opportunities. No procedures are undertaken for the purposes of training or development of staff - i.e. all procedures contribute to the scientific objectives. Researchers will be trained in the priority skills areas of whole organism physiology, quantitative skills (proteomic analysis), and interdisciplinary (particularly imaging).

Scientific Research Community

Academic researchers in several research areas will benefit from this work including those working on pathogenesis of osteoarthritis, musculoskeletal ageing, researchers in inflammatory diseases field, zebrafish research community and researchers in cell signalling and ubiquitination field.

Future Scientists

Our research group will work directly with student at GCSE and A-level through a work experience programme to enhance their understanding of scientific research and inspire career pathways in science.

Patients and wider public

Patients and the wider population will benefit from this research if we can identify novel pathways for future research and ultimately, targets for therapies to lessen the burden of diseases caused by tissue damage.

Pharma and Biotech companies

This work will identify drug targets that could be used to treat a huge unmet clinical need. It is likely that this will be of significant interest to pharmaceutical companies, large and small. We will develop strong collaborative links to enable commercialisation of any targets as they arise.

How will you look to maximise the outputs of this work?

We plan to maximise the outputs of this work through:

- effective collaboration with experts in the field of zebrafish mutagenesis as well as osteoarthritis research field which will extend our skill set and facilitate access to advanced technologies and approaches for improvements of our techniques and methods • dissemination of new knowledge at key meetings and conferences
- dissemination of work through press release via university media team publication and
- sharing of unsuccessful approaches.

Species and numbers of animals expected to be used

- Mice: 550
- Zebra fish: 9400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Fish are vertebrates (i.e. they have a skeleton) so represent a simple yet appropriate model for studying osteoarthritis disease. Zebrafish are an excellent model for these studies for two reasons: the larval stages are virtually transparent, making visualisation of injury dynamics and inflammation possible, and they are easy to use in genetic modification studies. The transparent nature of the larvae makes them uniquely suitable for the visualisation of the cell biology of inflammatory responses within a living host.
We therefore use zebrafish because they offer several technical advantages compared to alternative species

such as mice for most of our experiments.
We will only use mice for a specific surgical procedure that mimics osteoarthritis in human to understand the role of identified proteins in the development of the disease and to validate the mammalian relevance of our findings.
This model is proved to be an extremely valuable preclinical model i in which to carry out initial evaluation of novel potential therapies.

Typically, what will be done to an animal used in your project?

Zebrafish will be used to generate mutant lines of proteins in the ubiquitin system and downstream signalling. These proteins were identified to be modulated by mechanical injury to articular cartilage which is a key risk factor in tissue damage and progression of osteoarthritis. The role of this family of signalling enzymes in activating tissue damage will be tested by deletion in Zebrafish one at a time using gene-editing technology. These procedures involve microinjection techniques to deliver RNA and protein material to induce mutation at 1 cell stage zebrafish embryos (100 procedures over 3 months). We will then characterise the effect of these mutations in zebrafish on the response to inflammatory response induced by tissue injury and on the skeletal system development and function. This involves advanced imaging and histology techniques as well as gene expression and biochemical analysis (500 procedures over 1-2 years).
Success of the use of zebrafish model to mimic the human disease will allow us to use them to help to find new treatments for the human disease. This will usually involve treating the fish with drugs, typically delivered in their diet, and then seeing if drug-treated fish show any improvement compared to fish receiving placebo (200 procedures over 1-2 years). Further analysis of these drug trials will typically involve pathological and biochemical confirmation of the effects of the drug (no additional procedures, over 1 year).

What are the expected impacts and/or adverse effects for the animals during your project?

The types of adverse effects that we expect to see for the larval fish might include alterations to jaw shape and jaw function. We will carefully monitor these fish to ensure that they can feed even if their jaw shapes are abnormal. Occasionally when we are using a new drug or generating a new genetic modification a small number of larval fish may develop adverse effects such as heart oedema or brain malformation, these fish will be killed as soon as these defects are identified.
For adult and ageing fish, we expect the adverse effects to be the onset of joint conditions that resemble human osteoarthritis. These would be likely to cause stiffness in some joints (those of the jaw and the spine) which could in turn lead to reduced swimming performance and reduced speed of the fish. We will monitor the behaviour of the fish daily and any fish that can no longer maintain their position in the water will be killed under terminal anaesthesia. By carefully monitoring fish to ensure that that they do not exceed these end points we expect these studies to be of mild severity.
Procedures to induce osteoarthritis in mouse are of moderate severity. No specific adverse events are expected in relation to this beyond those related to any surgical procedure and therefore any pain associated will be controlled with appropriate analgesics.
Experiments are terminated after 12 weeks following induction of osteoarthritis using a humane endpoint procedure. Knees are then collected and analysed by histology to evaluate the disease progression. Mice will be killed if they show signs of ill health, such as piloerection and hunched posture, inactivity or inappetence that persist and cannot be ameliorated by mild veterinary interventions. In addition, any animal that loses 20% of its body weight when compared to age-matched control will also be killed
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most experiments will use zebrafish.

mild: 95% moderate:5%

Experiments using

mice moderate:100%

What will happen to animals at the end of this project?

- Used in other projects
- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The zebrafish has become widely accepted throughout the world as a particularly useful system to analyse human disease at genetic and molecular levels. The use of Zebrafish as an animal model for this study is essential for in vivo experiments involving targeting genes and generation of knockouts to study the role of signalling enzymes in connective tissue injury models in vivo. These models cannot be mimicked in cell culture or in our model of cartilage injury from pig trotters and is used as a replacement for mammalian models.

Which non-animal alternatives did you consider for use in this project?

In a number of biochemical experiments, a large amount of cartilage tissue for protein analysis studies is required. For that, we use pig trotters (known scientifically as porcine metacarpophalangeal joints) obtained from local abattoirs as a source of articular cartilage and a replacement of using animal models.
Additionally we use ex-vivo studies of articular cartilage models to inform on significance or proteins sets to be targeted in vivo or on the efficiency of chemical compounds and inhibitors.
Furthermore, we established a computational approach to predict the upstream the proteins acting as regulators in ubiquitin system based on proteomics data obtained from ex-vivo studies. This approach reduced significantly the number of animals needed for this study.

Why were they not suitable?

These approaches significantly helped to provide more concise information on the proteins needed to be targeted in vivo but they cannot mimic the actual cellular response occurs in the animal to this challenge. The joint is a complex 3-dimensional structure containing many different cell types and which is subject to frequent movement, as such there are very few non-animal models that exist and none that model all aspects of joint cell behaviour. We therefore need animals to understand what happens to the different cell types during common human joint disorders such as osteoarthritis.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

For those experiments that require animals we perform power calculations to define the minimum numbers required to achieve defined levels of statistical significance and we consult with statisticians and other biologists when planning experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

In this project the advancement of 3Rs is highly implemented in the proposed research. In a number of biochemical experiments, a large amount of cartilage tissue for protein analysis studies is required. For that, we use pig trotters or forefeet (known scientifically as porcine metacarpophalangeal joints) obtained from local abattoirs as a source of articular cartilage and a replacement of using animal models. This also helped significantly to reduce the animal numbers used in this study.
Almost all proposed fish experiments are performed on larvae before the onset of independent feeding– these larvae are not considered protected by the Animals (Scientific Procedures) Act. Procedures for making mutants in zebrafish are mild severity. Genotyping of Adult fish is done on anesthetised fish (small tail biopsy which regrows). To minimise animal use, once experiments have been performed, sperm will be frozen (for future IVF) and stocks will not be maintained.

Mammalian murine models are proposed to test the role of identified enzymes in well-established mammalian models of osteoarthritis. This is essential to investigate the disease relevance of the identified enzymes. Animal usage is minimised by proper power calculations based on previous studies and by having experienced researchers and technicians carry out surgery and histology, enabling us to reduce animal usage and maximise comparison between studies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Most of proposed fish experiments are performed on larvae before the onset of independent feeding– these larvae are not considered protected by the Animals (Scientific Procedures) Act. Based on ex-vivo work and proteomics analysis, we have established a computational model to inform on the number of targets employ prediction model to inform on proteins that will be targeted in vivo. Procedures for making mutants in zebrafish are mild severity. Genotyping of Adult fish is done on anaesthetised fish (small tail biopsy which regrows). To minimise animal use, once experiments have been performed, sperm will be frozen (for future IVF) and stocks will not be maintained.
Pilot studies are performed initially to inform on the optimum number of animals needed per experiment to see a significant effect. Spare larvae are used for other experiments or shared with other members of the laboratory for reasons of efficiency.

Mammalian murine models are proposed to test the role of identified enzymes in well-established mammalian models of osteoarthritis. This is essential to investigate the disease relevance of the identified enzymes. Animal usage is minimised by proper power calculations based on previous studies and by having experienced researchers and technicians carry out surgery and histology, enabling us to reduce animal usage and maximise comparison between studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use zebrafish in most of the experiments proposed in this application as a refinement over using mice for processes that are conserved. Zebrafish is the model of the lowest neurophysiological sensitivity in which the role of signalling enzymes in injury responses can be systematically analysed using genetic methods. Compared to mouse models, the adoption of zebrafish is having a significant effect on 3Rs and animal welfare, either by replacing mammalian models, or by informing experimental design in murine systems.

Zebrafish are the only experimental system in which proposed experiments can be performed. In vivo systems are required to model complex multi-cellular processes such as inflammation and injury dynamics. Zebrafish larvae remain the model of the lowest neurophysiological sensitivity. All the direct experiments proposed are performed on animals before the onset of independent feeding (before 5 days of age), not protected under the Animals (Scientific Procedures) Act. Generation of transgenic lines and mutants requires manipulated fish to grow to adulthood, which although considered a regulated procedure, is
“sub-threshold” in terms of the impact on the animal itself. Compared to mouse models, the adoption of zebrafish is having a significant effect on 3Rs and animal welfare, either by replacing mammalian models, or by informing experimental design in murine systems.
Mammalian murine models are proposed to test the role of identified ubiquitin enzymes in well-established mammalian models of osteoarthritis. This is essential to investigate the disease relevance of the identified enzymes. Animal usage is minimised by proper power calculations based on previous

studies and by having experienced researchers and technicians carry out surgery and histology, enabling us to reduce animal usage and maximise comparison between studies.

Why can't you use animals that are less sentient?

We have chosen the zebrafish as most refined animal model available (as worms and flies do not have a skeleton). By using the translucent zebrafish in which we express fluorescent proteins in cells of interest we can non-invasively watch many cellular processes in the skeleton, allowing us to collect dynamic data with minimal surgical intervention.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To minimise suffering and discomfort the animals will be monitored daily and when there is any concern advice will be sought from the named veterinary surgeon and/or the Named Animal Care Welfare Officer and appropriate action taken.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our laboratory is fully conversant with ARRIVE guidelines for the planning and reporting of animal experiments and fully compliant with best practice recommendations.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our group will stay informed about advances in the 3Rs through a number of channels of communications including animal users meetings, NC3Rs symposia and updates from husbandry and welfare conferences, collaborations and through direct advice and consultation with NTCO, NVS and NACWOs.

We aim to implement these advances in our work as appropriate.

Home Office

NON-TECHNICAL SUMMARY

177. Targeting therapeutics to sites of disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Targeted delivery, Gene Therapy, Immobilised molecules, Nanovehicles, Triggered release

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Whilst there has been tremendous progress in drug development and disease treatment in the last half century it is evident that most drugs are delivered systemically (oral or injection) , but often their action is only required at specific disease sites. Delivering, targeting and retaining molecules at sites of disease or developing approaches to control or trigger drug activity are the main themes of the work in this project licence application. We will explore different approaches to target treatments to sites of disease with the aim of increasing their efficacy whilst reducing side effects. The technologies we will be exploring range from genetic elements and protein engineering through to miniature vehicles. Many of the technologies are as a result of interdisciplinary collaboration between life sciences and materials engineering so we will be looking to develop novel delivery methods through the work of this licence. The primary target for our therapeutics is inflammation in joints. Many

therapeutics currently utilised clinically have significant ‘off target’ effects such as systemic immunosuppression which leaves patients vulnerable to opportunistic infections. We will be keen to determine if we can achieve long-term targeted effects from a single delivery; if we can control therapeutic delivery and if we can mirror delivery of therapeutics to the course of disease activity. If we can achieve these outcomes we are confident that this will aid in the development of new specific treatments for diseases.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Targeted therapeutics have the potential to be more efficacious because they are not distributed around the whole body but are selectively delivered to the disease site. Targeting will also reduce ‘off target’ side effects. Better targeting of treatment will mean that patients will be more effectively treated, have fewer complications of treatment due to side effects which will ultimately lead to better treatment outcomes for patients and clinicians.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

All the work proposed in this license is focused on the use of mice. Experiments will be designed with the aim of using the minimum number of animals that will determine if significant effects are achieved. All experiments will be informed by statistical power analysis and we will seek the advice of a resident statistician when necessary. I envisage that 1500 animals will be used over the 5 year lifetime of the license.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

Inflammation in joints causes pain, swelling and discomfort which can restrict movement to some degree. In this licence acute inflammation will be used which is short-term and resolves within a matter of days and has a severity limit of moderate. If suffering exceeds expected levels animals will be provided with analgesia and if their welfare does not improve animals will be humanely killed by an appropriate method.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

In programme of work described in this licence is aimed at achieving better delivery of drugs at disease sites through molecule design and through the use of drug carriers. Initial experiments have been performed with the molecules and drug carriers in experiments where we have tried to simulate aspects the disease environment. When the performance of molecules and carriers is effective and optimised in these systems they are ready for evaluation in an animal model. Mouse inflammation models have the advantage that we can monitor interactions of our molecules and carriers with the immune system and complex living structures which cannot currently be replicated in our laboratory based experiments. Should suitable alternatives to animals become available during the course of the proposed work then we will evaluate their application in these studies.

Reduction

Explain how you will assure the use of minimum numbers of animals.

Throughout the work of this project animal numbers will be kept to a minimum whilst ensuring that data obtained is rigorous and reproducible. This will be achieved by using a stop/go approach in experiments in disease models that are very reproducible which will mean that group sizes will be smaller and overall animal usage will be less. By this approach we will get an early indication that treatments are very effective or are ineffective following the use of small animal groups which will indicate if experiments should continue (go) or end (stop). Power analysis will be used in experimental design in order to ensure that group sizes are powered sufficiently to detect statistically meaningful effects.

State of the art imaging modalities will be utilised to enable monitoring at multiple time points in the same animal which not only overcomes issues with inter-animal variability but also greatly reduces animal usage. Imaging in anaesthetised animals can be used to demonstrate targeting of therapeutic or drug delivery particles in the whole animal at multiple time points. Where a single group of mice can be used for the whole experiment using imaging now, multiple groups of mice would have been used for each timepoint in the past.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse models provide the opportunity to examine our drug delivery systems in inflammation models that reflect aspects of human disease. The focus of the work in this license is joint inflammation so the outcomes of the work are of most relevance to diseases of this structure such as rheumatoid arthritis. There are many anatomical and functional similarities in the joint structure of rodent and human joints and the disease models listed in this license replicate changes that are seen in human disease. The models planned cause inflammation in a single paw and animals can readily move around their cage which is more refined than other models where inflammation develops in all paws. During the inflammation animals will be routinely measured and clinical signs will be monitored so that any intervention (such as analgesia) or humane end point can be employed promptly.

NON-TECHNICAL SUMMARY

178. Tau protein, glia and synapse damage in neurodegenerative diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Alzheimer's disease, Dementia, Therapy, Understanding disease

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We are interested in how changes to proteins disrupts communication between brain cells to cause dementia and other features of neurodegenerative diseases. We will use models of neurodegenerative disease to study alterations in protein structure, function, localisation and spread throughout the brain, on nerve cell health. We are also interested in how these processes are affected by the activation of immune cells, in the brain.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Alzheimer's disease and related neurodegenerative diseases that feature abnormal tau are the leading causes of dementia. The prevalence of dementia is increasing because age is the biggest risk factor and the global population is living longer. There are no therapies to slow or prevent dementing diseases, and this is in part due to an incomplete understanding of changes in the brain in dementia. There is emerging evidence that abnormal forms of tau protein act as an "executioner" to damage nerve cells and their connections (synapses), to cause dementia. Our work will build on these studies to better understand how tau changes in healthy ageing and in models of neurodegenerative dementing diseases. We hope that this work will identify new routes for treatment.

What outputs do you think you will see at the end of this project?

We expect this project to inform our understanding of how modifications in tau, occur in response to changes in nerve cells and other brain cell types that mediate inflammation. We seek to understand how these alterations affect disease progression and the communication between nerve cells and so underlie the clinical features of Alzheimer’s disease and related neurodegenerative disorders. The project will produce data that we will make openly available to scientists and other interested parties, and that will be included in open access publications. We will also present our work in other academic institutions, scientific conferences and in public engagement events.

Who or what will benefit from these outputs, and how?

The most immediate impact of our outputs will be on the scientific community, who will be able to use our results to expand or direct their own research. The subject of our research is a priority area and there are many groups around the world investigating related topics. It is hoped that in the long term our findings will be used to help devise or support the development of new therapeutic agents for Alzheimer’s disease and dementia. Importantly, our data might provide scientific “proof of concept” in support of clinical trials, as we have done before.

How will you look to maximise the outputs of this work?

We will maximise the outputs of our work by presenting our findings to a range of groups, including members of the public, healthcare providers and other key stakeholders at public engagement events or in funder publications. We will ensure that there is open access to our publications and data collections. We have previously published methods for some of the key protocols that we will use in this project license, and we will do so again for updated or new methods. This is important to allow others to reproduce our findings in their own labs and using their own reagents and models. We have trained researchers from pharmaceutical companies

and other laboratories in our methods to promote their uptake, and we will continue to do so. We will also endeavour to publish unsuccessful studies to inform the research community. This is important since reporting unsuccessful experiments will prevent other labs from using animals unnecessarily, wasting time and other resources to perform experiments that we have already shown are unsuccessful. Ruling out particular ideas will focus future research efforts into experiments with more chance of success, which should advance this field of research more rapidly.

Species and numbers of animals expected to be used

- Mice: 6000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice in this project since these are the least sentient species that allow us to produce meaningful results. We must conduct our research in vivo since we are examining changes in the brain that occur as a result of aging and as a consequence of Alzheimer's disease development. Less sentient animals do not have conservation of the brain structures that are most affected in Alzheimer's disease. In addition, the processes we are studying involve nerve cells and non-neuronal cells in the brain, and spread of abnormal proteins as a result of brain activity, and these aspects are very difficult to recapitulate without using an intact animal. However, some aspects of our project can be studied using a combination of primary neural cell cultures and we do this when it is appropriate to answer specific questions, with results related to those gained in experiments using human cells. We also culture brain slices that are prepared from postnatal animals for many of our experiments, since these can be aged in in vitro and they retain brain anatomy and connectivity across the slice.
We use pregnant mice, and embryonic mice to generate primary neurons. Postnatal mice are used to make long-term slice cultures. Protocols for these methods are well established and have been shown by us and others to be optimal at these developmental stages. In addition, aging brain slices in a dish negates the requirement to age mice until such time as they display detrimental age- or neurodegenerative -disease associated changes. We also use adult and aged mice to examine key age- and neurodegenerative disease-associated changes for comparison with postmortem human brain and validation of our culture models.
Typically, what will be done to an animal used in your project?

The work planned in this project falls into three main categories:

1. Normal and genetically modified mice will be aged typically to a maximum of 2 years of age. Brain and other tissues from these animals will be collected for examination of age- and disease-related changes in cell types, proteins, structure and markers of brain function.

2. Young mice may be used to provide brain tissue for primary neural cell and long term brain slice cultures.

3. Some normal and genetically modified mice may be treated with substances that affect ageing or neurodegenerative disease progression for up to 2 months, either as juveniles, adults or aged mice.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals on this project that are maintained out to old age may develop various age-related issues that are common to mice, such as benign tumours or hair loss, and in some cases sore patches on the skin. If these effects are only mild, and cause minimal distress, the animal may be maintained for several months, however, if any of these issues are thought to cause significant pain, discomfort or distress, the animal will be culled.

Animals modelling dementia may have learning and memory problems, that worsen throughout their life. However, these are not expected to have any major welfare issues for the affected animals, and a small number of animals will be kept for a maximum of two years as these memory problems develop. Some of these mice may also develop problems with mobility and motor functions. These are not expected to be accompanied by any pain, and in most cases, will not affect the mouse's ability to move around their home cage, feed, drink or groom.

A small number of animals may be treated by injection or by addition of substances to their food or drinking water to treat or exacerbate or disease. The injection is not expected to cause anything more than minimal discomfort, and those receiving drugs would in the most part be expected to improve. Treatments are short-term and should animals develop any sustained adverse effects, the study would be halted and animal treated accordingly.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the experimental work planned in this project will result in mild and transient harm to mice. A small proportion of work will cause moderate harm, as a result of ageing mice until they show disease phenotypes, or as a result of treatment with agents that may accelerate disease to help us understand the underlying biological causes. So, we estimate that 50% of animals will experience only mild harm and the remaining 50% will experience moderate harm.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to increase our understanding of the molecular events that occur in human neurodegenerative diseases. These diseases worsen as time passes. We seek to better understand the changes that occur in the brain as a result of ageing and worsening of neurodegenerative disease over time. Therefore, we must study an animal with a brain structure that is similar to humans, that has similar cells, cell connections and proteins, and in which disease worsens in a similar way to human disease. Both the complex circuitry of the brain and the process of aging are challenging to study outside of a living animal, hence using animals is generally considered as the most appropriate and sensitive way to address these questions.

Which non-animal alternatives did you consider for use in this project?

Human cell lines, human neurons and non-neuronal cells, and human postmortem brain.

Why were they not suitable?

It is essential to the aims of this project that we use a system in which we can study and manipulate brain changes that occur with aging and as neurodegenerative disease worsens over time. These complex changes cannot be replicated in cell lines, which do not grow or age like brain cells. Most protocols for establishing human brain cell cultures also involve steps that mean that the cells are newborn, therefore limiting their utility for ageing studies unless they are aged for years which is technically challenging. We do, however, use human nerve cells and other brain cells for aspects of our work, as appropriate. We also make use of postmortem human brain, which allows us to take snapshots of processes at different disease stages, but since these tissues are obtained from single individuals at specific disease stages, changes in each brain cannot be followed or the tissues manipulated.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The work outlined in this project will allow several projects that are aligned with the objectives of this study. We have calculated carefully the number of animals required to address the aims of each experiment and produce robust data, without using more animals than absolutely needed. Our previous experience, combined with published information and formal calculations, allows us to make informed judgements about how many mice, or primary cultures of mouse cells, are needed for routine experiments. For small scale pilot studies, numbers of animals will be kept as small as possible, and will be based on our and others prior experience of similar studies. In the case of follow-up studies for this new work, current number estimates are based on those typically required for similar experiments, but specific calculations will be conducted for each experiment to determine a sufficient number of animals before the experiment begins. We also take into account how many mice are required to maintain healthy colonies of each line.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

During the design phase of each experiment, where information was available, appropriate searches were conducted on each mouse line of interest to ensure we had access to all relevant information regarding expected outcomes in these animals. This knowledge, combined with our own extensive experience with these lines drove the calculations that informed our determination of animal numbers for each experiment. Extra consideration was made for a number of variables, including sex, age and background strain. The statistical approaches to be used at the end of the study formed a major part of the experimental design process, ensuring that all experimental approaches are robust.
The experimental design was also discussed with other researchers familiar with these kinds of studies, to further validate the design, and to ensure that we had included adequate control groups to each experiment, such that all data obtained will be valid.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have replaced much of the work that would previously have been conducted in mice, with studies using long term brain slice cultures. These methods allow us to examine several parameters (age, treatment) in tissue from a single animal. We also ensure that tissue collected from these cultures or from living mice is processed and stored to ensure that it can be used for multiple types of analysis (e.g. biochemical methods and pathological characterisation). All organs of interest will be harvested from each animal, and experiments will be designed to allow multiple follow ups in the tissue from each animal, thus minimising the total number of animals required. Thus, we aim to maximise the amount of data that we can obtain from our experiments.
In many cases, small scale pilot studies will be conducted prior to each full-scale study, with follow up analyses to ensure both that the objective is a valid one, and also that experimental design is optimised to use the minimal number of required animals. This will ensure that unnecessary or poorly planned large-scale experiments do not take place.
As far as possible, breeding strategies will be designed so that all animals from a mating are used for an experiment, and for general maintenance of a line, animal breeding will be monitored and controlled to ensure that we obtain sufficient mice to maintain the line, while minimizing the birth of mice that are not required.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mice since they are the lowest animal species that is sufficiently similar to humans to allow us to answer our research questions. We are interested in the spread of abnormal proteins in neurodegenerative diseases, and how brain cells other than nerve cells affect the connections between neurons to facilitate disease progression. Mice are the lowest mammalian species that show similar brain anatomy and regional connectivity that is similar to humans, that have similar non-neuronal and neuronal cells present and that allow us to study the effects of ageing.
We will use genetically altered mice that are considered to be the most appropriate and relevant for each experiment. These include mice in which:

1. Genes have been removed to enable us to understand their function for health and disease.

2. Human gene mutations have been introduced into mouse genes to allow us to determine how the mutation causes neurodegenerative disease.

3. An entire human gene has been introduced at low levels to allow us to investigate how these genes cause neurodegeneration as mice age.

Why can’t you use animals that are less sentient?

Abnormalities in human neurodegenerative diseases such as Alzheimer’s disease arise in specific brain regions and spread to other areas as the disease progresses. Each brain region possesses a different complement of cell types and connections that is considered key to this pattern of spread. In order to investigate disease progression in animals, it is essential that we use a model in which brain regions and their anatomical connections are similar to those in humans. Mice are the least sentient species of animal that meet these criteria. In particular, mice have a cerebral cortex and hippocampus with similar anatomy and functions to these areas in humans. These regions are critical for learning, memory and executive cognition that are affected in Alzheimer’s disease and related disorders. In addition, some of the key molecular pathways that are important in Alzheimer’s disease are not present in less sentient species such as fruit flies, worms or fish. These organisms would have to be further manipulated to make them suitable for our investigations. They also have a short life span, limiting their utility for studying age-related neurodegenerative diseases.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have refined our experiments to selectively use animal models that develop only mild-moderate features of human neurodegenerative diseases. We do not use animals that show the harmful features of terminal disease stages. We generally use the least adverse methods that are compatible with the aims of the study. For example, we preferentially study young rather than aged mice in which there are changes in brain chemistry, but no psychological or outward physical signs of disease. When we treat animals, dosing regimes will be designed to minimise stress and suffering to the animal. Animals will be handled prior to the onset of the experiment, to acclimatize them to this handling prior to the administration of any substance. Animals receiving substances will be particularly closely monitored during the initial treatment phase, to check for any unexpected issues that might arise.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow ARRIVE (most recently ARRIVE 2) guidelines when planning and conducting our research. We always include ARRIVE checklists with our publications.
We also take into account, and act accordingly, on recommendations and guidance provided by our NC3Rs liaison, and dedicated animal management, support and care teams.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have previously received funding from NC3Rs, an organisation committed to furthering 3Rs principles, to support our work and have attended many seminars/symposia and roadshows organised by their team so that we remain up to date with advances in this area. We receive regular communications from NC3Rs directly, and through our Institution.. We will implement, with advice from our vet and other trained and experienced staff, any recommendations that are in-line with the work outlined in this license and provided that any such change is not expected to have an impact on the animals such that it may alter research outcomes.

Home Office

NON-TECHNICAL SUMMARY

179. Testing advanced contrast agents to improve MRI diagnostics.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

MRI, hyperpolarisation, oncology

Animal types	Life stages
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to improve the quality of the pictures taken with magnetic resonance imaging (MRI); towards delivering better diagnostics in cancer. It uses novel chemically derived, injectable, 'contrast agents' to achieve this.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The direct monitoring of cell based activity in living animals will enhance our ability to treat disease and monitor subsequent progression. Currently the standard anatomical pictures that MRI produces are not sensitive enough to see the necessary subtle cellular changes.
If the pictures MRI takes could be improved so that the cellular development of disease could be seen, then it would be become possible to make earlier diagnosis and view the response to treatment.

What outputs do you think you will see at the end of this project?

We aim to produce evidence to show that novel MRI-based contrast agents permit the visualisation of cellular changes in health and disease. Pictures will be taken to map changes in cancer and blood flow.
Data from individual studies will be shared widely through journals, scientific conferences and meetings with clinical bodies to ensure the wider benefits are realised.
The intellectual property (IP) backing this project will be used to support the commercial developments needed to make this approach generally available.

Who or what will benefit from these outputs, and how?

Short-term (0-5 year) benefits:
We will produce a range of safe contrast agents for use in pre-clinical MRI to examine disease. The methods we use to take MRI pictures will be shared to help others. We expect to generate IP that will be of benefit to the UK.
Medium-term (5 year) benefits:
The resulting portfolio of information will support applications to the Medicines and Healthcare products Regulatory Agency for approval to use our methods in the clinic.
Long-term (6 year+) benefits:
Improved MRI picture quality will allow clinicians to map a range of bio-chemical functions within the cells of the human body. This will help them in diagnosing and tracking tumours, heart disease and a range of brain diseases (such as Alzheimer's and Parkinson's). Our methods offer quicker measurements, at low cost, thereby allowing doctors to offer such investigations to a growing number of patients whilst simultaneously improving outcomes. We expect these methods to help reduce the number of animal experiments needed in pre-clinical MRI.

How will you look to maximise the outputs of this work?

We are already collaborating with leading clinicians and researchers to identify suitable agents to use in the first instance. As the project develops we will seek to collaborate more widely as our technology is further recognized for its ability to transform the diagnostic use of both pre-clinical and clinical MRI. Beyond peer-reviewed publications, we expect this to be done through a dedicated website as a forum for targeted webinars.

Species and numbers of animals expected to be used

- Rats: 220

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult rats are a well-defined model for imaging research. The MRI equipment we are using is specifically designed for imaging these animals.

Typically, what will be done to an animal used in your project?

All animals will be anaesthetised, given pain killers and a contrast agent. They will then be examined by MRI over a period not exceeding 3 hrs. Respiration rate, heart rate and blood pressure will be monitored throughout. The animals will not recover after the MRI step. 100 of the rats used in this work will reflect a cancer model to test agent pooling and detection.
Data from all animals used can also inform us about perfusion (how fast agents reach particular organs/tumour sites).

What are the expected impacts and/or adverse effects for the animals during your project?

The animals used should not experience pain or discomfort, with pain relief and anesthics administered as appropriate. Any animal found to be suffering, following appropriate care, will be immediately and humanely killed.
Some of our rats will be used to grow subcutaneous tumours. Tumour size will not be large enough to cause discomfort. They are all humanely killed at the end of the experiment, and before they undergo any suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Our MRI experiments will be done under terminal anaesthesia where the animals will not be allowed to wake up,

so-called non-recovery experiments (220 rats).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Where possible, we make extensive use of alternative experimental resources, including computer simulations and cell culture models. It is impossible to accurately mimic the physiological conditions required to validate our novel MRI contrast agents through such methods. Thus, it is essential to use an experimental model such as the mouse/rat if these approaches are subsequently to be used for the diagnosis of disease in both animals and humans.

Which non-animal alternatives did you consider for use in this project?

Our contrast agents have already been tested widely in non-animal experiments. This has included simple test tube based imaging through to in-vitro models of blood-brain-barrier permeability.

Why were they not suitable?

While these studies have demonstrated that we can dramatically improve MRI picture quality, they do not account for the effects of physiology in living animals. We need to understand the effects of diluting our agents in a circulating blood system down to the capillary level. In addition we need to ensure that there is no significant change in blood pressure, breathing rate, heart rate and temperature as a result of agent injection. We need to understand whether transport times within the body from the injection location to the disease site are suitable.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All experiments are designed to use the minimum number of animals while still producing scientifically and statistically significant results. Animal numbers were estimated based on previous experience, discussions with the Medicines and Healthcare Products Regulatory Agency and published data.
The use of medical imaging allows the same animals to be studied over differing time points in life and thus increases data obtained whilst drastically decreasing animal numbers as without imaging animals would be killed at each time point to gain necessary data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

All experiments are designed to use the minimum number of animals while still producing scientifically and statistically significant results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Each new contrast agent will be tested on cells in a test tube to make sure they are safe before any invivo injection is done.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats are used because they age similarly to man. Furthermore cancer can be induced as in man.
The animals used in this work will include healthy rats and rats with tumours. By selecting existing models we can ensure that we are fully aware of any potential health concerns.
The studies will be completed under terminal anaesthesia from which the animal will not wake. Pain killers will be applied in conjunction with anaesthetics to make sure the animals feel no pain.
Imaging quality is improved/refined by ensuring that animals are kept still during the imaging process by anaesthesia.

Why can’t you use animals that are less sentient?

The rat models we propose to use mimic the corresponding disease in humans.
The physical limitations of the MRI system mean that work will start on rats as less sentient fish would be difficult to work with in terms of both required size, injection of a contrast agent and development of a water circulation system to keep the fish in a good physiological state.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Pain killers will be applied to ensure the animals feel no pain. Top-up doses of anaesthetic will be delivered as required to prevent animals waking up during experiments. If any procedural complications do arise advice will be sought immediately. During the programme we will ensure we remain fully up-to date with relevant new procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Injection volumes based on Recommended Dose Volumes for Common Laboratory Animals document

NON-TECHNICAL SUMMARY

180.Testing and Assessing FMD Vaccines

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Cattle	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The aim of this project is to assess the immunogenicity and efficacy of vaccines to foot-and-mouth disease virus.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Through testing vaccines in our facility we will be better equipped to deal with any future incursions into the UK. Internationally, we will be able to advise countries which vaccines are more efficacious for the strain they may be dealing with and whether there is any cross-protection to other strains that may be circulating in neighbouring regions.

What outputs do you think you will see at the end of this project?

This programme will contribute to national, European and global control of FMD. Vaccination is a fundamental part of FMD control measures and there is a need to confirm the efficacy of existing vaccines for field use. There is a regular need to identify new vaccine candidates to ensure that there are suitable vaccines for emerging FMDV strains. Once identified, these require additional testing to produce safe, potent, efficacious and stable vaccines. This work will have a global impact on animal health as it will help with international control and eradication of this economically devastating disease of cloven hoofed domestic and wild animals. Further vaccination with new adjuvants and constructs or manipulated capsids may increase the duration of immunity to FMD and the development of DIVA or marker vaccines for FMD will protect target species and act as efficient discriminatory tools to support serological surveillance and confirmation of disease free status.

Who or what will benefit from these outputs, and how?

A reliable supply of safe, potent and effective vaccines is essential for the maintenance of animal health and the successful operation of animal health programmes. Immunisation of animals with high quality vaccines is the primary means of control for many animal diseases including FMD.
The information gathered from these studies will ensure that the organisation is in a strong position to offer national and international advice on FMD. We will also have the ability to supply materials to research and diagnostic groups within the organisation to enhance our research activities into the infectious processes and immune responses associated with FMDV in the target species and our diagnostic capabilities.
How will you look to maximise the outputs of this work?

The approach to the data generated from non regulatory studies carried out under this PPL, whether successful or unsuccessful, will be published in peer reviewed journals to enable the immune responses to FMDV infection and or vaccination to be disseminated to the community.
Regulatory data remains confidential however this will be utilised to enable market authorisation for vaccines to be obtained, which has an obvious direct maximisation of output as this will lead to increased vaccine uptake being available across the globe.

Species and numbers of animals expected to be used

- Cattle: 420

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These animals and their ages are being used as these are mandated in the international OIE and EU standards for assessing Foot-and-mouth disease vaccines.

Typically, what will be done to an animal used in your project?

Animals will have blood samples taken at periodic time points throughout the course of the study, typically before vaccination and after vaccination. Animals may then have a vaccination. If the immunity of vaccinated animals is also being tested, animals will be injected with foot-and-mouth disease virus and may have blood and swab samples collected after challenge. A typical batch test of vaccine will take 21 days, and a potency test (assessing protective ability of the vaccine) will typically take 29 days. **What are the expected impacts and/or adverse effects for the animals during your project?**

Animals which are only vaccinated with vaccine are expected to only experience mild severity. Animals which are challenged with live virus are expected to experience moderate severity.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All animals which are only vaccinated with vaccine are expected to only experience mild severity. All animals which are challenged with live virus are expected to experience moderate severity. it is expected that around 70% of animals on this licence will experience moderate, and 30% mild severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The testing of vaccines requires the host species to be used under regulatory and licencing authorities. However, prior to animal testing, vaccine strains are screened using cell culture techniques to help match them to field viruses against which protection is sought and to check that they have growth and stability characteristics

suitable for vaccine manufacture and storage.

Research is ongoing to develop improved methods to evaluate vaccine performance in the field, reducing reliance on the use of experimental animals; some of the work from this project will generate data that can be used in models already developed to assist with their validation.

Which non-animal alternatives did you consider for use in this project?

It is not possible to assess vaccine efficacy and immunogenicity for regulatory purposes without using animals as the set international procedures stipulate the test. Titration of cattle adapted virus is now undertaken in vitro, animals are not used.

Why were they not suitable?

The regulatory tests could not be achieved without the use of animals as the law stipulates the test required.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This is based on:
2 Potency tests conducted per year, (17 animals per test) for 5 years = 170
8 batch tests per year (5 animals per test) for 5 years = 200
3 generalisation studies per year (2 animals per test) = 30
2 production studies per year (2 animals per test) = 20

Total = 420

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

These are the minimum number of animals used according to the OIE manual and EU Pharmacopeia.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Whilst the numbers of animals used in these studies is fixed by regulatory requirements, post-mortem tissues will be shared with other researchers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For safety and potency testing of these veterinary vaccines the target species for the products have to be used. To minimise suffering, we will ensure that the vaccines have been formulated in such a way as to maximise its chances of being efficacious before it is put into cattle, or that preliminary studies have been carried out to demonstrate immunogenicity before challenge. We can also use medicines under direction of the on call veterinary surgeon to reduce clinical signs.
When quantifying the virus in animals, all animals will be heavily sedated to reduce stress, and also allow more precise administration of virus to be given into the insensible target area of skin, thus reducing pain. Pain relief may be given before and during infection to reduce some of the clinical signs.
We have very strict humane end points and very well trained staff to prevent unnecessary suffering.

Why can’t you use animals that are less sentient?

international regulatory requirements stipulate cattle must be used to assess foot-and-mouth disease vaccines. This ensures that there is maximum confidence that the vaccine will protect cattle when they are vaccinated with it on farms around the world form FMD.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be housed together with bedding and other items of enrichment. Highly trained animal technicians will monitor these animals throughout the day, ensuring they are comfortable and to maximise their welfare status. We have 24/7 CCTV surveillance which can be used to monitor the animals behaviour over time.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Adherence to the ARRIVE guidelines for reporting these studies, as well as to the FELASA guidelines for large animal health monitoring to help ensure the most robust health assurance for animals used in this study.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Through continued CPD and frequent review of the CAAT (Centre for Alternatives to Animal Testing) I will keep informed about advances in the 3Rs. Included in CPD will be annual attendance at national lab animal science conferences as well as naturally reviewing the current literature surrounding infectious disease research, as well as attending relevant FMD conferences where updates and best practices are discussed.

Home Office

NON-TECHNICAL SUMMARY

181. Testing the efficacy of new vaccines against Clostridium difficile in two clinically relevant animal models

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

vaccines, mucosal, Clostridium difficile, infectious disease

Animal types	Life stages
Hamsters	adult
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To test the immunogenicity and protective efficacy of different vaccines given by different routes against Clostridium difficile infection (CDI) in two well established animal models.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

C. difficile is the leading cause of hospital-acquired infection worldwide, responsible for around 500,000 cases a year in the US alone, claiming the lives of around 30,000 people and costing $5Bn. In England and Wales, around 13,000 cases of CDI are reported each year costing the NHS over £120M (Public Health England, 2017). It is typically antibiotic-induced yet ironically the mainstay of therapy is Vancomycin or Metronidazole which, when taken, result in up to 35% of patients succumbing to a second infection and up to 60% of these, suffering a third infection.

There is no effective vaccine against CDI. After the Centers for Disease Control and Prevention (CDC) announced in 2013 that CDI is an urgent public health threat, three vaccines entered clinical trials, fast tracked by the FDA. All three vaccines are administered intra-muscularly and are based on inactivated forms of the 2 secreted C. difficile toxins, TcdA and TcdB. By the end of 2017, a Phase III trial was terminated. This vaccine generated high titres of systemic toxin-neutralising antibodies but did not prevent colonisation by C. difficile and thus failed to confer local protection in the gut. Given the similarity of the two vaccines remaining in trials to that of the failed trial, there are concerns that both will fail. Clearly a new vaccine is needed that specifically targets the gut to generate local antibody protection against CDI.

Our vaccines are designed for oral or nasal delivery to target the gut. The work proposed will generate proof of concept data with licensure of our technologies and prototypes to Pharma who can ultimately take our products to market. To this end, a Confidentiality Disclosure Agreement (CDA) for a collaboration with world-leading Pharma on vaccines has recently been signed.

What outputs do you think you will see at the end of this project?

New information

At the end of this project, we will have determined which type of vaccine and which delivery route (mouth or nose) is the most suitable to get protection against infection by Clostridium difficile in 2 clinically relevant rodent models.

Products

We would expect to have filed patents on some of our vaccine platform technologies and licensed these out to Pharma. We would also like to spin out a company based on the most successful technology which we will then apply to other infectious diseases.

Publications

We plan to publish our work in peer-reviewed journals following patent filing.

Presentation at conferences

We will present our findings at conferences locally and internationally.

Who or what will benefit from these outputs, and how?

In 2-3 years, completion of proof of concept data for our vaccines including immunogenicity and protective efficacy in hamsters and mice, and for some of these vaccines, identification of the most suitable delivery route.
In 2-3 years, patent filing of at least one vaccine platform with potential to spin out a company on vaccine platform technologies or licensure to Pharma.
After 3 years, dissemination of our findings in publications and at conferences.
In collaboration with Pharma, we expect to see one or more of our vaccines transition from our preclinical testing to human trials within 3-5 years.
Beyond this project, we will apply our platforms to higher priority pathogens such as ETEC and Shigella.

How will you look to maximise the outputs of this work?

I will apply for substantive translational funding for example, REDACTED. This will be aided by my collaboration with the world Pharma leaders in vaccine development. They have the infrastructure and finances to manufacture our products in accordance with GMP standards and perform clinical trials.

Once our platform technologies are patented, our data will be disseminated at conferences including the REDACTED, and through publications.

Species and numbers of animals expected to be used

- Hamsters: 784
- Mice: 784

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

It is important to test our vaccines in more than one animal model to acquire sufficient confidence in their efficacy. Hamsters (Golden Syrian) and mice (C57Bl6 and Balb/c) are the lowest vertebrates which display the same CDI disease symptoms as those observed in humans. The hamster is particularly susceptible to C. difficile but both rodents display the full spectrum of clinical symptoms including diarrhoea due to toxin-induced damage of the caecum, analogous to toxic megacolon in humans which manifests as wet tail and weight loss in hamsters, and as loose faeces and weight loss in mice. Within 48 to 72 hours post infection, the humane endpoint is typically reached. Comparing the length of time from infection to the humane endpoint between control and vaccinated groups is a powerful indicator of the success or failure of the vaccine being tested. Young adults of either sex are used for CDI studies, as shown in the literature, as they are capable of mounting

effective antibody responses. Hamsters are typically 10 to 12 weeks old weighing 100-130 grams and mice typically 6-10 weeks weighing 20 - 25 grams.

Typically, what will be done to an animal used in your project?

The procedures to be conducted include;

1. Optional general anaesthetic for animals to be immunised intranasally,

2. Immunisation with vaccines orally or intranasally. Animals will be immunised typically 3 times over 30 days to mount an antibody response. This is standard for C. difficile vaccines. Some animals will be euthanized around day 45, the experimental endpoint for this protocol (Protocol 1). Other animals will go on to Protocol 2 as described in procedures 3 and 4 below;

3. Administration of antibiotics. For hamsters, single dose orally with a wash-out period of up to 5 days before challenge with C. difficile. For mice, antibiotics in drinking water is given for 3 days then normal water for 2 days before challenge with C. difficile.

4. Challenge with C. difficile orally after the antibiotic wash-out, typically day 50. Animals will be closely monitored. Quantitative data will be obtained on length of time to established infection with humane end point assessed using an established monitoring scheme.

5. Vaccinated animals that do not show clinical symptoms up to 2 weeks post challenge will undergo antibiotic administration again to test for persistent protection of the vaccine being tested, against recurrent CDI. Briefly, antibiotic will be given in drinking water for 7 days followed by normal drinking water.

If they do not develop clinical signs after antibiotic administration for the second time, they will be culled 2 weeks after the last day of receiving antibiotics.

6. Once animals reach the humane end point, they will be killing by schedule 1 killing. Animals that show no clinical symptoms 2 weeks post re-administration of antibiotic will also be killing by schedule 1 killing (experimental endpoint). Serum and tissues will be collected for analysis. Total bacterial load in the caecum and histological changes in the caecum and intestinal tissue will be determined.

The duration of Protocol 1 is typically 45 days and the duration of protocol 2 is about 85 days for each experiment.

What are the expected impacts and/or adverse effects for the animals during your project?

1.General anaesthetic
All animals are expected to make a rapid recovery from the anaesthetic.
2.Immunisation studies.
We have not seen any adverse effects of our formulations. The majority of animals would be expected to experience some minor discomfort from administration.
3.Administration of antibiotic.
No adverse effects expected.
4.Challenge studies.
Animals in placebo groups are likely to experience moderate levels of severity. This is because they will develop symptoms of CDI usually 48-72 hours post infection. All animals showing signs of CDI will be monitored closely. The main clinical symptoms covered by the scoring system include diarrhoea which manifests as wet tail and weight loss in hamsters, and as loose faeces and weight loss in mice. Other symptoms monitored are indicative of poor well-being and include hunched posture, stary coat, pilo-erection, reduction in activity and response to stimuli, sunken eyes and unsteady gait.. For each parameter, a score of 0 to 3 is given; 0 for no change, 1 for a minor change, 2 for moderate and 3 for major change from the norm. The scores are then added together and

any animal scoring 15 or above will be humanely killed using a Schedule 1 method. For the weight parameter alone, any animal losing
20% of its starting weight or losing 10% between two concurrent welfare checks will be humanely killed.
Animals in vaccinated groups are likely to experience milder levels of severity because the vaccine is aimed at interfering with the colonisation of C. difficile and preventing the onset of disease symptoms. Those animals not displaying clinical symptoms of CDI up to 2 weeks after challenge with C. difficile will be given antibiotic again to monitor persistent protection of the vaccine. The experimental endpoint is 2 weeks after re-administration of antibiotic.
5.Schedule 1 killing. Animals will be exposed to the effects of the anaesthetic induction at the end of the study (terminal procedure).

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

100% of animals in negative control groups (not immunised) are likely to experience moderate levels of severity as they are expected to develop CDI. This equates to one third of the animals (n=8).
Vaccinated animals are likely to experience milder levels of severity depending on how protective the vaccine is. So far, we have only tested the antigen component of our formulations and have seen about 50% increase in protection in hamsters from CDI when immunised. We would expect to see a similar outcome in mice. We expect to see enhanced protection when the antigen is carried on one of our vaccine vehicles (platforms). The aim is to develop the formulation that gives 100% protection in both rodents.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The gut specificity of C. difficile (in particular, the requirements for an anaerobic environment and the availability of bile salts for germination of spores) has meant that suitable non-animal alternatives have so far not been identified.
The information that can be obtained from established tissue culture assays is limited as the infection process involves complex dynamic interactions between the bacterium and host such that C. difficile can undergo each stage of pathogenesis (germination of spores, colonisation of the intestine, secretion of toxins and sporulation) which are impossible to model effectively in non-animal alternatives at present.
Our vaccines require the generation of specific adaptive immune responses (antigen-specific secretory IgA and IgG) in the small intestine. Living animals are required to generate humoral immune responses.

Which non-animal alternatives did you consider for use in this project?

We have experimented with Galleria mellonella (wax moth larvae) in an attempt to replace the use of animals. This invertebrate model is widely used to study different bacterial-host interactions. There is potential for this model to be used to study colonisation by C. difficile following oral administration. I have discussed this idea with colleagues who are focused on developing alternative invertebrate models.

Discussions are on-going with another colleague to use their in vitro gut models and ethical approval is being sought in a separate collaboration to set up an ex-vivo gut model. However, these models will only be useful for investigating the blocking of colonisation of C. difficile by intestinal fluid and sera from vaccinated animals and therefore they do not present a non-animal alternative.

Why were they not suitable?

Oral inoculation with C. difficile results in a degree of infection, however since the intestinal tract of the wax worm differs significantly from that of higher vertebrates, the full spectrum of disease symptoms is not observed in the Galleria model.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Only small group sizes are needed for pilot studies. Based on our previous studies and based on the literature, we estimate all immunogenicity pilot studies (Protocol 1) and all challenge pilot studies (Protocol 2) will require 4 animals for the negative control groups (placebo group and control vaccine bench-mark group) and 4 animals for each experimental group which equates to 24 animals per study. Protocol 1 will be performed twice; the first time to compare different doses (concentrations) of formulation, the second time to compare different ratios of antigens in the formulation. For some vaccines, two routes of immunisation will be compared (oral and nasal). Protocol 2 pilot studies will be performed once, based on the optimised formulation from Protocol 1 studies and the study repeated with group sizes increased if an obvious protective effect of the vaccine is observed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I had a meeting with the NC3Rs Regional Programme Manager to discuss the protocols outlined in this application. Using, the EDA for Protocol 2, each step was discussed and mapped out to create a flow diagram. We discussed the rationale for the animal numbers based on previous pilot studies we have conducted and the method of randomisation and blinding to limit any bias and achieve greater accuracy.
When possible, two studies will be conducted in parallel using common control groups (placebo and benchmark groups) to reduce the number of animals. The EDA analysis tool will be used to analyse our data.
For planning larger scale challenge studies after these pilot studies, specific group sizes will be determined using online calculation tools such as G*POWER3.1 and professional statistical advice sought from statistician to ensure the minimal but relevant number of animals are used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

By using antigens known from the literature to elicit some protection, assessing them using computer programmes and testing them in the lab for antibody recognition using blood from C. difficile patients, before commencing animal studies we are confident about our choice of antigens in our formulations.
Personnel will be trained to administer doses competently which will reduce variability and therefore reduce the

number of animals needed in each group to achieve more consistent, reliable data.
By performing pilot immunogenicity studies with small group sizes to optimise dose and ratio of antigens, we are confident before we move on to challenge studies (infection with C. difficile) that we have fine-tuned our formulations to give the best possible protection. This means fewer groups of animals need to be vaccinated and infected as we already have some confidence in our formulations. Again a pilot study with small group sizes is performed to initially test the protective efficacy of our optimised formulations. After this, only if we see obvious protection will we go on to test larger group sizes based on power calculations. In this case, we will use the minimal but relevant group sizes to obtain statistically significant data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

According to a vast body of literature, two well-established clinically relevant animal models will be used for testing the efficacy of our vaccines against CDI. Hamsters and mice are the lowest vertebrates which display the same CDI disease symptoms as those observed in humans. Since disease progression is rapid in these animals, moderate adverse effects are experienced for a minimal length of time (usually 2 to 3 days) before humane end points are reached. Young adults of both rodent species generate similar antibody responses to those observed in humans making them suitable models for testing for immune responses to our vaccines.
For animals being dosed intranasally, general anaesthetic (AB) may be given beforehand to minimise any discomfort and distress. Only a very small volume of formulation (10 microlitres per nostril) will be used for dosing intranasally. The formulation is left to adsorb into the nasal mucosa during anaesthetisation so that the animal does not wake up with fluid in its nose.
For animals given antibiotics by oral gavage, flexible gavage needles will be used and small volumes, typically 50 to 100 microlitres.
For oral gavage of C. difficile spores, typically flexible gavage needles will be used and small volumes, typically 100 microlitres.
By trained, competent personnel carrying out all dosings, minimal discomfort will be experienced and minimal variation incurred.
Animals will be closely monitored after each procedure particularly after infection with C. difficile.
Animals will not experience adverse effects beyond moderate when euthanised at the humane endpoint or experimental endpoint by schedule 1 killing again by trained competent personnel performing this procedure.

Why can’t you use animals that are less sentient?

It is important to use hamsters and mice as these animals are the only known to be clinically relevant for CDI. They must be in their early adult stage of life as, at this stage, they will generate the most robust adaptive humoral immune responses than those younger or much older. It is important that live, well and active animals are vaccinated to be able to generate effective adaptive immune responses, mimicking those achieved in humans.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals will be handled regularly during their period of acclimatisation (including the refined mouse handling

methods developed for mice) and during the programme of work so that animals are trained to cooperate with procedures avoiding stress. Appropriate housing will include good husbandry practices such as appropriate changing of bedding, housing animals in groups of 2 to 3 per cage until antibiotic treatment prior to challenge studies. Mice are maintained in their groups throughout the study whereas single housing is adopted for hamsters which are solitary to ensure normal behaviour . Enrichment will be provided to allow species-specific behaviours, meeting or exceeding the standards prescribed under ASPA. For example, all animals will be provided with paper nesting material, cardboard tubes and wooden chew blocks in their cages. Hamsters may also be provided with wheels as a way of providing stimulation. Animals will be given free access to food and drinking water at all times.
Frequent welfare checks will be conducted and increased post procedures. Any signs of pain, suffering and distress will be monitored and advice sought from the NVS whenever necessary. To this end the use of established scoring systems will be used to monitor the welfare of the animals throughout the study and schedule 1 killing performed if animals reach the score associated with the humane end point. One way we are considering refining our accuracy in monitoring disease progression and to euthanise at earlier humane endpoints is to use temperature transponders. This practice has been established for the hamster CDI model at other institutes and a drop in core body temperature to 2C considered a suitable early humane endpoint along with weight loss. However the transponders have to be surgically implanted into the abdomen since when embedded subcutaneously into the nape, the readout fluctuates and does not accurately convey core body temperature. Since the adverse effects

associated with surgical implantation may outweigh the early symptoms of CDI, we are not going down this route. However, we are committed to reviewing the use of transponders if more refined implantation methods or devices become available. General anaesthetic will be given for a minimal length of time for animals to be intranasally-vaccinated to prevent distress, as agreed with the NVS, and animals will be allowed to recover fully before being returned to the home cage. Animals will be terminally anaesthetised prior to cardiac blood sampling.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the LASA guidelines for administration of substances. I will regularly check the nc3rs website (www.nc3rs.org.uk) for current guidelines, practical information and to get links to publications and online resources including videos. I will attend seminars given on refinement and discuss refinement with other scientists at conferences to learn best practices.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Maintain regular communication with scientists at other institutes who are conducting similar animal studies and glean helpful information based on their experience. Keep up to date with the literature on C. difficile infection studies, attend conferences, attend general seminars on the 3Rsand stay abreast of literature on the 3Rs with relevance to C. difficile. Refine protocols and procedures accordingly after consultation with Named animal staff, the NC3Rs Regional Programme Manager and with Home Office Inspector where a change to the license is required.

Home Office

NON-TECHNICAL SUMMARY

182. The assessment of analgesic mechanisms to support the development of novel analgesic therapies

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Analgesia, Neuroimmunology, Acute pain, Inflammatory pain, Neuropathic pain

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The aim of this project is to investigate the pathways involved in the sensation of pain and to identify and develop new and effective analgesics (pain killers).
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Chronic pain is the one of the biggest healthcare problems of the 21st century, affecting between 2050% of the adult population worldwide. In 2016, a study investigating the prevalence of chronic pain estimated that between one third to one half of the UK population are affected by chronic pain (Fayaz et al, 2016). Furthermore, chronic pain is also associated with the emergence of other serious healthcare issues, including depression, anxiety, fatigue, sleep disturbances, as well as changes in mental function, which often make the pain worse, severely affecting the physical and mental state of an affected individual, and increasing the demand on healthcare and support services. Across Europe, the economic cost associated with chronic pain has been estimated at around 450 billion euros per year (Breivik et al, 2013). These statistics highlight the need to develop new and effective analgesics for the treatment of chronic pain.
Our current understanding of the mechanisms involved in the development and maintenance of chronic pain are significantly limited, meaning that existing therapies for its treatment are largely unsuccessful, or have significant side effects associated with long-term use. One of the most prescribed classes of analgesics used in the treatment of chronic pain are opioids, however, in recent years they have been associated with significant levels of misuse and were responsible for 42,249 deaths in the US alone in 2016 (National Institute on Drug Abuse, US), highlighting the need for new non-opioid therapeutic options. In addition to chronic pain, there is also a substantial unmet need in the treatment of acute pain, specifically post-operative pain, which is commonly treated with opioid-based therapies.
Importantly, pre-operative opioid use is an important risk factor for persistent/chronic post-operative use and is linked to longer opioid prescriptions. Therefore, in addition to chronic pain conditions, there is also significant societal value in developing effective, non-opioid analgesics for the treatment of acute pain conditions.
This project aims to study the mechanisms involved in the development of acute and chronic pain conditions, in order to facilitate the development of new and effective analgesic therapies.
References:
Breivik et al. 2013. BMC Public Health.13:1229
Fayaz et al. 2016. BMJ Open. doi.org.10.1136/bmjopen-2015-010364.
What outputs do you think you will see at the end of this project?

The outputs from this project can be summarised by the following:

- New information: Outputs from this project will enhance our understanding of the mechanisms involved in pain, with the intent of facilitating the development of new and effective analgesics that have an improved benefit-risk profile over existing therapies.

- Publications: Our aim is to publish outputs from this project in open-access peer reviewed scientific journals.

- Products: The principal aim of this project is to further understand the mechanisms involved in the development and maintenance of pain in order to develop and produce new and effective analgesic therapies.

Who or what will benefit from these outputs, and how?

The overall aim of this programme of research is to directly benefit individuals currently suffering from pain through the identification and development of new analgesic therapies.
The short- and medium-term benefits of this work are to support the ongoing therapy development programmes at the establishment in order to test the analgesic potential of new immune cell-related therapies for the treatment of pain conditions (0-5 years).
The long-term benefits of this work include the identification of novel immune cell-related targets that are involved in the development and maintenance of pain conditions, which will form the basis of a continued effort to develop novel and effective analgesics (5-10 years).

How will you look to maximise the outputs of this work?

Where possible, every effort will be made to publish and share relevant outputs of these studies (e.g. identified mechanisms involved in the development/maintenance of pain) with the wider scientific community. This will be through scientific collaboration with external academics, as well as the publication of research findings in open access research journals. Where possible, interim updates will be presented at local and/or international conferences.

Species and numbers of animals expected to be used

- Mice: 6300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project aims to identify and develop novel analgesics (pain killers) for the treatment of chronic pain conditions. In order to assess the ability for a new drug to reduce pain, we first need to create a situation where there is pain to treat. As pain is a conscious sensation, this assessment needs to take place using a conscious animal. Within this project licence, we propose to use adult mice to assess the effectiveness of new analgesics. Mice display very similar behaviours (i.e. hypersensitivity to environmental stimuli) to humans with respect to pain, and their genetics can be readily altered in order to understand the mechanisms by which an analgesic may be working. Furthermore, there is a high level of translatability of the mechanisms that underlie painful conditions between mice and humans.
For example, the functional loss of a specific gene that causes pain insensitivity in humans (e.g. Scn9a), can also lead to pain insensitivity in mice. In addition, widely used analgesics used to treat human pain, such as aspirin, ibuprofen, gabapentin and opioids, are also highly effective at alleviating pain in mice.

Typically, what will be done to an animal used in your project?

An animal used under this project licence will typically experience the following:

- **The basal assessment of motor function and sensory sensitivity (protocol 1).** Within this protocol, the locomotor activity (ability to move) of an animal will be assessed, along with its ability to respond to a heat, cold and/or touch stimulation. All methods of assessment used within this project allow an animal to withdraw from testing at any time, and suitable maximum exposure periods are used to ensure that no

animal will be harmed by any of the assessments. An animal will be limited to two types of assessment per day (Max. 10 assessments per modality, over a maximum of 35 days), and will only undergo this protocol once. As part of this assessment, an animal is likely to receive a single course of treatment (administered by an injection, through topical application or provided within the food/water).

OR

- **The induction and assessment of inflammatory pain (protocol 2).** The induction of inflammatory pain will involve the injection of a chemical substance that causes inflammation. This will only occur once. Inflammation will last up to 14 days (depending on the chemical substance injected), and within this time an animal is likely to receive a single course of treatment (administered by an injection, through topical application or provided within the food/water). The presence of inflammation is expected to make an animal more sensitive to heat, cold and touch stimulation, which can be assessed for up to 14 days (depending upon the chemical substance injected). The effect of any given treatment to reduce pain will be assessed by measuring the time taken for an animal to withdraw from a specific sensory stimulus (e.g. heat, cold or touch). An animal will be limited to two types of assessment per day and will only undergo this protocol once.

OR

- **The induction and assessment of neuropathic pain (protocol 3).** The induction of neuropathic pain will involve the animal to undergo a brief surgical procedure, under general anaesthesia, in order to tie/cut part of the sensory nerve innervating the hind leg of the animal. Following this procedure, an animal becomes more sensitive to cold and touch stimulation, which can be assessed for up to 35 days. As part of this assessment, an animal is likely to receive a single course of treatment (administered by an injection, through topical application or provided within the food/water). The effect of any given treatment to reduce pain will be assessed by measuring the time taken for an animal to withdraw from a specific sensory stimulus (e.g. cold or touch). An animal will be limited to two types of assessment per day and will only undergo this protocol once.

OR

- **The induction and assessment of acute colorectal distension (protocol 4).** In this protocol, an animal will be withheld food overnight prior to the model being implemented. Under terminal anaesthesia, a balloon catheter will be inserted into rectum of an animal, and will undergo a series of short inflation cycles (inflation and deflation), which in turn will cause the colorectal region of the mouse to distend and recover. Once these cycles are complete, the animal will be immediately euthanised and tissues will be collected. As part of this assessment, and prior to model implementation, an animal is likely to receive a single course of treatment (administered by an injection, through topical application or provided within the food/water). The effect of any given treatment to potentially reduce pain will be assessed by measuring specific markers of cellular activity in tissues of the nervous system.

What are the expected impacts and/or adverse effects for the animals during your project?

The main adverse effect associated with this project is pain caused by inflammation or nerve injury.
The local injection of an inflammatory agent is likely to cause short lasting pain and hypersensitivity to specific sensory stimuli, as well as local swelling (oedema) and redness of the treated area. Where an injection is given at the paw or knee, animals may also exhibit reduced use of the affected limb immediately after injection, however, this should subside within hours. The majority of inflammatory agents to be administered are likely to only cause a mild inflammatory reaction, which should minimise the level of discomfort and pain experienced by the animal.
The tying or cutting of sensory nerves innervating the rear leg is likely to cause mild to moderate spontaneous pain, in addition to an increased sensitivity to specific sensory stimuli. Immediately after the induction of any nerve injury model, local inflammation is expected at the site of nerve injury as well as the site of surgery. An animal that has undergone this procedure is likely to show a reduction in affected limb use, although this should not affect normal rearing behaviour or feeding. These adverse effects are expected to last for the duration of the

model (up to 35 days). Any animal that has undergone sham surgery is likely to display mild and short-lasting signs of hyperalgesia associated with the local inflammation caused by sciatic nerve exposure. These adverse effects are not expected to last more than seven days.
Colorectal distension will be performed under terminal anaesthesia, therefore pain, suffering and distress is not expected.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Of the animals used under this licence, it is estimated that approximately 60% will experience mild severity, and 40% of animals will experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

This project aims to identify and develop novel analgesics for the treatment of chronic pain conditions. In order to assess the ability of new therapies to reduce pain, we first need to create a situation where pain is measurable, and therefore treatable. Importantly, pain is a conscious sensation, involving the integration of multiple molecular mechanisms across peripheral and central nervous systems. For this reason, the assessment of pain needs to be performed on sentient, behaving animals, with developed peripheral and central nervous systems.

Which non-animal alternatives did you consider for use in this project?

Suitable *in vitro* models have been considered to investigate whether a novel therapy/therapeutic target can directly affect isolated cellular processes involved in the processing of noxious stimuli. Examples of such models include the assessment of relevant cultured cell types (e.g. sensory neurons, astrocytes, immune cells) using a variety of methods (e.g. electrophysiology, calcium imaging, peptide release assays, transcriptomic analysis). Although these models do not model pain, they may indicate whether a therapy/therapeutic target can directly, or indirectly, affect mechanisms involved in the detection of noxious stimuli. Results from these studies will help in predicting the analgesic potential, in addition to the potential mechanism of action, of a novel therapy/therapeutic target before being tested *in vivo*.

Why were they not suitable?

While these models do offer some value in predicting the potential analgesic effect of a novel therapy, they do not model pain. Pain is a conscious behaviour, involving the integration of numerous genetic, molecular and cellular factors, within, and across, functional peripheral and central nervous systems. Given this level of complexity, to date, the mechanisms involved in the development and/or maintenance of chronic pain are poorly understood, and as such, there are no suitable alternatives to faithfully model pain behaviour *in vitro*.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals to be used under this licence has been estimated through the anticipated need, over a five-year period, to assess, develop and identify novel therapies/therapeutic targets for the treatment of different pain conditions within the licensed establishment. This estimation has been based on previous experience gained working under other pain-focused project licences at other licensed establishments within the United Kingdom.
Statistical advice has also been sought to determine the number of animals needed for each experimental model to ensure sufficient power for the measured endpoints and hypotheses being tested.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical advice is always sought as part of the study design process to ensure that the minimum number of animals is used to sufficiently meet to requirements of the experimental aim. Where appropriate, historic data will be used to support the experimental design process, however, if suitable data are not available, small pilot studies will be undertaken, under statistical guidance.
In addition to statistical support, all studies conducted under this licence will undergo internal peer review in order to ensure that all aspects of experimental design are suitable for the study being proposed.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Under this licence, the following measures will be taken to optimise animal use:

- *In vitro* cell culture systems will be used to analyse specific aspects of sensory physiology in isolation.
- Pilot studies will be used to ensure the effective design of experiments, and to keep the number of animals used to a minimum.
- Where appropriate, at the end of an experiment, spare tissues will be freely shared with other researchers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Methods of pain assessment: All methods of pain assessment described within this protocol have been designed to assess the threshold at which an animal withdraws from a given stimulus. The use of withdrawal thresholds to assess pain behaviour, means that an animal is free to withdrawal from any given stimulus at any

time, keeping the amount of pain, distress and lasting harm experienced by the animal to the absolute minimum, while still having utility in measuring pain behaviour. In addition, these methods are the least invasive to assess sensitivities to different sensory modalities, including mechanical, heat and cold. The use of these different sensory modalities enables the investigation into different types of pain that involve different signalling pathways, meaning that we can assess multiple pain pathways while using as few animals as possible. Importantly, suitable cut-offs/limits are put in place on all experimental models/methods in order to prevent damage and minimise distress to the animal.
Models of inflammatory pain (injection of pro-inflammatory substances): All of the inflammatory models proposed are well validated and widely published, with reproducible and reliable associated endpoints. The proposed models also cover various aspects of inflammation, which differ in their mechanism of action, duration of action, and effect on the animal. Importantly, these models allow for the assessment of specific, clinically relevant inflammatory pathways to be investigated. Furthermore, clinically relevant anti-inflammatory analgesics (e.g. NSAIDs) are effective in attenuating the pain behaviours induced by these models, highlighting the translatability of these models in assessing analgesic effectiveness of novel therapies/therapeutic targets for the treatment of inflammatory pain.
Models of neuropathic pain (sciatic nerve injury): All of the neuropathic pain models proposed are well validated and widely published models, with reproducible and reliable associated endpoints. Importantly, the models proposed elicit clinically relevant phenotypes commonly associated with neuropathic pain, such as sensory hyperalgesia and allodynia. In addition, the pain behaviours associated with the proposed models are resistant to commonly used anti-inflammatory analgesics (e.g. NSAIDs), which is a common hallmark of neuropathic pain in patients. Furthermore, therapies that are effective at treating neuropathic pain in the clinic (e.g. gabapentin, lidocaine, opioids) are also effective at alleviating the pain symptoms associated within the proposed models, highlighting their translatability in modelling clinically relevant neuropathic pain.
Models of acute visceral pain (colorectal distension): The model of acute visceral pain proposed is well validated and widely published, with reproducible and reliable associated endpoints. This model will be performed under terminal anaesthesia and assesses the activity of damage-sensing sensory neurons (nociceptors) that innervate the intestine. The activity of these neurons is correlated to the pain experienced by patients with visceral pain disorders (e.g. inflammatory bowel disease), and therefore understanding how therapies can affect these neurons will help with the development of therapies for treating visceral pain.

Why can’t you use animals that are less sentient?

Pain is a complex, conscious and integrative behaviour, relying upon the activation and integration of numerous neuronal pathways and cellular interactions. As such, pain behaviour needs to be modelled in awake animals with fully developed peripheral and central nervous systems.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The models described within this licence will undergo continual review and refinement to ensure that they cause the minimum harm to animals, while maintaining scientific utility. For example, the duration of model implementation will be continually reviewed to ensure that the earliest appropriate endpoint is used. Furthermore, the number and frequency of behavioural assessments will be kept to the minimum number needed for the study.
For each inflammatory and neuropathic model, animals will be assessed daily and monitoring score sheets will be followed to assess the welfare of the animal as the model progresses.
Current good practice in animal handling (e.g. using tunnels to move mice) will be reviewed and implemented where practicable. In addition, consideration will be taken with respect to the enrichment included within the cage along with specialised bedding (e.g. softer bedding), to minimise the welfare costs. Warming cabinets will be used for post-surgery recovery, and wet food/mash will be provided to ensure all animals recover as quickly as possible. Additional refinements to the cage environment and animal handling will be considered throughout the duration of this licence.

The use of home cage monitoring (e.g. Tecniplast DVC or Vium-based platforms) will be investigated in order to improve pain behaviour assessment. These platforms allow for a non-invasive assessment of animal behaviour within the home cage environment, and therefore have the potential to minimise welfare costs further, as long as the observed behaviours recorded are robust, reproducible and translatable with respect to monitoring pain.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The following is a list of the best practice guidance that we routinely follow.

- Deuis JR et al., (2017) Methods used to Evaluate Pain Behaviours in Rodents. Frontiers in Molecular Neuroscience 10:284. Diehl KH et al., (2001) A Good Practice Guide to the Administration of Substances and Removal of Blood, Including Routes and Volumes: JOURNAL OF APPLIED TOXICOLOGY 21, 15–23
- Hestehave et al. (2017) Is there a reasonable excuse for not providing post-operative analgesia when using animal models of peripheral neuropathic pain for research purposes. Plos One 12(11):e0188113.
- LASA - Guiding principles on good practice for Animal Welfare and Ethical Review Bodies Sep 2015
- LASA - Guiding Principles for Preparing for and Undertaking Aseptic Surgery 2017
  Mogil J. (2019). The translatability of pain across species. Phil Trans Roy Soc.
- Morton DB et al., (1993) Removal of blood from laboratory mammals and birds Laboratory Animals 27, 1-22
- NC3R's - Responsibility in the use of animals in bioscience research: Expectations of the major research council and charitable funding bodies
- Prescott MJ, Lidster K (2017) Improving the quality of science through better animal welfare: the NC3Rs strategy. Lab Animal 46(4):152-156.
- Review of harm-benefit analysis in the use of animals in research - Report of the Animals in Science Committee Harm-Benefit Analysis Sub-Group chaired by Professor Gail Davies Nov 2017

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs through regular referral to the NC3R's website, as well as other published literature. Furthermore, the establishment Named Information Officer (NIO) will facilitate the dissemination of information in relation to any such advances. In accordance with any updates, we will review and revise the protocols within this licence to ensure they have been adequately considered, and where applicable, applied.

NON-TECHNICAL SUMMARY

183. The cellular and synaptic basis of depression and anxiety

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

depression, anxiety, early life adversity, fragmented maternal care, hippocampus

Animal types	Life stages
Mice	juvenile, adult, neonate, embryo, pregnant
Rats	juvenile, adult, neonate, embryo, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to increase our understanding of the ways in which changes in the activity of neurons and the synapses by which they communicate can lead to depression and anxiety. The mechanism of action of existing antidepressant medications is poorly understood in many cases, and a parallel aim is to improve this understanding, and to identify novel therapeutic strategies. A particular focus will be the impact of early life adversity, and how this impact can be mitigated.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

There is a growing awareness of the key role of early life adversity as a risk factor for the development of psychiatric disorders in adulthood. Experience-dependent changes in the brain, as well as being involved in memory formation, also contribute to the development of mood disorders and anxiety. By understanding these changes, we may be able to identify novel therapeutic strategies for the treatment of these conditions.

What outputs do you think you will see at the end of this project?

Depressive disorders are the biggest single contributor to chronic disability worldwide. Despite many years of research, there has been limited progress in the development of new treatments in recent decades. Currently available drugs have limited and variable efficacy, and, when effective, typically take weeks or months to improve mood and behaviour. The problem stems, in part, from our lack of understanding of the brain mechanisms underlying depression, and uncertainty surrounding the ways in which antidepressants work, topics that we plan to address in this project. Regarding anxiety, currently available treatments often cause sedation and cognitive impairment as well as reducing anxiety. As part of a wider collaborative research effort, we are currently working on the development of non-sedating anti-anxiety drugs. The main outputs of this project will be new information about the brain mechanisms of depression and anxiety, and information about new drugs that might be useful to treat these conditions. Our work will mainly be communicated in the form of research publications, but also in seminars and conference presentations.

Who or what will benefit from these outputs, and how?

Our collaborators, and researchers working in related fields, will benefit from our research both during and beyond the time-frame of the project, as a result of informal information sharing, conference presentations, and reading our peer-reviewed research publications. This information will help to shape the research programmes of other researchers by alerting them to potential new avenues of research, preventing unnecessary duplication of work, and informing them of unsuccessful approaches. Longer-term benefits may include the development of potential new drugs for human clinical trials, or the identification of new strategies for future drug development. But these benefits—such as the development of a new drug or therapy—will occur over a timescale of several years and are likely to be realised beyond the lifetime of the licence itself.

How will you look to maximise the outputs of this work?

The work detailed in this project involves collaborations with other research groups. By bringing a variety of

sources of expertise and experimental approaches to bear on the project, we aim to maximise the visibility of the research publications and new knowledge that will be generated. If an experiment produces data that answer the question posed, they will be published, regardless of whether the result is positive or negative. Details of unsuccessful approaches will also be shared informally in discussions with colleagues and other researchers in the field, and at scientific conferences.

Species and numbers of animals expected to be used

- Mice: 2400
- Rats: 1600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in this project will be rats and mice. The brain regions that are thought to be involved in anxiety and depression in humans have clear structural and functional parallels to the same brain regions in rats and mice, something that is not true of non-mammalian or invertebrate species. Like humans, rodents that experience early life adversity show behavioural changes in adulthood, including depressive-like symptoms in behavioural tasks. In order to study the impact of early life adversity, neonatal animals will experience an interruption of maternal care. This will be caused by providing a reduced amount of nesting material, leading the mother to make more frequent trips away from the nest. The behavioural and physiological impact of this experience will be assessed in juvenile and adult animals.

Typically, what will be done to an animal used in your project?

In many cases, animals will be provided with a reduced amount of bedding during early postnatal development. This will cause the mother to make more frequent trips out of the nest, resulted in fragmented maternal care, a form of early life adversity. The effects of this experience on behaviour and brain function will then be assessed when the animals reach adulthood. Animals will often be injected with non-harmful drugs in conjunction with behavioural testing (typical duration = 1-4 weeks). In some cases, animals will be surgically implanted with electrodes for the direct recording of brain activity, either during behavioural testing, or under anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Fragmented maternal care will result in a slight reduction in body weight throughout development, and long-lasting, but subtle, behavioural changes. The procedure will not cause pain or lasting distress. Administration of drugs may cause mild and temporary changes in behaviour (< 24 hours). Behavioural tests will cause no lasting adverse effects or distress. Surgical procedures, such as the implantation of electrodes into the brain, may cause pain, but this will be controlled using surgical anaesthesia, and postoperative analgesia as required. Animals may also experience some postoperative weight loss, but these signs should last no more than 3 days.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximate proportions in each severity category will be as follows:

Mice:
mild: 55% moderate:

35% non-recovery:

10%

Rats:
mild: 30% moderate:

30% non-recovery:

40%

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The main aim of this project is to study the physiological basis of anxiety and depression-like symptoms, and the actions of antidepressant drugs that may improve these symptoms. This is not possible without the use of animals in which behavioural changes--or changes in brain circuits relevant to these behaviours--can be studied. This approach is not possible in human participants owing to the invasive nature of the techniques required to measure brain activity and plasticity.

Which non-animal alternatives did you consider for use in this project?

Human electrophysiological techniques such as EEG recording (recording oscillatory brain activity from the scalp), and brain imaging such as functional magnetic resonance imaging (fMRI), have provided valuable information about the brain areas involved in anxiety and depression.

Why were they not suitable?

Although the use of EEG and fMRI in human participants can reveal correlations between brain activity and behaviour, mood, and cognition (e.g. problem-solving and memory), there are some critical drawbacks. The central problem is the low spatial resolution of these techniques--meaning that the techniques cannot identify the molecular and cellular mechanisms responsible for behaviour, only the general areas of the brain that are active. It is impossible to study processes that occur at the level of the cell, including the ways that neurons communicate with other cells around them, without the without the use of invasive techniques that involve surgery and cannot be employed in healthy humans.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are based on an estimate of the numbers required to achieve statistically robust effects across all of the work laid out in the licence. In some cases, this includes the numbers of animals needed for breeding programmes to obtain the experimental animals. The estimate of numbers is based on past experience of similar experiments, the published literature, and, in some cases, on preliminary data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, we have designed experiments to minimise the impact of variables responsible for trial-to-trial or between-animal variability. For example, during behavioural tasks, animals will be handled by trained staff. They will also be allowed to get used to being handled, the person handling them, and the room in which behavioural testing will be carried out. Handling techniques that cause minimal stress will be used, such as cupping and tube-handling. Behavioural testing is conducted in quiet rooms away from human activity. Reducing variability by doing these things means that fewer animals are needed to achieve statistically significant results. In many cases, we will collect multiple measures in the same animal, either by repeating behavioural tests to increase reliability, or by recording multiple electrophysiological measures of the impact of a drug. It will often be possible to compare a measure before and after the administration of a drug, reducing the need for comparisons between different animals, and hence reducing the numbers required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will also minimise the numbers of animals used by conducting pilot studies when the effects of a treatment or manipulation are unknown. A pilot study will allow us to estimate the numbers needed to observe statistically robust effects in the main experiment, avoiding the problem of underpowered studies if the numbers are too low (and there is therefore not enough data to tell whether the change we are interested in has occurred), or unnecessary use of animals if the numbers are two high. Where animals are bred in-house, we will use efficient breeding programmes that generate the required numbers of animals and no more.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animals used in this project will be wild-type rodents (i.e. normal animals with no genetic alterations) or animals with non-harmful genetic alterations (changes in genes that do not result in obvious clinical signs, but only subtle behavioural changes that can be detected using specific tests). Some of these animals will undergo a form of fragmented maternal care known as the "reduced bedding model", in which a reduced amount of nesting material is provided for a number of days starting from the second day after pups are born. Reducing the amount of bedding causes the mother to enter and leave the nest more frequently than usual, resulting in an interruption of maternal care. This causes a range of phenotypic (behavioural and cellular) changes in adulthood that are consistent with the impact of early life adversity in humans. These include increased anxiety, increased depressive symptoms, and an increased risk of the development of drug addiction. For these reasons, we believe that we can use this procedure to increase our understanding of the changes in brain activity and plasticity (changes in the wiring of the brain resulting from experience) associated with this model, by studying the impact of antidepressant drugs in animals that have undergone the procedure.
Fragmented maternal care, has a mild to moderate rating and is considered less stressful than an alternative approach involving complete physical separation of the dam and pups. Previous experience demonstrates that a consequence of fragmented care can be a reduction in the speed that pups grow. However, the pups' feeding is normal, and they appear healthy, despite being slightly smaller at weaning.
Some of the work in this project will be carried out in brain tissue taken from animals that have been painlessly euthanised, or in animals under terminal anaesthesia (anaesthesia from which an animal does not wake up) that also suffer no pain or distress. However, while these techniques can provide information about the functioning of neurons, synapses, and brain circuits, they cannot alone establish the relationship between brain activity and behaviour. For this, it is necessary to record from animals in which electrodes have been implanted into specific areas of the brain under anaesthesia, before the animal is allowed to wake up so that, after recovery from surgery, we can investigate how the activity of neurons changes with different behaviours.
The animals will receive painkillers after surgery, as advised by a vet, they will be closely monitored, and they will be given other supportive measures such as being kept warm and provided with special food. Recording of brain activity will not begin until the animals have fully recovered from surgery.

Why can’t you use animals that are less sentient?

The brain regions involved in anxiety and even depression-like symptoms in rats and mice work in a similar way to the same regions in humans, something that is not true of non-mammalian or invertebrate systems. We can find out a lot of information by looking at the functioning of neurons and synapses in brain tissue taken from animals that have been painlessly euthanised, or in animals that are asleep under an anaesthetic from which they do not wake up (terminally anaesthetised). A substantial part of the work outlined in this project will be carried out in this way. However, while these techniques can tell us a lot about the functioning of neuronal circuits, they cannot alone establish connections between brain activity and behaviour.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All staff involved in animal experiments will be trained in handling techniques that minimise stress, and will receive extensive training in all other techniques with which they will be involved. All animals undergoing surgical procedures will receive postoperative pain management and will be closely monitored during recovery. During the project, we will continually seek to identify refinements to our animal husbandry and experimental techniques, and implement these as appropriate. For example, advances in electrophysiological techniques, such as the ability to record simultaneously from multiple sites in the brain, are making it possible to collect more information from each animal. We will adopt techniques such as this where feasible.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice as laid out in guidance documents published by the UK Home Office and NC3Rs. Our reporting of research findings will follow the NC3Rs ARRIVE 2.0 guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about advances in the 3Rs via the National Centre for the Replacement Refinement and Reduction of Animals in Research (NC3Rs). The Named Veterinary Surgeon and staff of REDACTED will also inform us of improvements in experimental and animal husbandry techniques, and we will implement these as appropriate. We will also identify relevant refinements to our techniques in the published scientific literature, and will seek to implement these where feasible.

Home Office

NON-TECHNICAL SUMMARY

184. The cellular and synaptic basis of learning and addiction

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

learning, memory, synaptic plasticity, neurodevelopmental disorders, addiction

Animal types	Life stages
Mice	adult, juvenile, pregnant, embryo, neonate
Rats	juvenile, adult, embryo, neonate, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs

it's addressing.

What's the aim of this project?

The aim of this project is to increase our understanding of the mechanisms that underlie the formation of memory—changes in the activity of neurons and the synaptic connections by which they communicate. The project focusses on the normal mechanisms of learning, their disruption by neurodevelopmental abnormalities, and the formation of maladaptive memories in addiction.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work will provide new information about the mechanisms of normal memory formation, and the ways in which these mechanisms are affected by neurodevelopmental disorders such as fragile-X syndrome. Experience-dependent changes in the brain also contribute to the development of drug addiction. By understanding these changes, we may be able to identify novel therapeutic strategies for the treatment of memory impairment and addiction.

What outputs do you think you will see at the end of this project?

The main outputs of this project will be new information regarding the neural and synaptic basis of learning and memory, as well as some of the maladaptive changes that occur in animal models of human disorders such as fragile X syndrome and addiction. These outputs will primarily be disseminated in the form of research publications, but also in seminars and conference presentations.

Who or what will benefit from these outputs, and how?

Our collaborators, and researchers working in related fields, will benefit from these outputs both during and beyond the time-frame of the project, as a result of informal information sharing, conference presentations, and reading our peer-reviewed research publications. This information will help to shape the research programmes of other researchers by alerting them to potential new avenues of research, preventing unnecessary duplication of work, and informing them of potentially unsuccessful approaches. Longer-term benefits will include the in vivo validation of potential therapeutic strategies, and the identification of possible new strategies for drug development. All the objectives of this project have a translational or drug-discovery component, and we anticipate that our work will inform future preclinical and clinical research programmes. But these benefits—such as the development of a new drug or therapy—will occur over a timescale of several years and are likely to be realised beyond the lifetime of the licence itself.

How will you look to maximise the outputs of this work?

The work detailed in this project involves collaborations with other researchers, both locally and in other labs around the world. By bringing a variety of sources of expertise and experimental approaches to bear on the project, we aim to maximise the visibility of the research outputs that will be generated. If an experiment produces data that answer the question posed, they will be published, regardless of whether the result is positive or negative. Details of unsuccessful approaches will also be shared informally in discussions with colleagues and other researchers in the field, and at scientific conferences.

Species and numbers of animals expected to be used

- Mice: 4370
- Rats: 1570

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The animals used in this project will be rats and mice. The brain regions involved in learning and memory in both species have clear structural and functional parallels to the same brain regions in humans, something that is not true of non-mammalian or invertebrate systems. In many cases, rats will be used owing to their proficiency and flexibility in a wide range of behavioural tests. In other cases we will use mice; these are capable of most of the same behavioural tasks that can be carried out using rats, and they offer the possibility of a greater range of genetic manipulations that is currently available in rats. In most cases, we will focus on juvenile or young adult animals, old enough to show robust performance in memory tasks.

Typically, what will be done to an animal used in your project?

Animals will typically be injected with non-harmful drugs in conjunction with testing in one or more behavioural tasks. This will usually continue for 1-4 weeks. In some cases, animals will be surgically implanted with electrodes for the direct recording of brain activity, either during behavioural testing, or under anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Administration of drugs may cause mild and temporary changes in behaviour (< 24 hours). Most behavioural tests will cause no adverse effects or distress, but the water maze task that involves swimming to find an escape platform may cause temporary stress. Surgical procedures, such as the implantation of electrodes into the brain, may cause pain, but this will be controlled using surgical anaesthesia, and postoperative analgesia as required. Animals may also experience some postoperative weight loss, but these signs should last no more than 3 days.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 70% of animals will experience a mild severity category, 20% moderate, and the remaining 10% will undergo non-recovery procedures only. The proportions will be similar for rats and mice.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A central purpose of this project is to study the physiological basis of memory and addiction, and this is not possible without the use of animals that can perform behavioural tasks. A major focus is the recording of neuronal and synaptic activity, and this is not possible in healthy human participants (see below).

Which non-animal alternatives did you consider for use in this project?

Human electrophysiological techniques such as EEG recording, and functional imaging such as fMRI, can provide information about which brain areas are active when someone carries out a specific behaviour. This avoids the use of animals, and these techniques have been very informative.

Why were they not suitable?

Although the use of EEG and fMRI can reveal correlations between brain activity and cognition, there are some drawbacks: first, the spatial resolution of these techniques is poor, and it is impossible to study cellular and synaptic processes without the use of invasive techniques that cannot be employed in humans. Second, EEG and functional imaging alone cannot establish whether activity in a specific brain region plays a causal role in the behaviour observed, or indeed is necessary for that behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers are based on an estimate of the numbers required to achieve statistically robust effects across all of the work laid out in the licence. In some cases, this includes the numbers of animals needed for breeding programmes to obtain the experimental animals. The estimate of numbers is based on past experience of similar experiments, the published literature, and, in some cases, on preliminary data.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible, we have designed experiments to minimise the impact of variables responsible for trial-to-trial or between-animal variability. For example, during behavioural tasks, animals will be handled by trained staff, and habituated to handling and the testing environment prior to the assessment of behaviour. Handling techniques that cause minimal stress will be used, such as cupping and tube-handling. Where possible, behavioural testing will be conducted in rooms free from excessive noise or disturbance. Reducing variability means that fewer animals are needed to achieve statistically significant results.

In many cases, we will collect multiple measures in the same animal, either by repeating behavioural tests to increase reliability, or by recording multiple electrophysiological measures of the impact of a drug. It will often be possible to compare a measure before and after the administration of a drug, reducing the need for between-subjects comparisons, and hence reducing the numbers required.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will also minimise the numbers of animals used by conducting pilot studies when the effects of a treatment or manipulation are unknown. A pilot study will allow us to estimate the numbers needed to observe statistically robust effects in the main experiment, avoiding the problem of underpowered studies if the numbers are too low, or unnecessary use of animals if the numbers are two high. Where animals are bred in-house, we will use efficient breeding programmes that generate the required numbers of animals and no more.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Because rats and mice have homologous brain structures to those in humans, it is possible to study behavioural processes such as learning and memory in these animals, without the need to use 'higher' mammalian species. Most of the animals tested in this project will be wild-types or animals with nonharmful genetic alterations. An exception is the FMR1 knockout mouse, an animal model of the neurodevelopmental abnormalities evident in Autism Spectrum Disorder. These animals have an increased risk of developing sound-induced epileptic seizures as they grow older. For this reason, these animals will be kept in a quiet environment, and testing will be carried out at the earliest age possible.

A large amount of the work in this project will be carried out in brain tissue taken from animals that have been painlessly euthanised, or in animals under terminal anaesthesia that also suffer no pain or distress. However, while these techniques can provide information about the functioning of neurons, synapses, and brain circuits, they cannot alone establish the relationship between brain activity and behaviour. For this, it is necessary to record from animals in which electrodes have been chronically implanted. This will be carried out under general surgical anaesthesia, and the animals will receive postoperative pain management, close monitoring, and other supportive measures as required. Recording of brain activity will not begin until the animals have fully recovered from surgery.

Why can’t you use animals that are less sentient?

The brain regions involved in learning and memory in rats and mice have clear functional parallels to the same regions in humans, something that is not true of non-mammalian or invertebrate systems. In most cases, our research requires the use of young adult animals in which memory-related brain circuitry and behavioural abilities are fully developed. However, a component of our work will involve the testing of the neurodevelopmental abnormalities in a mouse model of autism spectrum disorder. In this case, a substantial part of the work will be carried out using tissue from animals in the first weeks of life. It is also possible to study the functioning of neurons and synapses in brain tissue taken from animals that have been painlessly euthanised, or in animals that have been terminally anaesthetised. A substantial part of the work outlined in this project will be carried out in this way. However, while these techniques can tell us a lot about the functioning of neuronal circuits, they cannot alone establish connections between brain activity and behaviour.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All staff involved in animal experiments will be trained in handling techniques that minimise stress and will receive extensive training in all other techniques with which they will be involved. All animals undergoing surgical procedures will receive postoperative pain management and will be closely monitored during recovery. During the project, we will continually seek to identify refinements to our animal husbandry and experimental techniques and implement these as appropriate. For example, advances in electrophysiological techniques, such as multi-site recording, are making it possible to collect more information from each animal. We will adopt techniques such as this where feasible.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow best practice as laid out in guidance documents published by the UK Home Office and NC3Rs. Our reporting of research findings will follow the NC3Rs ARRIVE 2.0 guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep informed about advances in the 3Rs via the National Centre for the Replacement Refinement and Reduction of Animals in Research (NC3Rs). The Named Veterinary Surgeon and staff will also inform of improvements in experimental and animal husbandry techniques, and we will implement these as appropriate. We will also identify relevant refinements to our techniques in the published scientific literature and will seek to implement these where feasible.

Home Office

NON-TECHNICAL SUMMARY

185. The Development of Animal Health Products

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)
  - (d) Protection of the natural environment in the interests of the health or welfare of man or animals

Key words

Animal Health, Veterinary, Feed additives, Farm animals, Companion animals

Animal types	Life stages
Rats	adult
Mice	adult
Beagles	adult, juvenile
Cattle	juvenile, adult, pregnant

Animal types **Life stages**

Sheep	juvenile, adult, pregnant
Pigs	juvenile, adult, pregnant, neonate
Broiler Chickens, Laying Hens, Turkeys	neonate, juvenile, adult, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The intention of the work covered by this licence is to determine the safety and efficacy of animal health products. Animal health products generally fall into three categories: veterinary drugs, vaccines or medical feed products, however novel technologies such as monoclonal antibodies may also be developed for the treatment of sick animals. The work carried out under this licence will be designed to meet the requirements of government regulators in Europe and elsewhere, who must agree to the sale and use of these materials in society.

A retrospective assessment of these aims will be due by 19 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The work in this project will be performed to meet the requirements of regulatory authorities responsible for the authorising the marketing of veterinary medicines and medicated feed-stuffs. In doing so, the work enables the development of safe new medicines for use in animals. In addition, the work helps to assure the safety of human consumers who may be exposed to residues of veterinary medicines in the edible tissues and other products of food-producing animals.

As well as assuring the safety of animals and human consumers, the successful conduct of tests will help bring to market materials which improve the health and welfare of animals in which they are used.

What outputs do you think you will see at the end of this project?

Data collected will be information on how animals are affected by potential new veterinary medicines; or how much and for how long the animals retain the medicines in their body; or how much of the medicines are in animal tissues, eggs or milk which might contribute to human food.

Outputs will include simple measures like changes in behaviour, food consumption, growth rate and weight retention or loss. Samples will commonly be taken, particularly of blood, but also other excretions such as urine to assess any changes over time.
Post mortem examination can demonstrate change in function or structure of body organs, including examination at a microscopic level.
The data will be collected to the standards required by government regulators in the UK, Europe and elsewhere, for identifying and excluding inappropriate medicines due to safety concerns, and enabling further development of successful veterinary medicines.

Who or what will benefit from these outputs, and how?

Our clients, typically commercial animal health companies, will benefit from the provision of high quality data. This will help them in their work to produce safer and more effective medicines which can be safely made and used without increasing health risks for animals or for people who could potentially be exposed to them through the eating of animal-based food.
Enabling development of successful veterinary medicines will have a general benefit for animal welfare in society, through diagnosis, treatment or prevention of disease.

How will you look to maximise the outputs of this work?

By conducting the work to the expected quality standard (Good Laboratory Practice) and by following relevant internationally-agreed guidelines, the outputs of the work should be readily accepted in all markets of the world. Collaborations and information exchange with others within the organisation and with our clients, helps to identify and spread information on successful and unsuccessful approaches, and on product development.

Species and numbers of animals expected to be used

- Domestic fowl: No answer provided
- Beagles: 250
- Cattle: 800
- Sheep: 100
- Pigs: 500
- Mice: 150
- Rats: 250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Most of the animals and life stages used in the project are examples of species which will be given the test items in veterinary practice; the target species. Some laboratory rodents are used to help consider safety of test items which would be given to animals which contribute to human food.
They are also species included in relevant guidance accepted by government regulators in the UK, Europe and elsewhere.

Typically, what will be done to an animal used in your project?

Animals will be given a possible new veterinary medicine or other animal health product, by the same way that this would be done in veterinary practice. Some studies will be to check for any effects of the medicine; some studies will be to measure how much of the medicine is absorbed into the blood, or into the milk, eggs or meat of animal species which contribute to human food. Urine and faeces, and the excreta of birds, are commonly collected, which requires housing the animals singly, although next to each other, in a small cage which allows the urine and faeces to fall through a grid, typically for about a week.
Animals are normally humanely killed after the collection period, and tissues may be taken from the animals post mortem, and analysed.

What are the expected impacts and/or adverse effects for the animals during your project?

The process of dosing animals or taking blood samples may cause minimal discomfort during conduct; no lasting effects are expected.
The medicines are not normally expected to cause any significant harm for the animals.
Confinement for collection of excretions may cause a degree of discomfort and/or reduced activity; a degree of reduced food consumption and/or weight loss may be noted, but this is not expected to be significant based on experience of studies conducted over many years.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

No significant harms are normally identified by examining the animals. This and controlled limits on blood sampling are likely to result in no more than mild severity outcomes in most cases. The single housed confinement of animals for several days, particularly if it includes restricted movement, results in a consideration that this is of moderate severity. This is likely to be required for about half of the animals used in the project, because of the need to collect the excretions of individuals for a sufficient time to complete the scientific aims.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed
- Used in other projects

A retrospective assessment of these predicted harms will be due by 19 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

While non-animal methods are used in some aspects of the programme of safety assessment of new materials,

they are currently not able to predict effects on whole body systems or to provide information on how much of a material is absorbed, or how animals change and excrete materials. Animal products which contribute to food (meat, milk, eggs) need to be assessed for presence of drug residues which could cause harm to people. This work must be done using the same animals which will be given the medicines, some of which also contribute to human food.
The protocols described in this project are conducted according to internationally-agreed guidelines, to meet the requirements of UK and European law, and are expected to be performed before government authorities will authorise the marketing of new veterinary medicines for animals.

Which non-animal alternatives did you consider for use in this project?

The organisation conducts non-animal tests as part of the many programmes of safety assessment of new materials. However as noted above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes.
A potential *in vitro* approach to comparative metabolism is described in the relevant guideline, and will be considered as and when such studies are requested.

Why were they not suitable?

In vitro comparative metabolism will be used where it is deemed to be an appropriate scientific alternative, and acceptable to government regulators.

A retrospective assessment of replacement will be due by 19 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated upcoming studies.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The animal numbers for studies required by government regulators typically follow those identified in internationally-accepted guidelines, as expected to provide sufficiently significant outcomes.
In situations where there is no definitive guidance on the numbers of animals to be used, the applicant and colleagues will use their extensive experience of related programmes, taking account of statistical significance and scientific advice as necessary, to use sufficient animals for studies to provide robust results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

All studies are performed according to the principles of Good Laboratory Practice (GLP), which is an

international standard for the quality of experimental study conduct with animals, and is overseen by an independent agency of the government. Following this practice should ensure the quality of studies and acceptance of results by government regulators worldwide, and also reduce the potential for error.
By fully understanding the needs for testing in each case, and by following internationally-agreed guidelines and GLP, the same study should be acceptable to government regulators in all parts of the world where it is needed, removing any need to do the similar work more than once, and use more animals, to meet the needs of all markets where the medicines may be used.
Pilot studies may be used to confirm appropriate elements of study design in advance of full studies, for example, the best timing for taking samples of various body tissues or products to investigate the how much and when a drug is excreted or retained by the animals.
A retrospective assessment of reduction will be due by 19 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Materials are given to the animals by the same way in which they would be given in veterinary practice, most commonly by mouth, in food, or by injection. The dosing methods used are all very well established and common for the animals to be used, and known to cause minimal discomfort based on extensive experience at the site.
Blood sampling is a common need. We follow published guidance on methods and suitable volumes which can be taken while minimising harms to animals.
Restraint or confinement of animals is a common need, to allow collection of samples, generally urine and faeces. Methods used are those with which staff have extensive experience, and the duration of time is minimised wherever possible while allowing completion of the process.

Milk-producing animals are milked regularly using the same processes as are used on farms.

Why can’t you use animals that are less sentient?

The species used are in most cases the same species, and at a stage of life when they would be given the medicines in veterinary practice; and so are the most appropriate scientific models. Where laboratory animals (rodents) are used, they are to help confirm the suitability of study outcomes for people who could potentially be exposed to the medicines by presence in products of animals which contribute to human food. They are the species whose use is expected by government regulators.
The time required to study the outcome of giving the medicines, and for samples to be taken means that continued anaesthesia is impractical, and could interfere with the scientific outcomes.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement of procedures is an on-going consideration at the site, and new opportunities are particularly

assessed if any concerns are identified during or after studies; for example new methods or additional assessments may be included in future study designs as a result of a review.
Methods to enrich the housing are routinely considered, and changes are commonly introduced to seek to improve the housing. A standing group regularly considers potential refinements at the site, and reports to the animal welfare and ethics review body routinely on this topic.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Where required, blood volume limits are within those proposed in the 2001 publication of Diehl *et al*: A good practice guide to the administration of substances and removal of blood, including routes and volumes.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Both our clients and our colleagues conducting the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which propose refined approaches to conduct of work. **A retrospective assessment of refinement will be due by 19 April 2026**
The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

186. The genetics and therapy of skin disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To investigate skin and related tissues during health, disease and treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Major advances have been made in the understanding of skin diseases including severe birth mark disorders which are currently untreatable. These disorders affect not only the skin but other organs, and often also carry an increased risk of malignancy. To translate these genetic and biological research findings into clinical practice in humans, we must test our novel therapeutic approaches on appropriate mouse models. By doing this we can investigate whether our therapeutic approaches can be delivered successfully, and whether they are both safe and effective, so that they can be considered for clinical trials.

What outputs do you think you will see at the end of this project?

The research is intrinsically translational and focused on generating treatments for untreatable childhood diseases. The final output aim is to identify therapies and/or technologies that will benefit patients directly. There will also be research output in the form of publications, conference presentations and knowledge that will benefit colleagues and other scientists in the field.

Who or what will benefit from these outputs, and how?

Short term benefits (from 2020)

Ongoing participation in patient group events will inform the public of our research, engage them with our work and showcase developments into treating skin disease. We anticipate that early aspects of our research will be published in the coming two years and presented at conferences.

Medium term benefits (from 2023)

Publications and presentations will inform others of our work, assisting and advancing technologies, and forming the basis of further grant applications.

Long term benefits (from 2025)

Assuming successful outcomes, our preclinical research on mouse models will be translated into clinical trials on patients from around 2025. Longer term benefits would be extrapolation of this work to other disorders.

How will you look to maximise the outputs of this work?

This project is already the product of several key collaborations, particularly as regards the delivery systems. Results of the current projects will automatically be shared with the collaborators, allowing them to expand knowledge of their systems and share that knowledge within their respective fields.

Knowledge will therefore be disseminated by our team throughout clinical genetics, dermatology and oncology circles within the medical arena, human molecular genetics and genetic therapy circles in the scientific arena, and delivery systems arenas via our collaborators.

Publication of results will be a priority, as well as dissemination to stakeholder groups in person and using social media and mainstream media outlets. Where practical and possible we will publish unsuccessful approaches

Species and numbers of animals expected to be used

- Mice: 521

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using the mice as a model of skin disease because mouse models are available that have the same genetic mutation that humans with the disease have. This is ideal for progressing with our preclinical investigations of possible therapeutic agents as they will provide a platform to move forward with our research to a practical in vivo system (mice with skin disease causing genetic mutations). Therapeutic interventions on humans with skin disease might in the future be carried out on any postnatal stage. Therefore, all postnatal stages in the mice are of interest to our studies as they will model both early and later aspects of skin disease. In order to best model skin disease in mice, we may also cross any of these strains with other strains with genetic mutations associated with the disease which is not expected (from clinical observation in humans) to have a phenotype at all on its own, but may exacerbate any of the phenotypic features in the strains described here.

Typically, what will be done to an animal used in your project?

Mice with skin disease causing genetic mutations will be generated using standard breeding methods. Baseline phenotyping will involve recording the mouse's phenotypic features and basic non-invasive imaging methods (e.g. dermatoscopy). Where it will be of value, imaging methods requiring general anaesthesia may be carried out and skin or blood samples may be collected for analysis to see if the treatments have worked. Administration of substance will involve application of the substance, most likely to the ear but could be to any part of the body. The application procedure may involve preparation of the skin (e.g. shaving) followed by treatment with the topical cream or ointment. To ensure that the substance remains on the skin for an appropriate amount of time it may be necessary to house the mouse in a single cage for a period after the treatment to prevent other mice grooming away the substance. The mice will also be phenotyped after substance administration in order to investigate the efficacy of the substance for treating the phenotype. All experiments will end with culling of the mice using a schedule 1 procedure.

What are the expected impacts and/or adverse effects for the animals during your project?

Our experiments have been designed to minimise adverse effects on the mice. Phenotyping and sample taking may cause mild, transient pain or distress but this should last no longer than a few seconds. In the majority of imaging procedures, the mice will be under general anaesthetic to minimise distress. Substance administration can potentially cause minor skin irritation, but efforts are made to select candidate substances for their lack of toxicity. On an occasion where the skin is sore as a result of substance administration, local anaesthetic will be used to minimise suffering. As we will be observing the mice regularly following substance administration the mice will only suffer from mild irritation for a short period of time before it is detected. We intend to cull mice before any potential melanoma metastases develop. However, undetected disease may cause pain, weight loss, metastatic tumours and abnormal behaviours. We estimate that this will affect less than 5% of our animals and mice will be culled at the point in which the phenotype is detected.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Mild (expected of phenotyping / substance administration) = 90% Moderate

(unexpected) < 10%*

*Our goal is to achieve 0% moderate severity. However, we believe due to the nature of our mouse models and investigative nature of substance administration there is a small chance that some mice may experience moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

A mouse model with the precise genetic mutation that causes a skin disease that we are interested in treating in humans is available. This provides an excellent opportunity to study and treat the disease in vivo. Data from these studies will inform us on the effects of the drugs in a living system, with functioning networks (e.g. vasculature, nervous system etc.).

Which non-animal alternatives did you consider for use in this project?

We already and will use in vitro approaches in parallel to our mouse research to inform our experiments. These include experiments on human patient-derived biopsies and cell lines.

Why were they not suitable?

While non-animal alternatives can provide useful data, they limited in that they do not model the complete skin in vivo which is connected to the nervous system, immune system, vascularised, under the influence of endocrinological factors and systemic signalling molecules.

There is often limited availability of patient tissue which prevents the design of experiments as there is little to no knowledge of what will be available for study until the moment of surgery. Even when it is available, it is often variable in nature, from different parts of the body from different patients. This provides variable data with limited opportunity to carry out a carefully controlled, designed study.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may

include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to estimate the number of animals we will use we have carried out power calculations using an online tool. Estimations are listed below. Where possible, these estimations are carried out using what we can learn from published data. In cases where there is not yet published data we will need to carry out pilot studies with a limited number of mice to determine the distribution and difference of data points in two conditions in order to more accurately estimate the number of mice required for an experiment.

Estimation of number of mice required for breeding pairs

This depends on the length of time between experiments, the success of breeding and the numbers they generate. Therefore, assuming we were required to have 10 mice available for breeding at any given time, retiring them every 6 months to avoid detrimental phenotypes. We would use 20 each year. Over the 5 years of the project this would be 100 mice. At any given time we may need to breed both strain 1 and strain 2 mice. Therefore, for the 2 mouse lines we are estimating the maximum number of mice we will need for breeding is 200 (see table 2) Estimation of sample size for studies on strain 1 mice

a) The primary outcome measure will be a decrease in pigmentation

b) The statistical test is a paired one-sided students t-test, with 95% significance at 80% power

c) The effect size considered significant will be a 20% decrease in pigmentation for experiments designed to achieve successful treatment of the phenotype. We account for 10% variability in the results of these experiments between mice. However, until we do preliminary experiments we cannot accurately estimate this.

Using this data with an online calculator the sample size is 8 mice in each group, with two delivery approaches to be tested, with two different concentrations of genetic material. Therefore, the final sample size is 32 mice per experiment. For two experiments and accounting for a 10% attrition rate we estimate we will use 71 mice in protocol 4 (see table 2).
Some mice will be used for baseline characterisation for preliminary studies to establish baseline measurements to direct the therapeutic interventions experiments. We estimate we will require 10 mice in protocol 2 (see table 2)
Estimation of sample size for studies on strain 1 mice

a) The primary outcome measure is the number of melanocytic lesions over the first 6 months

b) The statistical test is a paired two-sided students t-test, with 95% significance at 80% power

c) The effect size considered significant will be a 10% difference in mean number of melanocytic lesions with the baseline estimated to be 3 per mouse, with a variability of 20%

Using this data with an online calculator the sample size is 31 mice in each group, with two variants to be tested, plus a wild-type control group – final sample size is 93 mice in either protocol 2 or protocol 3 (see table 2)
Estimation of sample size for studies on strain 2 mice

a) The primary outcome measure will be a change in pigmentation (also melanoma incidence will be closely monitored).

b) The statistical test is a paired one-sided students t-test, with 95% significance at 80% power

c) The effect size considered significant will be a 20% change in pigmentation for experiments designed to achieve successful treatment of the phenotype. We account for 10% variability in the results of these experiments between mice. However, until we do preliminary experiments we cannot accurately estimate this.

Using this data with an online calculator the sample size is 8 mice in each group, with one control group and two experimental groups, the final sample size is 24 mice. Accounting for a 10% attrition rate we estimate we will use 27 mice in protocol 2 or 3 (see table 2).
Table 2: Estimation of number of mice that will be used

	Protocol 1	Protocol 2	Protocol 3	Protocol 4
Strain 1	100	28	18*	71
Strain 2	100	102	102*	
Total (521)	200	130	120	71

*Protocol 3 will only be used if protocol 2 does not achieve experiment goals

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experiments follow a repeated measures design whereby mice will be treated and phenotyped repeatedly. This will allow us to monitor the effects of substance administration over multiple time points while avoiding the use of multiple groups of mice to carry out these experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To optimise the number of mice in our studies, pilot investigations have been and will be carried out on cell in vitro and skin biopsies ex vivo to determine which approaches are most promising and which are most likely to deliver a successful outcome. This will minimise the number of mice that are needed as fewer investigative experiments will be carried out on the mice whereby little is known about the potential outcome of the therapy being tested.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The animal models that we will use in the project are mice with genetic mutations / phenotypes which model skin disease. These models present with a phenotype which does not cause an aversive effect in the mice. In certain circumstances there will be an increased risk of melanoma but this can be managed by observation and culling of the mice before they reach a stage that causes pain or suffering. In particular, where a carcinogenic substance is used to induce melanoma at a particular location on the skin we are able to monitor this precise location to make sure procedures are carried out before the melanoma causes any aversive effects to the animal.

Phenotyping procedures which may cause distress to the animal because of restraint will be done under general anaesthetic. This will minimise the stress to the animal while allowing us to collect the data as quickly and efficiently as possible. In certain circumstances such as ear biopsies, the temporary restraint and minor transient pain may mean it is less intrusive and stressful to perform the procedure without anaesthesia, or with local anaesthesia instead.

Substance that will be administered to treat the phenotype will be selected for their reported or predicted lower toxicity. This is because the goal of our experiments is ultimately to treat patients and very toxic drugs would be unsuitable. In the event of an adverse reaction the mouse will be treated if this is possible (e.g. local anaesthetic) or culled to prevent worsening of the condition.

Why can't you use animals that are less sentient?

We cannot use animals that are less sentient than mice because:

a) Mouse embryos are not appropriate/accessible for topical application of substances

b) Procedures cannot be solely performed on terminally anaesthetised animals because the effect of the therapy needs to be monitored for some time after application.

c) In general, previous therapies for melanocytic disease including melanoma have been tested on mice before being translated into humans, with mice being considered the least sentient animal model close enough physiologically to humans for this disease. Our efficacy and safety data will therefore be comparable to previous work.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Staff will carry out procedures in an accurate and efficient manner. Given the nature of dermatology research, mice will be monitored for surface abnormalities which will be important for our results and carrying out experiments effectively. This will minimise harms to the animal by identifying phenotypes early that may eventually be harmful to the mouse.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Reference to the topic specific resources on the NC3Rs website will be used to ensure experiments are conducted in the most refined way. This resource provides guidelines and resources on anaesthesia, analgesia,

euthanasia, handling and restraint, humane endpoints, micro sampling and welfare assessment which will be relevant for our project. Experiments will be planned according to PREPARE guidance. Experiments will be conducted with care taken to design and collect information that satisfies ARRIVE (Animal Research: Reporting of In vivo Experiments) guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

By subscribing to the NC3Rs newsletter and discussing advances that could be implemented in our research with my research team. Additionally, we will receive communication from named persons and complete annual refresher training.

Home Office

NON-TECHNICAL SUMMARY

187. The gut microbiome's role in health and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

microbiome, colitis

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how the microbes that live inside the gut interact with each other, and with the gut environment. And, to understand how these interactions change between healthy and inflamed conditions.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our guts house trillions of microbes that together make up the gut microbiome. Over recent years, changes to the repertoire of microbes living in the gut, and the balance of numbers between these different types have been linked to a range of diseases with a major impact on global human health. Such diseases include inflammatory disease, infection, cancer, diabetes, obesity and neurodevelopmental disorders.

A better understanding of the gut microbiome could contribute major advances to the diagnosis, prevention and treatment of these diseases. Overall, however, there is still a very limited understanding of how changes to the microbiome come about and what their true roles in disease are. One important reason for this lack of understanding is the limited number of tools available for studying the gut and the microbes living within it. This project aims to address these holes in our understanding by developing new ways to study the gut microbiome.

What outputs do you think you will see at the end of this project?

- The development of new tools and methods to non-invasively study the gut
  The development and testing of new in vitro methods to study the gut microbiome
- The publication of new scientific knowledge about how bacteria in the gut respond to inflammatory diseases.
-

Who or what will benefit from these outputs, and how?

In the medium to long-term, the outputs from this project aim to help people suffering from diseases that are linked to the gut microbiome. The tools we develop and the knowledge we gain through this project may help to develop new types of: diagnostics, to identify disease earlier and with more accuracy; monitoring tools, to help track disease progression and how patients respond to treatment; and treatments for various gut disorders. Because there are many diseases with links to the gut microbiome, our methods, tools, and scientific advances should be of interest for researchers across a range of fields.
In the shorter term, the advances we make throughout this project will provide increased understanding of how bacteria interact inside the gut and how they respond to inflammatory diseases. They will also provide new approaches to study the gut microbiome. These are all of great interest to many researchers, biotechnologists, and clinicians. To maximise the potential reach of our work, we will present our findings at national and international conferences and publish them openly. The tools and data we develop, including advances to in vitro bacterial growth and testing methods that would allow researchers to replace animal experiments with non-animal alternatives will also be shared openly with the research community.

How will you look to maximise the outputs of this work?

Findings will be made available to the broader research community through open-access dissemination, by posting preprints and publishing in open-access journals, and through presentations at scientific conferences and meetings.
All bacterial tools that are developed and raw bacterial sequence data will also be shared openly with the research community through openly accessible strain banks and data repositories so that it can be used in others work.

Species and numbers of animals expected to be used

- Mice: 800

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

These studies will be done in mice because this is the lowest vertebrate species that can be used to adequately model the complex nature of the gut and its resident microbes, which is highly dynamic in its microbe-microbe and host-microbe interactions, as well as the gut's response to inflammation. Because the general control of the microbiome and the inflammatory disease response involve system wide responses, we need a model system that can provide this level of complexity.
We also require a model organism that can be maintained without bacteria in the gut so that we can complete experiments in which feed animals a specific set of microbes. So far, mouse models represent the best and most well studied models for both these purposes of bacterial colonisation of the gut and testing inflammatory disease, with several genetic and environmental models replicating a range of the key aspects of human disease
Animals older than 4-weeks old at the start of an experiment will be used to allow for development of the microbiota prior to testing. This is also consistent with the ages of mice studied previously in the published colitis models we will use.

Typically, what will be done to an animal used in your project?

Typically, animals in this project will be fed antibiotics either in their drinking water or by oral gavage. They will then be fed with harmless bacteria by oral gavage. In ~70% of animals our goal is to understand the response of bacteria to the healthy gut and/or to other bacteria in the gut. In ~30% of animals, we aim to understand the response of gut bacteria to inflammatory disease. Gut inflammation will be induced in these animals either by feeding mice with a chemical in their drinking water, feeding mice with a pathogen that causes diarrhoeal disease similar to that in humans, or using genetically altered animals that are susceptible to developing colitis in a similar way to inflammatory bowel disease in humans. In both healthy and inflamed scenarios the response of the gut and the gut microbiome will be monitored by non-invasive methods throughout the experiment - including the collection of faecal samples, the collection of blood samples, or imaging of labelled bacteria in live animals. The latter technique requires short term anaesthesia so that animals do not move during imaging. Most experiments will take between 1 and 4 weeks, although in a small number of experiments animals will continue to be observed for up to 1 year of age so as to study long-term bacterial growth behaviour and to better model

chronic diseases such as inflammatory bowel disease.

What are the expected impacts and/or adverse effects for the animals during your project?

Inflammation:
Animals that are being used in experiments to track inflammatory disease may experience a range of symptoms, which commonly include diarrhoea and weight loss, but may also be accompanied by signs of pain, discomfort and blood present in the faeces. The goal of all of our experiments is to induce the minimal degree and duration of adverse effects necessary to achieve our scientific aims.
Some experiments are designed to test chronic inflammation. Like humans suffering from inflammatory bowel disease, this level of inflammation may cause some discomfort and mild symptoms, but should not cause acute symptoms. Animals being studied for chronic inflammation will typically be studied over the course of 1-2 months, but may be studied up to 1 year old.
Other experiments are designed to test short periods of more acute inflammation, such as are experienced during pathogenic infections in humans. These experiments will usually involve acute inflammatory activation for around 1 week. Mice will be monitored particularly closely throughout any period of expected acute inflammation, and any animals that do show signs considerable weight loss or pain for more than 24 hours will either be humanely killed by a Schedule 1 method, or the induction of inflammation will be removed to allow recovery, thus limiting their suffering.
Imaging:
Some animals will be put under brief anaesthesia (less than 15 minutes), so that they stay still while we image the bacteria in their guts. They may also have an injection at this time to introduce dyes that help us to see more of their bodies. They are expected to recover quickly and will be given care following the anaesthesia if needed, just like a human would be.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect that ~70% of animals will experience only mild severity procedures, and ~30% will experience moderate procedures including inflammatory induction and short-term anaesthesia for non-invasive imaging studies.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are needed, because no alternative model currently incorporates all elements of the mammalian gut environment, including having different spatial regions that favour different bacterial species, immune responses and gradients of oxygen. These factors are particularly important for the goal of understanding the response of bacteria to the gut environment and to each other during inflammatory disease, which is known to involve changes to each of these elements. They are also important for our studies of how bacterial behaviour varies in different parts of the gut.

Which non-animal alternatives did you consider for use in this project?

Some experiments in this project fall within a broader research programme that aims to develop *in vitro* bacterial culture methods that can sufficiently reflect critical aspects of the gut microbiome in its native environment to allow for replacement of animal use for similar experiments in the future. An important factor in developing such a platform, however, is benchmarking of results against the *in vivo* system.
In addition to culture methods, we also considered the use of *in vitro* co-culture of bacteria with mammalian tissue, the 'gut-on-a-chip' culture system, and the use of human tissue or faecal samples.
Why were they not suitable?

In vitro co-culture of bacteria with mammalian tissue in general cannot be used to study long-term interactions due to the incompatibility of the conditions created for and by bacteria in culture and the conditions needed for mammalian cells to stay alive. Mammalian cells need oxygen and low acidity. Anaerobic bacteria cannot be exposed to oxygen and often make the media acidic. In in vitro cultures, mammalian cells generally don't produce the protective mucous layers that they would in the body, which provides an important barrier preventing direct interactions between bacteria and the cell. Without mucous present bacteria often have a direct toxic effect on the mammalian cells.
The most advanced examples of 'gut-on-a-chip' technology have shown co-culture of complex set of microbes including anaerobic bacteria for up to 5 days. However, they still have not replicated key aspects of the mammalian gut inflammatory environment including immune system responses and spatial community dynamics, thus making them inappropriate for our purposes.
Because we need to use controlled experimental conditions, and we need to administer specific bacterial strains our experiments also cannot be performed with human faecal or tissue samples.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

All experiments will be designed so that the minimum number of animals necessary will be used. In many cases, our experiments have been designed to perform an initial screen from a pooled set of samples followed by individual validation of top performing candidates. The estimated numbers are calculated assuming typically the top 5 candidates will be tested, along with relevant controls, however we will only individually test strongly performing candidates so this number may be reduced should less high quality candidates be identified.
Due to the potential for bacteria to be shared between co-housed animals the experimental unit has been defined as each individual cage initially and the numbers assume that mice will be socially housed for longer term experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental design is based on a combination of experience, consultation with published studies and experts in the field, and resources available on the NC3Rs website. Where possible, we will follow repeated measure experimental designs to allow animals to act as their own paired controls pre- and post- colitis induction. This

measure reduces animal numbers both by limiting the need for two different groups of animals, as well as reducing inter animal sources of variability.
While the experimental unit will initially be defined as a cage of animals, for experiments lasting less than one week we will individually house animals to reduce the number of animals needed. In addition, we will analyse results from co-housed mice throughout the study and should we find evidence that mouse-to-mouse transfer does not affect results in our experimental systems any subsequent experiments will instead use an individual mouse as the experimental unit. In some cases this could halve the number of animals used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The proposal outlines the use of established models of bacterial colonisation and colitis induction that require minimal optimisation. Where possible we will also use methods available to reduce variation between animals. Together these will reduce the number of animals required for statistical significance.
Where relevant, we will use female mice to allow for mixing of animals between cages prior to experiments. This aims to reduce cage-to-cage differences in the microbiome because mice share their microbes by eating each other's faeces. By reducing variation between cages this in turn reduces the number of animals and repeat experiments required.
For new analysis techniques we will use pilot studies on either unused tissues from collaborators or small numbers of mice, to reduce animal usage and ensure that measurement techniques will achieve their scientific aims before using them on larger numbers of animals.
Several experiments will also begin with screening studies, either in vitro or in vivo, which we have used to allow for testing of hundreds to thousands of bacterial strains in a single experiment. Only those bacterial strains that show the highest promise from screening studies will then be followed up individually in animals. Where possible we will use the screening data to calculate group sizes in these follow up experiments to use the minimum number of animals for our scientific goals. This strategy considerably reduces the number of animals needed to achieve the aims of the project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use well established models for colitis that replicate critical aspects of human diarrhoeal disease and inflammatory bowel disease. Our humane endpoints are in place to ensure that ongoing pain, suffering, distress or lasting harm is minimised.

Why can't you use animals that are less sentient?

Non-mammalian animals are not suitable for use this work as the required immune systems, physiological conditions and spatial variations in the gut that favour specific species do not exist in lower species. The

long-term nature of the experiments, from days to months, makes terminal anaestheisia inappropriate.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Dosage of inducers will be chosen with the aim of triggering colitis that is not severe enough to trigger our humane endpoints. Animal suffering will be minimised by regular checking of animals for relevant symptoms that constitute the end point of the experiment.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experimental procedures will follow LASA guidelines. Experiments will be designed and undertaken in accordance with the PREPARE guidelines and communicated in accordance with the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay informed about advances in the 3Rs though the NC3Rs website, and through monitoring up to date science in this area through regular literature, conference attendance and discussions with colleagues. Advances that would advance any of the 3Rs will be implemented throughout the project where possible.

NON-TECHNICAL SUMMARY

188. The Immune Response to Tissue Repair and Cancer

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

inflammation, wound healing, cancer, scarring, live imaging

Animal types	Life stages
Mice	adult, juvenile
Zebra fish	adult, neonate, embryo, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To advance understanding of the role inflammation plays in tissue healing and cancer progression with the aim of identifying interventions to improve the outcome of the repair process for traumatic injuries, surgery and cancer treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Scarring following injury is a major medical problem. In addition to the visible disfigurement of skin scars, scarring also results in a loss of tissue function that can restrict movement and can have adverse psychological effects. Scarring occurs as a result of the laying down of extra-cellular matrix, such as collagen, at the injury site. It is well recognised that while inflammation is pivotal in some aspects of healing, it also plays a major role in determining the extent of tissue scaring; however, the precise mechanisms that drive this process remains unclear. The outlined work aims to advance fundamental understanding of the processes involved in tissue repair and the associated inflammatory response and thereby identify interventions that could be used to improve the outcome of the healing process. It is also clear that inflammation plays a role in cancer initiation and progression in ways that are very related to the wound inflammatory response. Consequently, these studies will also investigate aspects of cancer inflammation in order to identify interventions for improving cancer therapies, particularly those therapies, such as surgery and radiotherapy, that trigger a wound inflammatory response in tissues.

What outputs do you think you will see at the end of this project?

The key output of these studies will be to advance understanding of the mechanisms underpinning normal healing of skin and other tissues and to identify how these alter when healing fails e.g. as in a chronic, non-healing wound, or in scenarios where major scarring occurs. The study will identify some of the key genes and signalling pathways involved in wound healing, in particular, those associated with the wound inflammatory response, and will evaluate if modifying these can improve the healing process e.g. by either speeding it up or reducing the level of tissue scaring. The study will also identify key genes and signalling pathways involved in the inflammatory response to cancer and determine the importance of these in influencing the progression or retardation of the cancer. In particular, we expect to determine the influence that the inflammatory response initiated by clinical interventions used in the treatment of cancer (e.g. biopsy, surgery or radiotherapy) has on the progression of the cancer and whether modulating this could improve outcomes. For each arm of this research our goal will be to publish our findings in top ranking, open access journals.

Who or what will benefit from these outputs, and how?

In the short term, the findings of our study will benefit scientists working in the field of wound healing and cancer treatment. In the medium term, the findings are expected to benefit biotech companies/big pharma developing new products and interventions to minimise scarring and improve would healing. In the long term, the findings are expected to benefit clinicians and patients through the development of more effective treatments and interventions to improve the outcome of tissue repair and cancer treatments.

How will you look to maximise the outputs of this work?

To maximise the outputs and the impact of our research we will collaborate, as we already do extensively, with clinicians specialising in plastic surgery and cancer therapy. In so doing, our research directions are guided by real and relevant clinical problems. In addition, these collaborations facilitate the rapid translation of our findings into the clinical setting. The findings of our research will be widely disseminated through presentations at international scientific meetings and by publications in high impact, open access journals and review articles.

Species and numbers of animals expected to be used

- Mice: 2500
- Zebra fish: 57500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our work will adopt an integrated approach utilising in vitro and in vivo models. With respect to the latter, our studies will utilise the fruit fly, Drosophila melanogaster (not HO regulated), and zebrafish and mice to investigate aspects of inflammation following wounding and cancer initiation.
In zebrafish we do our work wherever possible at larval stages because these are translucent and enable live imaging studies. Some studies progress to adult fish, in particular where we wish to study later stages of cancer progression and/or the role of the adaptive immune system which is not present at larval stages. Our mouse studies are only of the wound inflammatory response (not cancer studies) and are largely performed on adult animals where we can study how inflammation impacts all of the cell lineages of the repair process (wound fibroblasts, endothelial cells of vessels etc). On occasions we also study neonatal mice where it is useful for there to be no hair, or if the KO line is not healthy at later stages.

Typically, what will be done to an animal used in your project?

The majority of the animals we require are only used for creating and maintaining lines i.e. for breeding. For our fish studies these are often of reporter lines where, for example, specific cells are labelled with a fluorescent marker. For our mouse studies the breeding will be of heterozygous mice to generate litters where some of the progeny are -/- KO mice.

A relatively small number of our fish (approximately 10%) are required for wound healing and cancer experiments; much of our data can be collected from 5dpf (non-regulated) larvae. Of those progressed to wound healing studies, the majority of those beyond 5days post fertilisation will be anaesthetised and receive a small single wound produced using either with a laser or needle; they will subsequently be either immediately live imaged (for up to several hours) while still under anaesthetic, or allowed to recover from anaesthesia and subsequently imaging on a number of occasions (not more than once daily) under anaesthesia before being killed. Generally they will only be imaged once but on occasions we will image the same fish up to 6 times, over 2 weeks. Those fish used to model various cancers will be anaesthetised at various timepoints during cancer progression and imaged as above. A small number of fish with cancer will receive a localised lesion, using a laser or needle, close to the cancer or be given radiation treatment in order to replicate routine procedures conducted on cancer patients so as to study how these influences the progression of the cancer.

For wound healing studies in mice: the mice will be anaesthetised, the wound site cleared of hair, and up to 4 small full depth punch biopsies made through the skin before being allowed to recover form anaesthesia. Subsequently, the mice will be killed at predetermined time points and tissue collected for analysis.
What are the expected impacts and/or adverse effects for the animals during your project?

The zebrafish used in wound healing studies are not expected to show any adverse signs, and are expected to

continue to swim, feed and interact with other fish completely normally. The fish used in the cancer studies are expected to grow into adulthood and to continue to swim, feed and interact with other fish completely normally whilst carrying the tumour. All fish are carefully monitored and any showing any abnormal behaviour are promptly killed.

Following recovery from anaesthesia post wounding, mice are expected to immediately resume normal behaviour and to appear unperturbed by the skin injury. The wound created scab over within 24 hours and are usually fully healed over within 7 days. All mice are carefully monitored and any showing abnormal behaviour are promptly killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of animals (~78% of fish and 80% of mice) will only be used for breeding in mild severity protocols; another 12% of all fish will be used in breeding/line generation protocols that could be up to moderate. Animals entering the wound healing protocols (~7.5% of fish and 20% of mice) will undergo general anaesthesia and a small surgical injury will be made to superficial tissues. Upon recovery from anaesthesia these animals are expected to immediately resume normal behaviour and to show no outward signs of suffering, nevertheless since a surgical procedure has been performed a moderate severity level has been allocated to these studies. Only about 2.5% of fish will be used for cancer studies. The fish are not expected to show outward signs of suffering as a result of the cancers. However, as the study involves imaging under anaesthesia, and in a small number of cases wounding of the tissues close to the cancer under anaesthesia, a moderate severity level has been allocated to these animals.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The use of vertebrate animal models is crucial to studies of the wound inflammatory response and its influences on other cell lineages since these processes are far too complex and involve too many individual and interacting cell lineages (ie several different immune cell lineages, fibroblasts endothelial cells, pericytes, adipocytes) to be effectively modelled using cell culture, computer simulation, or non-vertebrate animal models such as the fruit fly (see below). For these reasons, and because ultimately we want our experiments to be clinically relevant, at least some of our experiments must be performed in vertebrate species such as the zebrafish and mouse. Nevertheless, to minimise animal numbers, as far as possible zebrafish studies will be performed during the embryonic larval stages of development.

Which non-animal alternatives did you consider for use in this project?

Some aspects of tissue repair can be modelled to a certain extent by various in vitro experiments. The most basic of these is the "scratch wound" assay which is performed on a layer of cultured cells. Where feasible we will use the “scratch wounds model” for preliminary studies of re-epithelialisation. In addition, we will also use a modified version of the "scratch wound" assay involving co-cultured cells for biochemical investigation of how

two wound cell lineages interact with one another (e.g.
macrophages and endothelial cells). Our lab has also pioneered the use of the fruit fly (Drosophila) as a model of wound healing and its associated wound inflammatory response and we have published several Drosophila papers addressing the genetics and cell biology of these processes during the period of our last PPL. Nevertheless, to validate the clinical relevance of findings made in cell culture and fruit flies will always require the use of vertebrates models and, in particular, a mammal. However, wherever possible, zebrafish studies will be performed during the embryonic larval (nonregulated) stages of development.

Why were they not suitable?

In vitro studies can never completely replicate the complex interactions that occur in vivo and many aspects of wound and cancer inflammation can't be fully modelled in flies; for example, Drosophila have only one "leukocyte-like" lineage (the hemocyte), and have no real equivalents to the fibroblasts or melanocytes of mammalian skin, and so we are unable assess how these cells are influenced by wound inflammation in this model. Consequently, whilst we use cell culture and fruit fly studies to complement our studies of vertebrate repair and cancer, they cannot completely replace them.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals requested is based upon our estimate of the likely number of genes and cell types that will require manipulation in order to meet our objectives. In estimating the group size for the studies we have undertaken extensive analysis of data from our previous studies as well as drawing on data published by others and undertaken power calculations, with the help of G*power software. These calculations have been further checked by a specialist bio-statistician. The vast majority of animals requested will not be used in experimental studies but are required in order to breed animals with the genetic make-up needed for the experimental study. Here again we have drawn on our own extensive experience and published information in estimating the number needed.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have and will continue to use the Experimental Design Assistant (EDA) from NC3R, to plan all experiments. We are also constantly alert to the possibility that effect size differences for new assays will be greater than we expect and mean we can reduce n's and retain power to detect significance between experimental groups. Prior to undertaking animal studies, preliminary investigations using our established cell culture and fruit fly models will be used, wherever possible, to test developing hypothesis and to assess the safety of novel compounds.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The vast majority of animals used are needed to create more animals with the correct genetic make-up for experimental studies. Care will be taken to ensure that the breeding programmes is undertaken with optimal efficiency. Wherever possible, and utilised a lot during our last PPL period, we will coordinate breeding with colleagues working in related fields to maximise the usage of the animal produced e.g. by sharing clutches of transgenic fish amongst several researchers all using the same line/cross.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use both mice and zebrafish to model the wound inflammatory response, but only zebrafish to investigate the cancer inflammatory response. All procedures that could cause pain, suffering or distress to the animal will be performed under general anaesthesia. Upon recovery from anaesthesia the animals will be carefully monitored and any showing more than transient signs of pain or distress will be killed. The use of zebrafish enables us to minimise the numbers of mice needed but unfortunately, not all the complexities of mammalian skin healing and inflammation will be perfectly modelled in a fish and so we need to continue some studies in mice.

Why can’t you use animals that are less sentient?

A large proportion of our studies will be conducted using zebrafish larvae; however, to generate these still requires the use of adult fish (for breeding). We also use Drosophila as a wound inflammation model but due to some fundamental differences in their immune system (e.g., only one “catch all” lineage of immune cell (rather than several lineages of innate and adaptive immune cells in vertebrates), and no known chemokines), we must use vertebrate models to investigate some of the complexities of the inflammatory response to tissue repair and cancer. Wherever possible zebrafish will be used in preference to mice for our studies; however, not all of the complexities of mammalian skin healing and inflammation will be perfectly modelled in a fish and so we need to continue some studies in mice, where validation of a mechanism in mammalian tissues will make it more likely for our findings to be of clinical relevance.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All procedures that could cause the animals pain, suffering or distress will be conducted under general anaesthesia. Upon recovery from anaesthesia any animal that show more than transient signs of pain will be killed. in addition. we will be guided by colleagues within our scientific community (and beyond) with regards to best 3Rs practice for the procedures being undertaken. In particular, because zebrafish is a relatively new animal mode, we are continually hearing from colleagues at international meetings about innovative ways for minimising "harms" to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All surgical procedures will be conducted in line with LASA recommendations. For our mouse studies we are constantly keeping up-to-date with published studies on, for example, optimal anaesthesia etc. Our zebrafish husbandry is in line with that recommended by FELASA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We have a continuing dialogue with NC3Rs team; indeed I have talked at several NCR3s conferences in recent years about the use of flies and fish as substitutes for the use of rodent models. In our lab we constantly strive to develop models that might complement/partially substitute for investigations normally only possible in mammalian studies. For example, in one recent published study, during the period of our last PPL, we showed that Drosophila, despite their largely "open" circulatory system, can be used to investigate the rate limiting step in inflammation of extravasation of immune cells from vessels to wounds.

NON-TECHNICAL SUMMARY

189. The immunobiology of mycobacterial infection

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Tuberculosis, mycobacteria, vaccination, therapy, pathogenesis

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall goal of this project is to investigate the interaction between the bacterial pathogen, *Mycobacterium tuberculosis*, and its vertebrate host with the aim of finding better ways to treat and prevent Tuberculosis. The work aims to develop new antimicrobial treatments and therapies that promote the host response, thus improving treatment outcomes and tackling antimicrobial resistance. We will also develop tools to find and test novel Tuberculosis vaccines.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tuberculosis is a major threat to global health with 9 to 10 million new cases annually and 1.5 million lives lost every year. In addition, the World Health Organisation estimate that 2 billion people carry a latent or dormant *Mycobacterium tuberculosis* infection and thus provide a reservoir of potential infection that will be with us for many years to come.

Current drugs are effective in treating infections, but this takes 6-months leading to poor patient compliance and an increase in drug resistant infections. In fact, about 29% of all deaths caused by antimicrobial infections today are due to drug-resistant TB, making it a priority to development of new drugs and therapies that work faster, more efficiently and can treat drug resistant infection.

The current tuberculosis vaccine (BCG) prevents childhood disease but is ineffective against adult tuberculosis in the countries that bear the highest burden of infection. There is an urgent need for new vaccines to prevent active disease, as well as to prevent reactivation of latent infection.

The aim of our research is to understand the biology of tuberculosis in terms of the interaction between host and pathogen with a view to developing improved TB control strategies.

What outputs do you think you will see at the end of this project?

Outputs will include new information on the role those various mycobacterial genes play in the infection process and whether they are suitable as intervention points for new drugs, vaccines or immunotherapies. This information will be disseminated by publications in the scientific literature.

Outputs will include validation of a novel model for vaccine testing that uses fluorescent mycobacteria to report on how well the vaccine works, and validation of ways to deliver drugs to the infected lung. This information will be disseminated by publication in the scientific literature and will form part of the data required to take some of this work into human clinical trials.

Who or what will benefit from these outputs, and how?

In the short 5-year term the outputs will benefit the research community by establishing the suitability (or not) of specific genes as targets for drugs, vaccines or immunotherapy.
In the longer-term suitable lead compounds, fluorescent reporter models and lung delivery systems may be taken on by companies in the Bioscience sector, and ultimately lead to patient benefits.

How will you look to maximise the outputs of this work?

Findings will be made available to other scientists through publication in open-access journals and presentations at scientific conferences and meetings. Tissues harvested at post-mortem are stored and made available to other researchers.

Species and numbers of animals expected to be used

- Mice: 2,500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The interactions between bacteria and the infected human are very complex and for now we need to use animals to study the progress of infection and how best to either prevent it with a vaccine or treat it with a drug. Current non-animal alternatives cannot reproduce all of the complexity of this system. The inbred mouse model used here is well characterised and clinical signs of infection are readily recognisable; it also causes the least overall harm compared to other animal models of tuberculosis whilst still achieving the objectives.

Typically, what will be done to an animal used in your project?

In a typical experiment to test a new vaccine for tuberculosis, two groups of animals will be vaccinated by an appropriate route and rested for 4 weeks; another two groups will receive a sham vaccine as control.

One group of vaccinated and one group of unvaccinated animals are then given an dose of fluorescent reporter mycobacteria in the skin to test how well the vaccine works. The fluorescent signal from the bacteria in the skin will then be photographed three times a week with a modified camera over 3 weeks to measure the loss of the signal over time as the bacteria are killed by the vaccine immune response.

Other groups of vaccinated and unvaccinated animals are given an infected by the intranasal route with virulent mycobacteria. Animals are humanely culled around 4 weeks after infection and the number of bacteria in the lungs and spleen are counted and compared between vaccinated and non-vaccinated. Tissue samples are collected for immunological analyses.

What are the expected impacts and/or adverse effects for the animals during your project?

None of the procedures used should cause lasting harm, and anaesthetics are used when the procedure may cause stress. Infection with wild type virulent mycobacteria eventually leads to a pneumonia-like illness with respiratory distress and weight loss. Any animal that shows such deviation from normal health (piloerection, hunched posture, abnormal gait, respiratory distress, inactivity or inappetence) will be monitored more frequently and supportive treatment provided such as warming and wet mash. Should the signs persist for a period of 24 hours the animal will be humanely killed. In addition, any animal that loses 20% of its starting body weight will be culled.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Around 50% of animals will experience mild severity, with the remainder moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The interactions between bacteria and the infected human are very complex and for now we need to use animals to study the progress of an infection and how best to either prevent it with a vaccine or treat it with a drug. Current non-animal alternatives cannot reproduce all of the complexity in this system. The inbred mouse model used here is well characterised and clinical signs of infection are readily recognisable; it also causes the least overall harm compared to other animal models of tuberculosis whilst still achieving the objectives.

Which non-animal alternatives did you consider for use in this project?

We make extensive use of laboratory cell culture models to characterise as many aspects of the infection process as possible. Novel cell culture systems are being developed with combinations of cells, which we are planning to test. Models of *in vitro* granulomas and *Galleria mellonella* larvae are available to monitor the early stages of infection and the factors involved; where possible these models will be used as a replacement. Part of this project will be the development of a mycobacterial system that can be used in humans to rapidly test novel vaccines and drugs.

Why were they not suitable?

The *in vitro* models are useful for preliminary screening of therapeutic agents but cannot replicate the immune response need for vaccine evaluation. The *Galleria mellonella* model is similarly useful as a screening tool for therapeutic agents, but its internal anatomy and physiology are distinct from mammals. Thus, therapeutic agents ultimately need to be tested in animal models of infection so that effects like tissue absorption and penetration, agent stability and half-life can be assessed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals is estimated based on previous experience of the number and type of experiments we will do over the duration of the project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where possible we will compare different treatments or regimens in the same experiment so that control mice are shared, thereby reducing the overall number of animals. Experiments are repeated for scientific validation and to ensure reproducibility of the results.

Mice are marked to allow individual analysis. Each group of mice is randomly assigned to an experimental or control group and, where appropriate, analysis is blinded to prevent bias.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We have developed bioluminescence and fluorescence imaging tools for mycobacteria that allow non-invasive detection of bacteria within animals in real-time. The combination of imaging and monitoring weight loss results in a reduction in the numbers of animals used during experiments and the level of suffering, by the implementation of more humane endpoints. We routinely collect and store fixed tissues from infected animals that are shared to with collaborators in the field.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.
Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse model causes the least overall harm compared to guinea pigs, rabbits and non-human primates, which experience more severe disease. Inbred mice are widely accepted as models for human infectious diseases; they are genetically identical which reduces the number of animals required, compared with outbred animals, where the genetic makeup varies unpredictably. Mice will be infected with mycobacteria through the nose, and some treatments are given via the trachea into the lungs. Both of these procedures are performed under anaesthesia to limit stress, and neither cause lasting harm, although mice may eventually develop symptoms due to the infection.
Why can’t you use animals that are less sentient?

As we aim to model human infection, we need to use adult mice, as a model. Infection and symptoms are followed over time, so live animals are required.

The *Galleria mellonella* insect larvae model is used for screening but has a primitive immune system and anatomy and is not suitable for vaccination or therapeutic testing.

The natural infection of zebra fish larvae with *Mycobacterium marinum* has been used in a number of studies to investigate the interaction between the bacteria and cells of the innate immune response, with some studies using adult fish in which the adaptive immune response has also developed. However, *M. marinum* does not cause human tuberculosis and these microorganisms are genetically quite different from *M. tuberculosis*. This means the zebra fish-marinum model is of limited use for evaluating the role of specific *M. tuberculosis* genes in pathogenesis, or for vaccination or therapeutic studies.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Daily monitoring of infected animals, with monitoring of body weight allows us to define more humane endpoints. Pain management will be provided on the advice of the Veterinary Surgeon for any procedure or situation that requires it. Training is continual making use of new developments and technologies as they come available.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow published guidelines issued by the *Laboratory Animal Science Association*, the *National Centre for the Replacement, Refinement and Reduction of Animals in Research*, and the RSPCA.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The scientific literature and conferences are sources of information on new developments and technologies, as are workshops run internally on the Replacement, Refinement and Reduction of animal use. Our previous work has developed and implemented imaging tools for use in infection models, and the reporter systems we developed have been widely distributed.

NON-TECHNICAL SUMMARY

190. The role of genes in blood vessel formation

Project duration

3 years 0 months

Project purpose

- (a) Basic research **Key**

words

blood vessels, development, Protocadherin 1

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to assess the role of genes in the formation of blood vessels. Blood vessel formation is an essential process in development of organisms and it also plays a pivotal role in a number of diseases including cancer and inflammatory disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work because we are not able to model all aspects of blood vessel formation in vitro. This is because there is a complex interaction between a number of different cell types which drives this process. It is known that vessel formation is strongly driven by low levels of oxygen. Then as new vessels form and blood flows, there is increased oxygenation of tissues terminating the signals for this process. Modelling these dynamic changes in oxygen and the element of blood flow is not yet possible in vitro. Understanding how blood vessels form has the potential to yield novel therapeutic interventions for diseases where vessel formation contributes to the pathology of the disease; this included solid tumours, chronic inflammatory diseases such as rheumatoid arthritis and eye diseases including diabetic retinopathy and age related macular degeneration. There are also diseases, including ischaemic heart disease, where a better understanding of vessel formation, may enable the development of therapies that will drive vessel development to restore blood flow to damaged tissue.

What outputs do you think you will see at the end of this project?

At the end of this project we will generate new information about the function of PCDH1 and whether this gene products plays a role vessel formation both during development and in the adult. Information will be disseminated in the form of conference presentations and publications. Indications that PCDH1 does regulate vessel formation could yield novel therapeutic strategies for manipulating vessel formations in diseases such as cancer where this process contributes to the pathology. Thus, positive results could generate further funding to explore these options.

Who or what will benefit from these outputs, and how?

In the short term this project will yield novel information about the role of PCDH1 in vessel development, this has not been investigated and so our findings will be of benefit to the scientific community. They will gain a greater understanding of the function of this gene and gain greater insight into the role of this family of genes as a whole. In the longer term, if we discover a role for PCDH1 in vessel development, this will yield the potential for future funding to investigate ways of modulating PCDH1 function to regulate the process of vessel formation, This could have impacts on diseases such as cancer, since solid tumours depend on vessel formation for their growth and metastasis. In addition, discovering new ways to promote vessel formation could impact upon the treatment of heart attack or peripheral artery disease where promotion of new vessel growth would be beneficial.

How will you look to maximise the outputs of this work?

We will publish our work in open-access peer-reviewed journals in accordance with the ARRIVE guidelines and present at conferences to disseminate new knowledge about the function of this gene.

Any results, including negative data, about the extent to which loss of PCDH1 affects vessel formation will be reported. We collaborate with a group external to our establishment on this gene and our results will be of benefit to them. We will also share our findings with groups internal to the establishment who have an interest in some of the proteins with which PCDH1 interacts.

Species and numbers of animals expected to be used

- Mice: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice as the process of vessel formation has been well studied in this species and closely resembles that found in humans. In addition, the technology of manipulating the genome is well developed in mice enabling us to investigate mice lacking our gene of interest in either all cells or cells of a particular type. The tissue distribution of our gene of interest PCDH1 in mouse very closely resembles that of human PCDH1; this not the case for lower organisms such as zebrafish which can be used to study the function of some genes in vessel formation.

Because we are investigating developmental blood vessel formation we will evaluate the vascularisation of embryos and also in the retina, where vessels develop shortly after birth. To study blood vessel formation in adult mice, we will also use mice at this stage of life.

Typically, what will be done to an animal used in your project?

The project involves breeding mice which lack PCDH1 in either all cells or just endothelial cells, the cells that line blood vessels. We will then examine blood vessel development at various stages of development in mice after they have been humanely killed. Of particular interest will be to examine vessel development in embryos just prior to mid-gestation and the vessels of the retina examined shortly after birth. We will also investigate vessel formation in adult mice in two contexts. In the first we will examine vessels that develop in tumours. To investigate this, tumour cells are implanted under the skin into the flanks of mice. The size of the tumours, which take about 3 weeks to grow, will be monitored using callipers (that provides precise measurements in millimetres). Once the tumours have reached their size limit the experiment will be ended and the mice killed, as well as measuring the rate at which the tumours grow the tumours will be examined for various parameters of vessel formation and functionality. We will also use a second method to investigate vessel formation in adult mice, this is driven by different growth factors more associated with wound healing, in this model small pieces of sponge are implanted under the skin under anaesthetic, these sponges are then injected with factors to promote vessel development every 2-3 days for two weeks. The mice are then humanely killed and the sponges are removed and examined for vessel growth.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect the breeding to be associated with adverse impacts, reports from our collaborators suggest that mice lacking PCDH1 are smaller than those that do not lack PCDH1 but are otherwise healthy.

Mice implanted with tumour cells will experience tumour growth which will not cause any pain. When the tumour is become larger, they can impede the normal behaviour of the mouse. Rarely the skin around the tumours may ulcerate. Animals will be killed according to monitoring for adverse effects set out in the protocols.

Mice implanted with sponge will suffer discomfort immediately after the implantation of the sponge, however analgesics are administered to minimise the pain. After this has healed the mice tolerate the implanted sponge well and the injections into the sponge are done while the mice are lightly anaesthetised and this does not result in adverse effects. Rare adverse effects associated with poor wound closure and infection can occur and if they do animals will be killed according the monitoring for this as set out in the protocol.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding protocol is associated with a moderate severity, this is because mice lacking PCDH1 in all cells are smaller and there is a greater pre-weaning loss of these mice. Though smaller they do not show any signs of ill health. We expect to see this severity in around 25% mice.

The tumour implantation protocol has a moderate severity expected in 90% of the animals, it is probable that in 10% of the animals the tumours may not grow properly.

The sponge implantation protocol has a moderate severity in all animals, this is because the severity is associated with surgical implantation of the sponge which occurs in all animals undergoing this protocol. Once implanted the sponge does not change in size.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use a number of non-animal systems which replicate limited aspects of vessel formation to investigate genes of interest before considering the use of animals to more fully explore the functions

of these genes. Animals are needed to assess blood vessel formation because at the moment there are no laboratory models that can fully replicate this process. This is because it is not yet possible to incorporate the different types of cells, signals and the aspect of blood flow that are all involved in driving vessel development.

Which non-animal alternatives did you consider for use in this project?

We have explored a number of experimental systems that replicate aspects of blood vessel formation. The models that best replicate this process involves co-culturing endothelial cells, which are the cells which form new vessels, with other cell types that can provide supporting signals and scaffold. The Chick embryo CAM chorioallantoic membrane (CAM) model is another method that can be used to investigate blood vessel formation.

Why were they not suitable?

Our co-culture model promotes the formation of endothelial tubes, but these do not fully resemble vessels found in the animal and the aspect of blood flow is missing. It is not yet possible to fully replicate the conditions found in the animal which cause blood vessels to be formed. We are constantly reviewing and exploring new non-animal systems to try to better model vessel development. We are currently investigating the possibility of using stem cells which can be differentiated into endothelial cells and used in organoid systems which support the formation of vessel like structures. While these models show promise they do not yet fully replicate the process of vessel formation as it occurs in animals. While the chick embryo CAM model has been very useful in testing the angiogenic properties of various factors, it would not be suitable for investigating PCDH1 because we are not able to undertake genomic modifications in the chicken and expression of PCDH1 in chicken has not been reported to have a vascular expression pattern.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated based on our previous experience with these experimental models combined with the use of statistical tools (power analyses) to determine the numbers of mice required to give meaningful data. Given that our gene of interest has not been previously studied in the context of vessel formation, effect size will be determined small pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs experimental design tool and its associated statistical analysis tool has been used to assist with experimental design and reduce the number of animals used. We will use methods to reduce

subjective bias, and maximise the information obtained from a minimal number of animals by, for example, longitudinal studies monitoring tumours as they grow.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use the most efficient breeding strategies to generate mice of the correct phenoytpe and monitor breeding closely so as not to generate excess animals. All experiments will be designed in line with the PREPARE guidelines checklist to ensure the best possible design. In addition, data will be published in Open Access Journals and in accordance with the ARRIVE guidelines. Negative data, should it be generated will also be reported.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The angiogenesis assay we propose in this application is the rodent subcutaneous sponge model. This model is robust, sensitive and reliable with the result that we use a minimum number of animals for each experiment. This model is the most refined being far less invasive –than other angiogenesis assays typically used such as the rabbit corneal assay, skin flap assays or the dorsal air sac assay. The subcutaneous implantation model of tumour growth is one of the most refined tumour models combining ease of implantation by subcutaneous injection and facile monitoring of tumour growth.

Why can’t you use animals that are less sentient?

Previous research by many groups has documented that the mouse is the lowest organism with sufficiently similar angiogenic patterns to man to allow meaningful evaluation of mechanisms of blood vessel formation. It is possible to use vessel development in zebrafish embryos to determine the role target genes may play in developmental angiogenesis. However, use of this model is contingent on the genes of interest having zebrafish orthologues with similar expression patterns to their mammalian counterparts. The gene of interest in this study has been duplicated in the zebrafish genome and has an altered expression pattern in this species. By contrast, mouse and human show similar expression patterns of the gene being studied in this licence application. We will evaluate vessel development in mouse embryos from day 9.5 – 13, during which time the early vessels and first angiogenic vessels are formed, and before embryos are covered by ASPA.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. We will continually review our procedures from a welfare standpoint to identify any potential for refinement. We will use the most refined handling techniques.

For example, post-operative care and pain management are critical refinements for the sponge angiogenesis assays . We will seek to refine the administration of the substances to assess vessel perfusion, hypoxia and tumour cell proliferation by evaluating if administration via the more refined intravenous or subcutaneous routes would result in the adequate delivery to the tumour or sponge.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Information from the NC3Rs will be regularly reviewed and the following publications consulted.

PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

The LASA guidelines: RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare
and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)

Guidelines for the welfare and use of animals in cancer research Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.

Angiogenesis assays – A critical appraisal of current techniques (ed Staton, Lewis and Bicknell) 2006 Wiley.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay updated via literature searches, seminars and conferences to find out about new technology and new approaches that we could implement.

We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.

We will regularly review guidance from the NC3Rs and implement any changes that would lead to the refinement of our work and sign up to the NC3Rs newsletter..

Home Office

NON-TECHNICAL SUMMARY

191. The role of clotting proteins in inflammation and immunity

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

thrombin, inflammation, atherosclerosis

Animal types	Life stages
Mice	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Most are aware of the role that clotting proteins, such as thrombin, play in blood clotting. But few are aware that they also play a role, independent from clotting, in inflammation and immunity. This project will investigate the cellular and molecular mechanisms by which thrombin and other members of this family of enzymes influence the inflammatory responses involved in three different models of human disease; development of fatty arteries (atherosclerosis), fibrous narrowing of blood vessels (intimal hyperplasia), and an archetypal response to foreign proteins (delayed type hypersensitivity) that underpins many human immune responses. It will also explore the potential to use novel therapeutics to influence these fundamental processes

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There are several reasons why this project is important;

a) Inhibiting clotting proteins has a profound effect on inflammation in many animal models, but translation into the clinic has been hampered by the impact that anti-coagulants have on bleeding, which can be serious, if for instance patients experience bleeding into the brain. We have developed a way, for the first time, to uncouple the effects of an anti-thrombin on clotting from inflammation, so that when used, animals are prone to excessive bleeding for only 1/7th of the time that inflammation is inhibited. Part of this project will be to test this and other novel reagents in different models of inflammation, as part of an exploratory programme to advise on potential clinical uses.

b) If we can work out the molecules, receptors and cells involved in how thrombin and other clotting proteins influence inflammation, we may be able to work out ways to inhibit the thrombin effect without affecting clotting and bleeding, so the other part of this project is to work out how these proteins influence different aspects of the inflammatory and immune response, to discover novel routes of inhibition.

What outputs do you think you will see at the end of this project?

Several primary outputs are envisaged:

a) Publications: we have a good track record of converting our work into primary publications in high quality peer-reviewed journals

b) Therapeutics with clearly defined clinical application. This will be obvious from our published work. We are actively pursuing sources of funding to enable translation into the clinic. For PTL060, this has undergone pre-clinical development resulting in toxicity data and GMP material and its ready for first in man studies. For the newer 'cytotopic' agents which are the prime focus of this project, it is hoped similar development will flow from this new work

Who or what will benefit from these outputs, and how?

Short-term: my team members doing the work will benefit from the experience of designing and performing experiments, reviewing and auditing procedures and data, presenting and publishing their work, and in some cases obtaining a PhD thesis. I will also benefit from their success. 'Short-term' begins before completion of this project

Medium term: the scientific community will benefit from the new knowledge gained, which will hopefully be built upon by other groups to advance the field. 'Medium term' begins before completion of this project and extends into the distance

Longer term: assuming we are successful at showing the potential of our new therapeutics, patients may

benefit from translation of our findings into novel drug treatments. 'Longer term' begins after completion of the project and may be dependent on further projects **How will you look to maximise the outputs of this work?**

Submission of abstracts and manuscripts to meetings and journals (respectively)
Presentation of data at meetings and seminars during local, national and international conferences
Use of our webpages to publicise high impact findings
Timely submission of new grant applications, with appropriate collaborations, to continue down fruitful avenues of exploration
Submission of patents, if appropriately novel findings warrant

Species and numbers of animals expected to be used

- Mice: 2900

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Juvenile and adult mice have been chosen because of the vast array of reagents available, the number of genetically modified strains available to work with and the relative in expense of working with these animals compared to larger species.

Typically, what will be done to an animal used in your project?

Some animals will be maintained for breeding only. In all other protocols, most animals will receive at least one injection of non-toxic substances, and in some protocols, blood will be sampled at various time points. In the fatty artery model (atherosclerosis), the only other fixed intervention is that most mice will be given a high fat diet to eat. In the archetypal immune response model (delayed type hypersensitivity), mice will be exposed to foreign antigen on the skin twice, first on the abdomen, and second on the ear lobe (pinna). In the fibrous narrowing of blood vessels model (intimal hyperplasia), mice will undergo recovery surgery, with a small scar on the front of their upper thorax/lower neck.
Up to 20% of the mice in the non-breeding protocols will receive radiation treatment to facilitate bone marrow transplantation before undergoing the above procedures approximately 1 month later.

What are the expected impacts and/or adverse effects for the animals during your project?

Radiation treatment followed by bone marrow transplantation causes weight loss in all animals, of approximately 8% of body weight, which begins to recover beyond day 5. Most mice receiving the maximum dose of radiation are expected to develop mild self-limiting dry eyes and later, a degree of cataracts, but neither is expected to cause pain, discomfort or distress. The other potential major harms associated with radiation treatment and bone marrow transplantation include severe diarrhoea, breathing difficulties and an inflammatory disease called ‘graft versus host disease’. Only 1% or fewer suffer these serious side effects.

Approximately 20% of animals fed a high fat diet in the fatty artery model develop skin irritation followed by severe scratching (excoriation), which can be managed to relieve pain and distress, if necessary, by claw trimming and antibiotic ointments.
Recovery surgery in the fibrous narrowing of blood vessels model is rarely (<1% animals) followed by signs of a blocked blood vessel causing a 'stroke'. If this occurs, it is obvious immediately post-recovery so animals will be killed straight away to minimise suffering.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

A minority of mice (≤20%) undergoing radiation treatment followed by bone marrow transplantation have been ascribed a moderate severity level. Up to 20% of genetically modified mice on a high fat diet can develop skin irritation and scratching which is also ascribed moderate severity level. The remaining mice are expected to suffer only mild levels of distress or morbidity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Each of the models we are studying involves multiple different elements of the immune system and also elements of repair/healing that respond in a complex and coordinated way to either blood vessel inflammation due to altered fat metabolism or blood vessel injury after a wire insertion, or foreign protein antigens applied to the skin. Each of these is a model of human disease.

Which non-animal alternatives did you consider for use in this project?

We already use non-animal, 'test-tube' alternatives where possible, to minimise animal use. Therefore, we use petri-dish cultured cells to study the impact of clotting proteins on cell growth, differentiation, death and protein production. With regard to the application of protein antigens to the skin, our interest is in the involvement of cells other than T lymphocytes, for which there is no 'test-tube' counterpart.
In addition, we are using laboratory models of human organ perfusion to study the impact of our therapies on blood clotting.

Why were they not suitable?

There are no suitable test-tube (or other models) of fatty artery regression, fibrous narrowing of blood vessels or archetypal non-T cells responses to protein antigens.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This has been done in two ways. First, I have examined the number of animals used on my existing licence for the last four years, which has been particularly useful to estimate the number of future mice to breed, as I envisage no major change in the overall nature of the work I will be performing. Second, i have tried to assess the number of experiments to be performed, and numbers per group, considering all controls, and used this to estimate the mice used in procedures

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I have taken extensive advice, in the past from statistical colleagues. The basic design of in vivo experiments has not altered over the years; all involve comparison of a control group with an experimental group with a specific biological read-out. Use of 6-7 animals per group, in each experiment, will enable the differentiation of a 20% difference in read-out between groups at 90% power and 5% significance. We have already performed pilot dose-comparison studies on a previous PPL to determine the minimum effective IV dose of the cytotopic proteins.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We plan to collect all tissue, blood and cells from every animal used in each experiment, and store appropriately, in a local tissue bank in our laboratory, to avoid having to repeat experiments to examine new aspects of the model - we can instead revert to stored tissue to ask exploratory questions, only having to use new animals if our exploratory findings are positive.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Compared to previous licences, I have limited the number of models to be studied to three; dietary modification to result in accelerated fatty artery inflammation in genetically modified mice, development of ear swelling after protein antigen exposure, and development of fibrous narrowing of blood vessels after mechanical damage. These three represent models that encompass three fundamentally different immune and repair processes, that will allow my group to extrapolate findings to multiple diseases. That the scientific community will embrace this approach is best illustrated by the fact that one of my PhD students won a major award at national meeting of transplantation experts in 2020, despite the fact that her presentation was entirely based on results from the ear swelling model: this is because the type of immune response that develops is representative of that which develops to all localised antigens, including transplanted organs. Despite being a transplant immunologist, this is my first licence that does not contain transplant models.
The fatty artery inflammation and archetypal immune response model are essentially 'mild' in severity, but classed here as moderate because a minority of the animals will undergo radiation treatment followed by bone marrow transplantation to allow us to dissect underlying mechanisms. The majority of animals will suffer no pain or distress. As stated below, we will adopt contemporary methods to minimise distress associated with repeated handling and injections and use local anaesthetic appropriately. In the third model, involving recovery surgery, we will use peri-operative analgesia, and animals will be closely monitored for signs of distress. All experiments will be terminated at the earliest time point that enables best measurement of the endpoints under study.

Why can’t you use animals that are less sentient?

The three disease processes being studied are diseases of mammals. The mouse represents the smallest of the models that are used by investigators in the field (the others being rabbit and pig). The types of immune response to be studied take longer than a few hours to develop, and for practical purposes we need juvenile or adult mice of the appropriate size (for instance with big enough arteries in which to insert a fine wire) to enable efficient and reproducible study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I will endeavour to stay abreast of advances in all areas. As an example of how we can refine our procedures, several of our models involve repeated handling (for injection, for instance). We will stop using the tail to pick up mice and instead use cupped hands (or a tunnel if available) to minimise distress and optimise reproducibility of our data.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We aim to report our work according to the latest ARRIVE guidelines (2.0), and in doing this will help ensure our experiments, from the planning stage, are performed in the most refined way.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will use the NC3R website as the primary way to stay informed about the latest advances in the 3Rs

Home Office

NON-TECHNICAL SUMMARY

192.The role of genes in blood vessel formation

Project duration

3 years 0 months

Project purpose

- (a) Basic research **Key**

words

blood vessels, development, Protocadherin 1

Animal types	Life stages
Mice	neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to assess the role of genes in the formation of blood vessels. Blood vessel formation is an essential process in development of organisms and it also plays a pivotal role in a number of diseases including cancer and inflammatory disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

It is important to undertake this work because we are not able to model all aspects of blood vessel formation in vitro. This is because there is a complex interaction between a number of different cell types which drives this process. It is known that vessel formation is strongly driven by low levels of oxygen. Then as new vessels form and blood flows, there is increased oxygenation of tissues terminating the signals for this process. Modelling these dynamic changes in oxygen and the element of blood flow is not yet possible in vitro. Understanding how blood vessels form has the potential to yield novel therapeutic interventions for diseases where vessel formation contributes to the pathology of the disease; this included solid tumours, chronic inflammatory diseases such as rheumatoid arthritis and eye diseases including diabetic retinopathy and age related macular degeneration. There are also diseases, including ischaemic heart disease, where a better understanding of vessel formation, may enable the development of therapies that will drive vessel development to restore blood flow to damaged tissue.

What outputs do you think you will see at the end of this project?

At the end of this project we will generate new information about the function of PCDH1 and whether this gene products plays a role vessel formation both during development and in the adult. Information will be disseminated in the form of conference presentations and publications. Indications that PCDH1 does regulate vessel formation could yield novel therapeutic strategies for manipulating vessel formations in diseases such as cancer where this process contributes to the pathology. Thus, positive results could generate further funding to explore these options.

Who or what will benefit from these outputs, and how?

In the short term this project will yield novel information about the role of PCDH1 in vessel development, this has not been investigated and so our findings will be of benefit to the scientific community. They will gain a greater understanding of the function of this gene and gain greater insight into the role of this family of genes as a whole. In the longer term, if we discover a role for PCDH1 in vessel development, this will yield the potential for future funding to investigate ways of modulating PCDH1 function to regulate the process of vessel formation, This could have impacts on diseases such as cancer, since solid tumours depend on vessel formation for their growth and metastasis. In addition, discovering new ways to promote vessel formation could impact upon the treatment of heart attack or peripheral artery disease where promotion of new vessel growth would be beneficial.

How will you look to maximise the outputs of this work?

We will publish our work in open-access peer-reviewed journals in accordance with the ARRIVE guidelines and present at conferences to disseminate new knowledge about the function of this gene. Any results, including negative data, about the extent to which loss of PCDH1 affects vessel formation will be reported. We collaborate with a group external to this university on this gene and our results will be of benefit to them. We will also share our findings with groups internal to the university who have an interest in some of the proteins with which PCDH1 interacts.

Species and numbers of animals expected to be used

- Mice: 200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using mice as the process of vessel formation has been well studied in this species and closely resembles that found in humans. In addition, the technology of manipulating the genome is well developed in mice enabling us to investigate mice lacking our gene of interest in either all cells or cells of a particular type. The tissue distribution of our gene of interest PCDH1 in mouse very closely resembles that of human PCDH1; this not the case for lower organisms such as zebrafish which can be used to study the function of some genes in vessel formation.
Because we are investigating developmental blood vessel formation we will evaluate the vascularisation of embryos and also in the retina, where vessels develop shortly after birth. To study blood vessel formation in adult mice, we will also use mice at this stage of life.

Typically, what will be done to an animal used in your project?

The project involves breeding mice which lack PCDH1 in either all cells or just endothelial cells, the cells that line blood vessels. We will then examine blood vessel development at various stages of development in mice after they have been humanely killed. Of particular interest will be to examine vessel development in embryos just prior to mid-gestation and the vessels of the retina examined shortly after birth. We will also investigate vessel formation in adult mice in two contexts. In the first we will examine vessels that develop in tumours. To investigate this, tumour cells are implanted under the skin into the flanks of mice. The size of the tumours, which take about 3 weeks to grow, will be monitored using callipers (that provides precise measurements in millimetres). Once the tumours have reached their size limit the experiment will be ended and the mice killed, as well as measuring the rate at which the tumours grow the tumours will be examined for various parameters of vessel formation and functionality. We will also use a second method to investigate vessel formation in adult mice, this is driven by different growth factors more associated with wound healing, in this model small pieces of sponge are implanted under the skin under anaesthetic, these sponges are then injected with factors to promote vessel development every 2-3 days for two weeks. The mice are then humanely killed and the sponges are removed and examined for vessel growth.

What are the expected impacts and/or adverse effects for the animals during your project?

We do not expect the breeding to be associated with adverse impacts, reports from our collaborators suggest that mice lacking PCDH1 are smaller than those that do not lack PCDH1 but are otherwise healthy.
Mice implanted with tumour cells will experience tumour growth which will not cause any pain. When the tumour is become larger, they can impede the normal behaviour of the mouse. Rarely the skin around the tumours may ulcerate. Animals will be killed according to monitoring for adverse effects set out in the protocols.
Mice implanted with sponge will suffer discomfort immediately after the implantation of the sponge, however analgesics are administered to minimise the pain. After this has healed the mice tolerate the implanted sponge well and the injections into the sponge are done while the mice are lightly anaesthetised and this does not result

in adverse effects. Rare adverse effects associated with poor wound closure and infection can occur and if they do animals will be killed according the monitoring for this as set out in the protocol.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The breeding protocol is associated with a moderate severity, this is because mice lacking PCDH1 in all cells are smaller and there is a greater pre-weaning loss of these mice. Though smaller they do not show any signs of ill health. We expect to see this severity in around 25% mice.
The tumour implantation protocol has a moderate severity expected in 90% of the animals, it is probable that in 10% of the animals the tumours may not grow properly.
The sponge implantation protocol has a moderate severity in all animals, this is because the severity is associated with surgical implantation of the sponge which occurs in all animals undergoing this protocol. Once implanted the sponge does not change in size.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We use a number of non-animal systems which replicate limited aspects of vessel formation to investigate genes of interest before considering the use of animals to more fully explore the functions of these genes. Animals are needed to assess blood vessel formation because at the moment there are no laboratory models that can fully replicate this process. This is because it is not yet possible to incorporate the different types of cells, signals and the aspect of blood flow that are all involved in driving vessel development.

Which non-animal alternatives did you consider for use in this project?

We have explored a number of experimental systems that replicate aspects of blood vessel formation. The models that best replicate this process involves co-culturing endothelial cells, which are the cells which form new vessels, with other cell types that can provide supporting signals and scaffold. The Chick embryo CAM chorioallantoic membrane (CAM) model is another method that can be used to investigate blood vessel formation.

Why were they not suitable?

Our co-culture model promotes the formation of endothelial tubes, but these do not fully resemble vessels found in the animal and the aspect of blood flow is missing. It is not yet possible to fully replicate the conditions found in the animal which cause blood vessels to be formed. We are constantly reviewing and exploring new non-animal systems to try to better model vessel development. We are currently investigating the possibility of using stem cells which can be differentiated into endothelial cells and used in organoid systems which support the formation of vessel like structures. While these models show promise they do not yet fully replicate the process of vessel formation as it occurs in animals. While the chick embryo CAM model has been very useful in testing

the angiogenic properties of various factors, it would not be suitable for investigating PCDH1 because we are not able to undertake genomic modifications in the chicken and expression of PCDH1 in chicken has not been reported to have a vascular expression pattern.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers have been estimated based on our previous experience with these experimental models combined with the use of statistical tools (power analyses) to determine the numbers of mice required to give meaningful data. Given that our gene of interest has not been previously studied in the context of vessel formation, effect size will be determined small pilot experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The NC3Rs experimental design tool and its associated statistical analysis tool has been used to assist with experimental design and reduce the number of animals used. We will use methods to reduce subjective bias, and maximise the information obtained from a minimal number of animals by, for example, longitudinal studies monitoring tumours as they grow.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use the most efficient breeding strategies to generate mice of the correct phenoytpe and monitor breeding closely so as not to generate excess animals. All experiments will be designed in line with the PREPARE guidelines checklist to ensure the best possible design. In addition, data will be published in Open Access Journals and in accordance with the ARRIVE guidelines. Negative data, should it be generated will also be reported.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The angiogenesis assay we propose in this application is the rodent subcutaneous sponge model. This model is robust, sensitive and reliable with the result that we use a minimum number of animals for each experiment. This model is the most refined being far less invasive –than other angiogenesis assays typically used such as the rabbit corneal assay, skin flap assays or the dorsal air sac assay. The subcutaneous implantation model of

tumour growth is one of the most refined tumour models combining ease of implantation by subcutaneous injection and facile monitoring of tumour growth.

Why can't you use animals that are less sentient?

Previous research by many groups has documented that the mouse is the lowest organism with sufficiently similar angiogenic patterns to man to allow meaningful evaluation of mechanisms of blood vessel formation. It is possible to use vessel development in zebrafish embryos to determine the role target genes may play in developmental angiogenesis. However, use of this model is contingent on the genes of interest having zebrafish orthologues with similar expression patterns to their mammalian counterparts. The gene of interest in this study has been duplicated in the zebrafish genome and has an altered expression pattern in this species. By contrast, mouse and human show similar expression patterns of the gene being studied in this licence application. We will evaluate vessel development in mouse embryos from day 9.5 – 13, during which time the early vessels and first angiogenic vessels are formed, and before embryos are covered by ASPA.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animal welfare is a key consideration in all of our protocols and we will be guided by our NACWO and NVS in always ensuring that we are using best practice and the most refined techniques. All staff involved in animal experiments will review the literature on animal welfare provided by the local AWERB. We will continually review our procedures from a welfare standpoint to identify any potential for refinement. We will use the most refined handling techniques.

For example, post-operative care and pain management are critical refinements for the sponge angiogenesis assays . We will seek to refine the administration of the substances to assess vessel perfusion, hypoxia and tumour cell proliferation by evaluating if administration via the more refined intravenous or subcutaneous routes would result in the adequate delivery to the tumour or sponge.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Information from the NC3Rs will be regularly reviewed and the following publications consulted.
PREPARE: guidelines for planning animal research and testing. Smith AJ, Clutton RE, Lilley E, Hansen KEA, Brattelid T. Lab Anim. 2018 Apr;52(2):135-141. doi: 10.1177/0023677217724823. Epub 2017 Aug 3.PMID: 28771074).

The LASA giudlines: RSPCA and LASA, 2015, Guiding Principles on Good Practice for Animal Welfare and Ethical Review Bodies. A report by the RSPCA Research Animals Department and LASA Education, Training and Ethics Section. (M. Jennings ed.)
Guidelines for the welfare and use of animals in cancer research Workman P, Aboagye EO, Balkwill F, Balmain A, Bruder G, Chaplin DJ, Double JA, Everitt J, Farningham DA, Glennie MJ, Kelland LR, Robinson V, Stratford IJ, Tozer GM, Watson S, Wedge SR, Eccles SA; Committee of the National Cancer Research Institute. Br J Cancer. 2010 May 25;102(11):1555-77. doi: 10.1038/sj.bjc.6605642.
Angiogenesis assays – A critical appraisal of current techniques (ed Staton, Lewis and Bicknell) 2006 Wiley.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will stay updated via literature searches, seminars and conferences to find out about new technology and new approaches that we could implement.
We will comply with the ARRIVE guidelines (Animal Research: Reporting In Vivo Experiments; www.nc3rs.org.uk/arrive), a NC3Rs-developed checklist of the essential information that should be included in publications reporting animal research.
We will regularly review guidance from the NC3Rs and implement any changes that would lead to the refinement of our work and sign up to the NC3Rs newsletter.

Home Office

NON-TECHNICAL SUMMARY

193.The role of neurohormones in the control of brain circuitries and behaviour

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants

Key words

Physiology and behaviour, Mechanisms of regulating brain activity, Neurohormones as signalling molecules, Social behaviours, Neurological disorders

Animal types	Life stages
Rats	neonate, juvenile, adult, pregnant, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project examines the importance of neurohormones, in particular oxytocin and vasopressin, in the control of brain circuitries and behaviours.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Within the brain, the neurohormones vasopressin and oxytocin are synthesised by a number of different populations of nerve cells and these different populations are responsible for specific neurohormone-dependent behaviours. Understanding how vasopressin and oxytocin trigger behavioural effects; including appetite, sexual and aggressive behaviours, social interaction, maternal care and bonding has attracted widespread attention because of the possibility that drugs mimicking peptide actions may be valuable therapeutically. For vasopressin and oxytocin, there is evidence of links with neuropsychiatric disorders, including eating disorders, stress disorder, anxiety, depression and autism.

What outputs do you think you will see at the end of this project?

This project will address fundamental principles in neuroscience and is therefore likely to have implications for many neurological disorders such as autism and obesity. As such, the primary output will be generation of knowledge that will be largely disseminated by publication in peer reviewed journals and presentation at conferences, seminars and workshops. I will also continue active participation in public engagement events, media interviews and our institute’s Public Engagement and Communications Committee to increase the public’s awareness of our work and its implications for health.

Who or what will benefit from these outputs, and how?

The ‘discovery research’ nature of this project means that the short-term beneficiaries will primarily be the academic community. Our previous work has led to high-impact publications and this has given us a high profile in the academic community.

The outcomes of this project could also steer future research towards new therapeutic strategies using neuropeptides and hence will be of long-term benefit to the pharmaceutical industry and charitable organisations that fund medical research and ultimately to human health. The timeframe for improvements to human health would be expected in the decades, while increased investment in Research and Development in these areas could occur within 3-5 years.

How will you look to maximise the outputs of this work?

Findings from this project will primarily be communicated and disseminated through publication in widely-read international peer-reviewed journals, but also presentation at local, national and international congresses and individual institute seminars. To ensure maximum dissemination, only journals with green or gold open access options will be considered.

To disseminate knowledge to the public, we will accompany published papers with targeted press releases, using the University Press Office, and also will target science journalists and use social media channels. It is important that the outcomes of this project are effectively disseminated not only to scientific peers, but also to the general public to help explain how public investment in basic science brings benefits to health and well-being. We have been extremely active in outreach activities, including public lectures, media appearances, science festivals, articles in the popular press, and online briefings and education.

The project has potentially important translational implications, and these will be managed with the support of the University, which has extensive expertise in the protection of intellectual property arising from grant-funded research, and in fostering translational outcomes.

Species and numbers of animals expected to be used

- Rats: 4500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rats will be used throughout this programme of research. Rats have been extensively used as a model organism in this line of research, in our lab and by many others. In term of brain regions and peptides involved in regulating behaviours, the rat is well understood and is comparable to the relevant systems in humans. Using rats lets us avoid repetition of earlier work, builds on current knowledge, and allows direct comparisons of our studies with others.

Typically, what will be done to an animal used in your project?

Some rats will be used for breeding purposes only. Some of the experiments proposed in this study require surgery, for delivery of drugs to specific brain regions and measurements of peptide release. For these experiments, pain will be controlled during surgery by general anaesthesia and pre- and post-surgery by analgesics. The highest severity rating of this programme of work will be moderate but the majority of experiments will have a mild rating. A significant proportion of our experiments will be done under anaesthesia and take no more than a few hours (max 6 hours for long single cell recordings)

What are the expected impacts and/or adverse effects for the animals during your project?

Expected impacts will include appropriately managed post-operative pain in the case of recovery procedures. Transient stress in the case of some behavioural experiments, short lasting sickness in the case of osmotic studies and some weight loss in the case of some dietary restricting experiments. Deaths resulting from anaesthesia or surgical complications are uncommon (<1%) and will be minimised by rigorous training, correct dosing of anaesthetics, by accurate weighing and maintenance of body temperature during and post-surgery. Risk of infection will be minimised by aseptic techniques. At the end of each protocol, animals will be killed by using approved humane methods and tissues from these animals may be used for post hoc histology. All rats will be monitored closely by experienced staff during the protocols and humanely killed at the end of each experiment, or in the unlikely situation that they present with clinical signs of illness.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately 40% of animals will be used for establishment and maintenance in genetically altered animal breeding programmes or for production of genetically altered rats. These animals will fall will into a subthreshold limit of severity. Of the remainder, approximately half of animals will experience degrees of suffering that fall within a mild severity category, the other half into the moderate category.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this programme of research is to understand how individual and networks of neurons in the brain produce behaviour. To truly understand how the brain processes information, it is imperative that experiments are done at the level of the whole animal. For this reason, it is impossible to avoid the use of animals when addressing the aims of the outlined proposal. However, large amounts of work will be done on in vitro preparations.

Which non-animal alternatives did you consider for use in this project?

There is on-going work in the laboratory using computer models of single neurons. Neuronal models will be used to generate predictions and testable hypotheses based on existing biological data. The use of simple analytical approaches and complex computer models provides a useful method for exploring possible outcomes that can then be tested in rats.

Why were they not suitable?

These approaches are unlikely to replace the need for suitable animal models in which to generate new physiological data. They can however be used to predict hypotheses and design experiments.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals has been estimated based on experience gained under my previous Home Office license. In this regard, the work plan and nature of experiments covered by this project are similar in design to those covered under my previous license. Hence, I have based estimates on average yearly animal use per group member returned under my current license.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For all of our experiments in-bred rats are used to reduce inter-individual differences. We also generally use a randomized block design for experiments to further reduce factors that could cause differences between animals that are unrelated to factors being tested in experiments (e.g. cage to cage variation). By reducing natural differences between animals in this way, we reduce the number of animals needed to identify differences caused our experimental test. In cases where we cannot use randomized blocking to reduce cage effects, we will still ensure that animals are littermate-controlled to reduce variations that can arise between litters. Our experiments are also designed to reduce the number of variables to as few as possible and thereby reduce the number of control groups required. In this respect, we will always consider carefully whether it is important to include ‘naïve’ as well as ‘vehicle’ control groups in experiments, or if the latter alone is sufficient for interpretation of results.

To ensure best practice in statistical analysis and experimental design all new staff members working under this license will attend the in-house ‘Experimental Design Course’. Planned experiments are discussed regularly within group meetings to ensure all are correctly controlled and to facilitate sharing of tissues/data for the most effective use of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

My group routinely perform pilot experiments to determine sample sizes required by power calculations. We standardly base power calculations on the ability to detect at least a 2-fold difference between groups, which we regard as an acceptable cut-off for identifying important biological effects with the benefit of reducing the group sizes required. Experiments are then performed on a minimum of

two separate occasions to ensure reproducibility, following which meta-analysis of data from pooled experiments is used to reveal less pronounced effects but without increasing overall animal use.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Rats will be used. They are the lowest mammalian group in which neuroendocrine systems are well characterised. We will build on our basis of knowledge and experience in the field, using appropriate and sophisticated techniques to study neuroendocrine neurones in these species. Previous data on which this application is based were also obtained from this species. Experience and the wealth of published literature in these animals has informed and will continue to inform the best use of techniques and choices of experimental approaches that are optimal for minimising potential adverse effects.

Why can’t you use animals that are less sentient?

Adult rats will be used. They are the lowest mammalian group in which neuroendocrine systems are well characterised. Recovery surgical procedures, behavioural testing and conscious animal experiments cannot always be replaced by alternatives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The department that manages the University’s animal facilities includes a team of dedicated veterinarians that are continually seeking to improve animal welfare and refine animal use. My group will consult closely with them and take full advantage of the extensive resources provided by them to ensure we are following current best practices. These resources include comprehensive guidelines and standard operating procedures for most common rodent procedures. The University is also in the process of adopting the improved rodent handling methods that reduce animal stress (detailed by Hurst et al. Nat Methods 2010) and now provide environment enrichment as standard. Singly housed rats will be housed in clear open topped cages to allow visual and olfactory contact with their neighbours. In experiments that require handling of the conscious rats the animals will be habituated to the experimenter in order to reduce stress. My group will adopt these methods alongside the animal facility staff. Anaesthesia and analgesia will be provided where suitable. To reduce infection risk, the best aseptic technique will be used during surgery (e.g. sterilization of instruments between animals, full surgical drapes). We will also routinely consult the NC3R’s website (nc3rs.org.uk) and take full advantage of the annual 3R’s seminar day organized by the University’s Animal Welfare Committee to find out about pioneering developments in best practice and methods to improve animal welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Our institute employs a dedicated team of veterinarians that are continually seeking to improve animal welfare and refine animal use. My group consults closely with this team and takes full advantage of the extensive resources provided on their website to ensure we are following current best practices. These resources include comprehensive guidelines and standard operating procedures for most common rodent procedures. We have also consulted the NC3Rs research strategy paper by Prescott MJ, Lidster K (2017). We also regularly review the scientific literature in the field to keep abreast of current best practice in experimental design and approaches.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Our institute employs a team of dedicated veterinarians that are continually seeking to improve animal welfare and refine animal use. My group consult closely with this team and take full advantage of the extensive resources provided on their website to ensure we are following current best practices. These resources include comprehensive guidelines and standard operating procedures for most common rodent procedures that are continually being updated. Our university is also in the process of adopting the improved rodent handling methods that reduce animal stress (detailed by Hurst et al. Nat Methods 2010) and our animal facilities now provide environment enrichment as standard. My group will adopt these methods alongside the staff in our animal facilities. We will also take full advantage of the annual 3R’s seminar day organized by the University’s Animal Welfare Committee to find out about pioneering developments in best practice.

NON-TECHNICAL SUMMARY

195. Therapeutic targeting of C-reactive protein

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

C-reactive protein, drug discovery, inflammation, tissue damage

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Development of new drugs to target the adverse, tissue damaging effects of C reactive protein (CRP).

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our laboratory was the first to show that human CRP exacerbates tissue damage after ischaemic necrosis in heart attacks and strokes and to validate CRP as a therapeutic target in these diseases. We have also highlighted the role of CRP in pathogenesis of a wide variety of other tissue damaging conditions, including trauma, infection, immunoinflammatory diseases and cancer cachexia. CRP contributes to disease severity in influenza and other human respiratory virus infections, including the current Covid-19 pandemic. We have invented a family of CRP inhibitor compounds, the drug candidate from which is now in accelerated development towards first in human testing and the earliest possible clinical efficacy studies in patients with Covid-19. The work for which the present licence is sought is critical for uninterrupted development of this potential medicine, which should reduce morbidity and mortality from Covid-19.

What outputs do you think you will see at the end of this project?

We will have identified one or more CRP inhibitor compounds suitable for investment of the tens or hundreds of millions of pounds required to develop them into licensed medicines for use in patients to treat unmet medical needs. After ensuring the robust patent protection that is essential for creation of any new medicine, we will certainly report our findings in high impact peer reviewed scientific and medical journals.

Who or what will benefit from these outputs, and how?

We confidently expect that within the duration of this licence, one or more CRP inhibitor compounds will have progressed through the development process to become licensed medicine(s) being used for patient benefit. As previously noted in this application, the diseases for which there will be potential benefit include infections, inflammatory diseases, trauma and cancer.

The obvious proviso is that there is never a guarantee of drug development success. Candidates can fail at any stage in the process, either through adverse effects or lack of efficacy. Although the supportive evidence is overwhelmingly strong, the only robust test of our underlying hypothesis about the pathogenicity of human CRP will be the demonstration of efficacy of CRP inhibition in human clinical practice. Progression of drug development to enable such a demonstration depends on the work for which the present licence is sought.

How will you look to maximise the outputs of this work?

We are already supported by a consortium of UK universities and major international pharma companies, whose purpose is to develop new medicines from the inventions and discoveries made in its constituent universities. They will energetically ensure that an effective compound from our work is licensed to the optimal pharma company for progression through to medicine licensing and commercial production. In addition, we are in direct discussions with a number of suitable major international pharma companies, in order to have alternative commercialisation opportunities. As soon as patent applications have been filed on our new inventions, the work will be as widely reported as possible in scientific and medical media, as well as in clinical educational literature of all types, so that clinicians are promptly made aware of this novel, and we hope significant, new therapeutic intervention.

Species and numbers of animals expected to be used

- Mice: 350

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Adult mice are ideal for the present project because well developed and thoroughly characterised models exist for all of the pathological process and diseases to be studied, closely resembling their human counterparts.
Typically, what will be done to an animal used in your project?

Most animals used in this project will be injected with substances and/or receive subcutaneous osmotic pump implants. Most inflammation experiments will be completed in 2-3 days and none will last longer than 7 days. Most PK/PD studies will also last only 2-3 days and none will exceed 28 days.
What are the expected impacts and/or adverse effects for the animals during your project?

There will be some local soreness/irritation of the skin around the wound following the osmotic pumps implantation, with discomfort for 2-7 days post operatively. Dehiscence, weight loss and post-surgical infection, can occur, but are uncommon (<5% of animals).

The Shwartzman reaction, which occurs in response to LPS injection, is expected to be accompanied by discomfort, which may be recognised by scratching or licking of the injection site. The 24 hour interval after LPS injection is required to allow consistent development of the Shwartzman reaction, while minimising the duration.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

For the whole project we expect that about 70% of the animals will be in the mild severity category and about 30% in the moderate category.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The initiation, development and evolution of pathology causing clinical diseases in living organisms are extremely complex. Similarly the mode of action and efficacy of disease modifying therapeutic interventions are also very complex, as are the PK and PD of all therapeutic agents, including those to be studied here. There is

no alternative to use of living animals to achieve the level of knowledge and understanding of these processes which is necessary for the new approaches to treatment which we have invented to be taken into clinical testing in humans.

Which non-animal alternatives did you consider for use in this project?

No existing or conceivable in vitro studies can possibly provide the necessary information and in vivo animal testing will in any case be a legal and regulatory requirement for drug development. Only candidates tested in vitro and bound with greatest affinity by the human CRP target will be tested in vivo.

Why were they not suitable?

See above.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use only the standard experimental protocols with which we have extensive experience that we have established to provide robust, statistically rigorous results. We expect to undertake approximately 10-15 studies using 20-30 mice in each

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental design replicates precisely the protocols we have been using for these and similar studies over the past 50 years under the Project Licences held by my predecessor and then myself.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We decided to use wild-type C57BL/6 mice in this project in order to keep the number of animals as low as possible. We won't have to breed a colony of GA animals and only use some of them as we did in previous studies.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice are ideal for the present project because well developed and thoroughly characterised models exist for all of the pathological process and diseases to be studied, closely resembling their human counterparts. In the case of the Shwartzman reaction, some dermal inflammation is necessary to obtain the desired result of

demonstration its reduction. Our model, with killing of the mice as soon as possible, involves the minimal possible pathology consistent with this requirement.

Why can't you use animals that are less sentient?

Humans are warm blooded (endothermic) and are very different from cold blooded (exothermic) animals. All aspects of human organ, systems and whole body physiology and pathophysiology are markedly different from those of fish, amphibians and non-protected species. Thus, although proteins homologous to human CRP exist in many species, the acute phase response of plasma proteins, which is a key feature of the endothermic animal response to injury, infection and inflammation and which underlies the pathogenicity of human CRP, does not exist in exothermic animals. In contrast, many relevant aspects of murine and human physiology and pathophysiology, specifically including those related to C-reactive protein, are very similar. There is also a substantial body of relevant knowledge in the mouse, to which we have previously made the most substantial contributions. The mouse is therefore the only species suitable for our required studies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

If we can elicit a less intense inflammatory response in the Shwartzman reaction and still get the output we need to generate sufficient data, we will try to do so. Monitoring, post-operative care and pain management will always be part of our priorities.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will always try to follow the guidelines issued by LASA and NC3Rs when possible.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

NC3Rs resources (website, publications...).

Home Office

NON-TECHNICAL SUMMARY

196. Therapies to Protect and Regenerate the Newborn Brain following Perinatal Injury

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

neonatal encephalopathy, neuroprotection, therapeutic hypothermia, birth asphyxia, inflammation sensitisation

Animal types	Life stages
Pigs	neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this project is to reduce death and disability in newborn babies who have complications around the time of birth. These complications include lack of oxygen, infection/inflammation or a combination of the two and lead to an abnormal conscious state and problems with breathing called **neonatal encephalopathy (NE).**
Therapeutic hypothermia (HT) or cooling is a partially effective treatment but despite its widespread introduction in high income settings, disability rates remain unacceptably high. However, HT is not routinely given in all settings in low and middle income countries.
The project aims to study therapies given after birth that can reduce brain injury in NE and stimulate regeneration and repair with and without cooling.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

NE is an important cause of death and disability, affecting 1-3/1000 births in the UK and 10-25/1000 births in Sub-Saharan Africa. With current practice of therapeutic hypothermia (HT), mortality of NE has reduced from 25% to 9% and disability from 20% to around 16% with a reduction in the rate of cerebral palsy. However, not all children benefit from treatment and intellectual impairment may remain even in the absence of cerebral palsy. The events which follow a period of lack of oxygen around the time of birth are complex and involve changes in blood flow, tissue oxygen levels, abnormal brain transmitters, different types of cell death and inflammation. Optimizing neuroprotection of the new-born requires the use of living models to take into account the influence of other organs, circulating factors and changes in brain perfusion. We are not aware of any alternative that does not use animals that would allow us to achieve this aim.

What outputs do you think you will see at the end of this project?

These studies will provide advancement in the understanding of the beneficial effects of different therapies for babies following a complicated birth with lack of oxygen.
The outputs will be captured on the MRC Research fish site.

- We will seek to engage the public by working closely with relevant Media Relations to publicise our research findings via open-access journals, media interviews, press conferences and releases. As is currently happening with HT, talks would be given at meetings organised by charities such as Bliss, Wellbeing of Women (who supported the original pre-clinical study of melatonin-augmented cooling) and Action Medical Research, at which parent representatives attend. We work with parents of babies with neonatal encephalopathy, and with the Neonatologists treating those babies, in raising the awareness and acceptability of new therapies for brain protection and of clinical neuroprotection trials.

- Professional presentation and publication in high impact journals will enhance the impact of our research and patient benefit on national and international stages. We will use open access publishing for key outcomes to ensure wide dissemination of results.

Who or what will benefit from these outputs, and how?

The information will benefit all disciplines of medicine, including

1. Neonatologists focused on neuroprotection of the term newborn infant in high and low income settings

2. Neonatologists focused on neuroprotection of the preterm infant in high and low income settings 3.

Obstetricians managing fetal distress

4. Paediatricians focused on neuroprotection, for example paediatric intensive care specialists treating HI-reperfusion injuries (e.g. traumatic brain injury and cardiac surgery) in high and low income settings
5. Adult medical specialities treating HI-reperfusion injuries e.g. stroke, myocardial infarction, trauma. HT is already used in out of hospital cardiac arrest and these data will have relevance for single or adjunct therapy
6. Clinicians wishing to conduct clinical trials in babies using outcome bioamarkers (MRS and blood biomarkers)

7. Army doctors and those wishing to protect the brain after injury in the field.

The economy and society will benefit from these studies. NE is the 4th leading cause of death in children and accounts for 50 million disability life adjusted years worldwide. These studies have the potential to reduce suffering from life-long neurologic disabilities and to significantly reduce the societal costs of caring for survivors with neonatal brain injury. The lifetime costs of caring for an individual with cerebral palsy (CP) is estimated at $1.15 million. Using a conservative estimate of 20% CP rates in NE infants treated with therapeutic hypothermia (HT) and conservative estimate of NE incidence of 2/1000 in high resource settings, the economic burden in the US would be $1.7 billion in lifetime costs (similar pro-rata costs in the UK). NE is also estimated to produces additional lifetime costs of $1.6 billion for intellectual disability from NE. HT has been shown to reduce the burden of these costs. If these therapies augment cooling, these costs will be reduced further.

How will you look to maximise the outputs of this work?

Dissemination of New Knowledge

Confirmation of the safety and efficacy therapies with and without hypothermia, in males and females will provide a rich source of information for future clinical trials in babies at risk of brain injury after a complicated birth. We will set up a Brain Protection website as a focus for parents looking for information and support on NE, including treatments. We will increase traffic through this route by marketing the site in social media settings and leading parents in need of support either through the Bliss Parent-line or to seek local professional help. We use the Science Media Centre as a professional support environment for developing media friendly messages and act as expert opinion where required. Press releases for important papers helps raise both public and professional profile of the study. We will work with a range of national and local charitable organizations via lectures, hospital visits and event support. We plan to hold two meetings throughout the project (evening meetings with a councillor and refreshments) to showcase the potential benefit of therapies, whilst maintaining discretion about the translational nature of our work. Feedback and opinion on the acceptability of our studies from parents are vital to the success of future clinical trials.

Collaboration

Our findings could change the trajectory of perinatal neuroprotection both in the UK and worldwide. Our team works closely with an international cohort of Neonatologists and Perinatal Neuroscientists in developing standards of care for perinatal neuroprotection. This work will inform an urgent review of those standards, including an update to the UK NICE Cooling guidance (last updated 2010).

Species and numbers of animals expected to be used

- Pigs: 1250 piglets

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The neonatal piglet has significant strengths compared to the rodent for neonatal neuroprotection research: the size allows for the same intravenous lines and catheters to be used as in babies, the medications are based on NICU protocols and the maturational stage with a brain growth spurt around the time of birth is similar to human brain.

Typically, what will be done to an animal used in your project?

The animal is sedated and transported to the designated facility. The animal is given an inhaled anesthetic and remains insentient throughout the study.

1. A breathing tube is inserted down the windpipe and the animal's breathing performed by the neonatal ventilator throughout the study.
2. Catheters with remotely operated balloons are gently placed round the carotid arteries that supply the brain.
3. Central lines (for infusing fluids and sampling blood non-invasively) are inserted through the umbilical cord.
4. A short period of reduced oxygen and blood supply is induced after surgery and stabilization
5. An injection of lipopolysacchride may be given before the period of lack of oxygen in some piglets
6. The studies will typically last 72h (in some cases where we are assessing seizures, we will perform shorter studies of 12-36h)

What are the expected impacts and/or adverse effects for the animals during your project?

Expected adverse effects and likely incidence

General anaesthesia will be maintained and hence the animal will be insentient throughout the entire procedure. If any unforeseen complications with anaesthesia or monitoring occur that cannot be rectified the animal will be terminated.

How the adverse effect will be recognised

Complications with the anaesthesia will be recognised by changes in the heart rate and movement of the piglet.

Refinement control measures

We have an isoflurane meter installed so that we can see immediately the isoflurane concentration delivered to the piglet and can rectify any problem with isoflurance delivery immediately. Humane end-

points and limits of severity

With any unforeseen complications that cannot be rectified, the animal will be terminated.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The severity classification is AC - unclassified code. All studies are terminal.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Optimising neuroprotection of the newborn requires the use of in vivo rather than in vitro models to take into account the influence of other organs, circulating factors and changes in cerebral perfusion.

Which non-animal alternatives did you consider for use in this project?

We are not aware of any alternative that does not use animals that would allow us to assess the safety and efficacy of therapies for birth asphyxia. A model is needed in which meticulous intensive care and temperature control can be maintained.

Why were they not suitable?

Mathematical modelling could not replace the use of experimental animals. The body of knowledge about therapies and combinations of drugs is not sufficient to allow for a clinical trial in human infants without these pre-clinical studies in the piglet providing important, safety, dosing and efficacy data.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We use the minimal number of animals in each group to be able to show a biologically important neuroprotective effect in our pre-defined primary outcome measures. The group size is based on the data variability in previous studies. The proposed experimental designs and methods of analysis have been discussed with our statistics

department and other biomedical statisticians. The outcome measures (aEEG and brain lactate/NAA biomarkers and immunohistochemistry) are quantitative and random effects regression is an appropriate statistical analysis for this. To reduce the effect of the insult severity and thus reduce group size, we include the insult severity index in the analysis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We are aware of the NC3R's Experimental Design Assistant and work within this framework. Studies adhere to the ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines.
The potential sources of bias in the study (for example time of day or season of the year) have been addressed Developing the model further will include both male and female animals. Cell death pathways differ between sexes. We will use the minimal number of animals to ensure we can detect a sex difference in response to therapies.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We use pilot studies to ensure optimal dose and therapeutic levels are known before starting the randomized studies of safety and efficacy. This ensures that wastage and negative studies are avoided due to sub therapeutic drug levels.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use the neonatal piglet with transient hypoxia ischemia and various neuroprotective interventions in this project. The piglet is insentient throughout the study.

Why can’t you use animals that are less sentient?

While a rodent model is typically the first step in testing a
potential neuroprotective treatment, confirmation in a larger animal model provides critical complementary safety and efficacy data to justify applying for the regulatory approvals necessary for clinical trials. The similarity of anatomy, size and maturation of the piglet brain to the human infant allows for regional histopathology and vulnerability of the brain to be assessed. The model allows for meticulous neonatal intensive care support for up to 72h, enabling metabolic and temperature homeostasis to be maintained during this time. This ensures that the model provides data that is relevant to the human neonate who would be cared for with similar intensive care support. The model allows for brain magnetic resonance imaging and spectroscopy studies to be acquired at 30 and 66h; these data are similar to those acquired in babies and therefore adds to the model’s clinical translational relevance.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will continue to monitor the piglets closely throughout the studies, ensuring adequate sedation and anesthesia at all times. The new laboratory will allow for more collaboration with vets and this will refine the model further. Complications with the anaesthesia will be recognised by changes in the heart rate and movement of the piglet. We have an isoflurane meter installed so that we can monitor the isoflurane concentration delivered to the piglet and can rectify any problem with isoflurance delivery immediately.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere closely to the ARRIVE guidelines (www.ARRIVEguidelines.com) from the National Centre for the Replacement, Refinement & Reduction of Animals in Research (NC3Rs).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will circulate the ARRIVE (https://arriveguidelines.org) and PREPARE guidelines (https://pubmed.ncbi.nlm.nih.gov/28771074/) to the research team and ensure the team are aware and can talk through these guidelines. We will include the NC3Rs as an item on the Agenda at each monthly lab meeting. As we start up a new laboratory, the closer collaboration with vets will refine the model.

Home Office

NON-TECHNICAL SUMMARY

197. Tissue-level control of stem cell identity

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Embryo, Stem Cells, Tissues, Regeneration, Pregnancy loss

Animal types	Life stages
Mice	adult, embryo, pregnant, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to understand how the 3D organisation of a tissue affects stem cell identity and fate during embryonic development and tissue regeneration.

Potential benefits likely to derive from the project, for example how science might be advanced or how

humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

During the development of an embryo and the maintenance of healthy tissues, stem cells are subjected to a number of external factors that can change their identity and fate. An important aspect of how stem cells decide their fate is the immediate environment in the tissue in which they reside, in other words, their spatial three-dimensional neighbourhood. We still know very little about how this process happens. Understanding how stem cells respond to these external spatial cues and decide which cell type to become is important for embryo development and tissue regeneration. During the formation and growth of an embryo, dramatic changes in the shape of the embryo are tightly coordinated with the specialisation of stem cells to form different mature cell types. Alterations in this process lead to pregnancy loss, and therefore studying how embryo shape affects stem cell fate will allow us to explore the potential reasons behind failed embryo development, and potentially to devise strategies to correct it. Similarly, during adult regeneration, stem cells play a critical role to replace damaged tissues.
Studying how external spatial cues affect adult stem cell fate would allow us to devise new protocols for stem cell differentiation, and potentially to develop new strategies to promote tissue repair.

What outputs do you think you will see at the end of this project?

- We will publish our findings in high impact journals

- We will determine how the organisation of embryonic stem cells into an epithelial tissue influences their ability to form the cell types of the mature organism

- We will describe how the formation of specialised regions within a cell determines their fate during development.

- We will analyse whether the organisation of a tissue influences the plasticity of adult stem cells, in other words, their ability to become a different cell type.

Who or what will benefit from these outputs, and how?

The proposed research would contribute to academic progress within and beyond the relevant disciplines:
- Throughout the project: embryonic stem cells are mainly studied in 2D cultures that do not mimic the organisation of tissues in the embryo. The proposed research will clarify how the 3D organisation of the embryo changes stem cell fate decisions. Therefore, the findings will benefit stem cell and developmental biologists. Similarly, the mechanisms that change the identity (reprogram) of an adult cell to an embryonic state have been mainly studied in 2D cultures. The use of 3D *in vitro* models of an organ to study reprogramming represents a novel approach of relevance for the stem cell field.

- Long-term: the proposed research has the potential to impact other disciplines such as human reproduction, regenerative medicine, and cancer biology.

Human embryos are prone to failure during the first weeks of development, but why this happens remains unknown. Understanding how cells commit to a specific fate during physiological conditions is the first requirement to characterise what goes wrong in situations of pregnancy loss.
In terms of regenerative medicine, the knowledge generated during the course of this project has the potential to help us design better protocols and strategies for the *in vitro* generation of tissues for regeneration. *In vivo* reprogramming has been recently proposed as a novel tool to improve aging and induce regeneration. However,

the same strategy may lead to tumour formation. Therefore, understanding how tissue shape affects stem cells may have a direct impact on the development of novel regenerative approaches.
One of the hallmarks of tumour formation is loss of tissue shape. Therefore, understanding how tissue shape changes cell identity will be potentially relevant for the study of cell fate in the context of cancer. **How will you look to maximise the outputs of this work?**

- Generation of tools: genetically modified stem cells generated during the course of this project will be made freely available to academic researchers.

- Dissemination of new knowledge: we will present the results of this project in relevant local, national and international meetings devoted to stem cell biology, organoids, and embryo development. The findings of the research will also be published in high impact journals in accordance with open access policies. Sequencing data will be deposited in appropriate public data repositories.

- Public engagement: we plan to present at events such as the Stem Cell Club, Pint of Science, and Science Week. With the help of a team dedicated to news and public engagement, we will promote our research through the use of social media and news processes.

Species and numbers of animals expected to be used

- Mice: 4,100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse is an ideal model system to study pluripotency - the capability to generate all the cell types in the organism - and embryo development. There are a number of critical tools that are well established in the mouse and allow us to study gene function in a physiological context (e.g. generation of mouse embryonic stem cells - mouse embryo chimeras). Moreover, there is a mouse model already available that allow us to explore the consequences of reverting adult cells back to an embryonic pluripotent state. Since we are interested in pluripotent stem cells during development and regeneration, we will use embryos, pregnant females and adult mice.

Typically, what will be done to an animal used in your project?

Approximately half of the mice used in this project will not undergo any intervention. They will be used for breeding or collection of tissues for *in vitro* experiments.
Approximately half of the mice will undergo an experimental procedure. In most of the cases this will be an injection. We will inject hormones to increase the number of embryos that can be collected from a single female,

and we will inject stem cells to test their ability to form embryonic tumours called teratomas.
To study the development of embryos beyond implantation we will transfer embryos to pseudo-pregnant female mice. This will involve surgical procedures - vasectomy of males and embryo transfers to females. Mice are expected to make a full recovery.
Lastly, we will treat mice with specific compounds, administered orally or via injection, to trigger the expression of specific genes of interest (e.g. pluripotency genes). Expression of these genes will lead to the formation of embryonic tumours.

What are the expected impacts and/or adverse effects for the animals during your project?

Half of the mice used in this project will not experience any pain, discomfort or lasting harm.
Female mice used for superovulation will only experience mild discomfort and will recover fully from the procedure.
Females used for surgical embryo transfers and vasectomised males will experience moderate postoperative pain and discomfort. They are expected to make a full and uneventful recovery.
Mice injected with pluripotent stem cells will develop teratomas in 95-100% of cases. This typically takes around 6-8 weeks. Similarly, mice in which pluripotent genes are induced will develop embryonic tumours in approximately 80% of cases. The formation of embryonic tumours and weight loss will be carefully monitored. Weight loss represents a good indication of the health status of a mouse, and therefore mice will not be allowed to lose more than 10% of their body weight (mild severity). Mice will be sacrificed before tumours are bigger than 1.2 cm, if there are any signs of anaemia, or if there is any deviation from normal behaviour.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Half of the mice used in this project will not experience any pain, discomfort or lasting harm.
Females used for superovulation will only experience mild discomfort following the injection.
Females used for surgical embryo transfers and vasectomised males will experience moderate postoperative pain.
80-95% of mice injected with stem cells and mice in which pluripotent factors are expressed will develop teratomas (mild severity).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of this project is to understand how the 3D organisation of a tissue regulates stem cell identity and fate during embryonic development and tissue regeneration. The mouse is the ideal model system to achieve this goal because:
- Early developmental processes are similar in mouse and human embryos.

- Mice have short breeding times, consistent with the realistic timeframe of the experiments.

- There are excellent tools available to study molecular mechanisms and manipulate gene expression.

Having said this, we will use alternative *in vitro* models in most of our experiments. Stem cells can be cultured *in vitro* using 3D techniques to mimic the structure of tissues, organs and embryos. These are ideal model systems to discover molecular mechanisms. We will use mice to obtain primary tissues for our *in vitro* experiments, and to validate our *in vitro* findings in a physiological *in vivo* setting.

Which non-animal alternatives did you consider for use in this project?

We will complement our studies using human organoids and human embryos.

Why were they not suitable?

We cannot rely solely on the use of human embryos (to study development) and human organoids (to study regeneration) to achieve our goal.
Human embryos are difficult to obtain and there are numerous technical and ethical limitations to perform genetic manipulations.
The availability of genetically modified mice allows us to readily obtain genetically modified organoids. This is more challenging when working with human organoids, as the genetic modifications need to be introduced de novo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

- Protocol 1: the number of females needed has been estimated based on our previous experience. We have taken into consideration that: 80% of females treated with hormones (to increase the number of eggs they produce) and mated with a male will become pregnant; from a pregnant female we expect to have an average of 25 embryos; 95% of the recovered embryos will successfully develop *in vitro*. This means that from 2,000 females, 1,600 will be pregnant, and therefore we will obtain 38,000 well developed embryos.

These embryos will be manipulated *in vitro* to generate either chimeras (embryos in which stem cells are injected to study their behaviour) or enlarged embryos (embryos with an increased number of cells), and transferred to females to allow embryo implantation into the uterus and subsequent development. A typical embryo transfer experiment with two groups (control, experimental and rescue) requires approximately 90 embryos (15 embryos per recipient, two recipients per group). Taking into consideration each experiment will be repeated 4 times and 10% of the embryos may not be chimeric we estimate that we will need a total of 20,000 embryos which could potentially allow us to analyse the phenotype of 50 genetic modifications. For size regulation experiments we estimate that we will need 18,000 embryos. This will allow us to generate 6,000 single and enlarged (double-sized) embryos and to explore the function of approximately 20 genes (four conditions -control single, control double, mutant single and mutant double-).
- Protocols 3 and 4: based on the above-mentioned numbers we will need approximately 700 recipients and 50 vasectomised males for the embryo transfers.

- Protocol 5: approximately half of the mice under this protocol will be used to generate new genetically modified animals (by either creating new mutations or by combining multiple alleles to generate a new line), and half will be used in protocols 1 and 7.

- Protocol 6: we plan to use 50 immunocompromised mice to assess formation of embryonic tumours. This will allow us to test the pluripotent status of 10 different stem cell lines.

- Protocol 7: we estimate we will use 300 mice based on previous literature results. The exact number of mice per condition and group will be estimated using POWER statistics based on the proposed *in vitro* experiments.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have taken into consideration the different variables that affect embryo yield. We have estimated the number of mice needed in each protocol based on our previous experience working with embryos and published reports. We will use our proposed *in vitro* experiments to perform POWER calculations and predefine sample size in the different experimental groups before performing the experiments. We have sufficient in-house statistical knowledge to be able to plan the experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

For conventional breedings we will regularly monitor breeding efficiency. We will cryopreserve our strains to maintain only the colonies that are needed at the different stages of the project, rather than perpetuating the strain throughout the course of the project. We will follow the Home Office guidelines for efficient breeding of animals.

To study the consequences of specific genetic modifications for embryo development we will follow a chimera approach (stem cells are injected into embryos to study their behaviour). This will allow us to analyse the genetically modified chimeras at the desired embryonic stage, without generating genetically modified animals. Our experimental approach is based on the use of the 3D *in vitro* models as a tool to screen for phenotypes of interest, and only using the mouse as an *in vivo* model for physiological validation. This greatly decreases the number of animals used for research.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use mice as our model system to understand how tissue shape controls stem cell fate. Half of the mice in this project will be used to obtain primary tissue for *in vitro* culture or to generate genetically modified animals, and they will not experience pain, suffering, distress or lasting harm.

When adult cells revert back to an embryonic stage, they give rise to embryonic tumours. We will minimise the suffering caused by the formation of embryonic tumours by restricting our analyses to the initial phases of tumour formation.
Embryonic tumours will be induced by injecting pluripotent stem cells subcutaneously. This is an alternative to the injection of stem cells into the kidney capsule, which involves a surgical procedure. We will therefore avoid surgical procedures.

Why can’t you use animals that are less sentient?

The majority of the animals used for our experiments will be at embryonic stages. This means that the specific mutations in the genes of interest will only affect the embryos, not the adults. Therefore, we minimise the number of adults born with potentially detrimental mutations.
An exception is the use of adult mice to study reprogramming to pluripotency. To understand how adult cells become reprogrammed to a pluripotent state in the physiological context of the tissue we need to use adults. Mice are the ideal model system as the genetic tools to study pluripotency *in vivo* are already available. We will minimise suffering by first performing experiments in organoids (*in vitro* models of an organ), *an*d only inducing pluripotent gene expression in adult mice for validation of the *in vitro* findings.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will induce genetic modifications only the tissue of interest and during a specific time frame. This will allow us to restrict potential harmful phenotypes in space (tissue of interest) and time (stage of interest).
Pain caused by surgery will be managed with analgesics.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult the 3Rs website to ensure that we are following the most refined procedures.
We will follow the ARRIVE guidelines when performing and reporting animal experiments.
We will follow P. Workman et al, British Journal of Cancer, 2010 "Guidelines for the welfare and use of animals in cancer research" in experiments that lead to tumour formation.
We will follow K.H. Diehl et al, Journal of Applied Toxicology, 2001 "A good practice guide to the administration of substances and removal of blood, including routes and volumes" when substances are administered.
We will follow Home Office efficient breeding of animals guidelines:
https://assets.publishing.service.gov.uk/government/uploads/system/uploads/attachment_data/file/773553/GAA_Framework_Oct_18.pdf

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Throughout the course of this project we will stay informed about advances in the 3Rs. Our named information officer provides us with up to date information on 3Rs research and training opportunities. We will also maintain a close interaction with animal technicians. They attend multiple meetings and courses, and thus represent an invaluable source of information. In addition, given their experience and expertise on animal research they are uniquely poised to identify ways of improving the welfare of animals. The implementation of any welfare advances will be done with the help and support of the veterinarian and animal care staff.

Home Office

NON-TECHNICAL SUMMARY

198. To Investigate Switching Genes Off and On In Haemopoiesis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Thalassemia, Haemoglobin, Genome organisation, Genomics

Animal types	Life stages
Mice	adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The human genome contains ~20,000 genes, which code for the proteins that constitute the cells that comprise our bodies. Only a subset of the full set of genes are active in any given cell type. For example, the genes coding for the keratin protein in human hair and nails or those coding for haemoglobin in red blood cells are present in every cell, yet normally only active in their appropriate cell type. Abnormal expression of genes in inappropriate cell types is a major cause of human genetic disease and cancers. Although the sequence of the human genome was deciphered in 2003, the mechanisms by which genes are appropriately activated and silenced are poorly understood. This project aims to understand the general principles of how genes are turned off and on in each cell type and developmental stage, how this goes wrong in human disease and how it may be corrected. The aims include determining how genes are activated, silenced and how chromosomal movements influence gene activity in health and disease. We will use the alpha-globin genes as a well characterised example to test hypotheses about gene regulation that will be widely applicable to many diseases.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The majority of human genetic and acquired disease arises from abnormal gene expression, with genes either becoming active when they should be silent or vice versa. Our current understanding of the mechanisms by which genes are expressed and repressed, and how this may be manipulated for therapeutic purposes, is rudimentary at best. The aim of this project is to establish a comprehensive model of how this fundamental process in cell biology and biomedicine occurs within its normal genetic environment (we seek to introduce only subtle genetic modifications so as not to confound our results). We anticipate this will continue to provide direct insight into the mechanisms underlying human disease.

What outputs do you think you will see at the end of this project?

The disorders of the globin genes comprise the commonest single genes disorders worldwide and are responsible for a huge burden of morbidity and mortality, these include diseases such as thalassaemia and sickle cell disease. Although their genetic basis is understood, there are still tens of thousands of cases requiring long term treatments which are still unsatisfactory. To improve treatments of both acquired and inherited disorders we need to understand more fully how these genes are normally regulated. The work to be carried out under the authority of this licence is aimed at using the knowledge obtained from our understanding of gene expression to modify human genetic diseases. Investigating the transcription factors, regulatory environment and epigenetic control of globin-gene expression will enable exact understanding of how globin-genes are activated in these cells. We will generate new information, which will be published in leading journals, detailing how the globin genes are regulated and how this may be manipulated for the benefit of human health. We will also generate regents including genome editing reagents and small molecules that will alter expression of the genes and form the basis of novel treatments for thalassemia and sickle cell disease.

Who or what will benefit from these outputs, and how?

In the short term our findings will allow biomedical scientists to better understand how genes are regulated and how they may be manipulated for the benefit of human health. In addition, our approaches may lead to better diagnosis for atypical forms of thalassemia. In the medium term the disease models we generate will facilitate drug discovery via small molecule screening in culture systems. In the longer term we anticipate that this knowledge will benefit a large number of patients with a disorder of haemoglobin and also a wider group of patients, with a range of disorders, who would benefit from interventions to modulate gene expression.

How will you look to maximise the outputs of this work?

We will disseminate our findings at scientific meetings and by publication in leading peer reviewed journals. Where appropriate we will approach commercial partners to develop novel therapies for the haemoglobinopathies.

Species and numbers of animals expected to be used

- Mice: 5000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Effects of disruption of a normal gene or its regulatory sequences may vary in early, middle or late development and also in different tissues. To study the interactions between different factors during different stages of development and in adulthood a whole animal model is needed. Although zebrafish and lower vertebrates may be appropriate model systems for studying many developmental processes, a mammalian model still remains necessary in order to fully understand the effects of many human genes and their disease-associated mutants and other complex physiological systems that only mammals share. Cell lines, differentiated mouse embryonic stem cells and human patient samples will used wherever possible but for much of this work mouse models will be essential.

Typically, what will be done to an animal used in your project?

Typically, mice will be bred and killed by a Schedule 1 method and material such as liver, spleen, bone marrow and peripheral blood will be collected for ex vivo culture and downstream analyses. Some mice may be mated and killed by a Schedule 1 method so that embryos at different developmental stages may be collected for analysis. In approximately 20% of mice, substances will be administered to induce erythropoiesis, to induce gene recombination and/or label cells prior to Schedule 1 killing and collection of biological samples and embryos.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority (we would expect >80%) of the mice in this project should not exceed the mild severity limit but adverse effects that arise occasionally in new GM mice are unpredictable. These effects may be as a result the genetic material introduced, its site of insertion or level of gene expression and although rare are unpredictable. Embryonic mortality may occur and there may be unpredictable effects caused by interference with expression of normal genes or inappropriate expression of the transgene.
New models will be closely inspected for harmful phenotypes, if these arise we will seek advice from the NACWO and /or vet.
In some cases, there will be embryonic lethality (before day 13.5) as a result of the loss of function of the gene of interest.
The administration of substances in this project to disrupt steady state haematopoiesis should only have temporary effects on blood production lineages with full recovery. Thus there should only be mild effects on the overall wellbeing of the animals with a temporary reduction in general activity.

Adverse effects as a result of induction for Cre recombinase are rare but will depend on the nature of the genetic modification and the dose of substance administered. Animals exhibiting any unexpected harmful phenotypes will be killed, or in the case of individual animals of particular scientific interest, advice will be sought from the local Home Office Inspector.
All animals in this project will be carefully inspected and monitored closely to ensure that they do not exceed the moderate severity limit.
Any animal showing a severity that is likely to exceed this level will be humanely killed unless it is of particular scientific interest in which case advice from the Home Office Inspector will be sought.
Ear notching should involve only slight and transient pain, and no healing problems.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

80% of mice would be expected to experience mild severity
20% of mice would be expected to experience moderate severity

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Effects of disruption of a normal gene or its regulatory sequences may vary in early, middle or late development or in maturity and also in different tissues. To study the interactions between different factors during different stages of development and in adulthood a whole animal model is needed. Although zebrafish and lower vertebrates may be appropriate model systems for studying many developmental processes, a mammalian model still remains necessary in order to fully understand the effects of many human genes and their disease-associated mutants and other complex physiological systems that only mammals share. Cell lines, differentiated mouse embryonic stem cells and human patient samples will used wherever possible but for much of this work mouse models will be essential.

Which non-animal alternatives did you consider for use in this project?

Where possible we will employ ex vivo culture of blood from patients and healthy individuals and immortalised human erythroid cells. We have also developed a system of obtaining erythroid cells by in vitro culture of pre-existing mouse ES cells in specific conditions, which has already replaced ~20 lines of mice in our laboratory. This would enable us to apply the in vitro culture system more widely within our institute and more broadly within the university and replace many further lines of mice and more broadly within the university and replace many further lines of mice.

Why were they not suitable?

The culture of human erythroblasts is limited by variation between individuals and the system is limited in only yielding erythroblasts from the pro-erythroblast stage onwards and these stages are limited in numbers. Also, this system cannot accurately recapitulate embryonic erythropoiesis, which we will need to study to achieve our aims.
The system of culturing mouse ES cells to become erythroblasts is extremely useful and we currently use this to test our models, however, this system offers relatively low numbers of cells, it is not possible to accurately stage the cells as they do not express characteristic cell surface markers and they also show an embryonic program of gene expression that does not mature into an adult programme. As stated above we are working to resolve these issues to allow this system to be expanded further.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

Based on the number of mice used in our expiring PPL and our planned experiments, taking into account our analysis pipelines and power calculations.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Improvements have been made in the experimental techniques used to analyse animal material in our projects, fewer and fewer cells can now be used to gain more information. The fetal liver culture system is now being used more widely and continual improvements are being made to expand the number of cells that can be used for downstream analysis.
Further optimisation of this system for particular project can be summarised as follows:

- Selection stem cells prior to culture results in a higher yield of progenitor cells and increases cell viability, reducing need to "pool" individual livers to obtain replicates and thus reducing animal use.

- A recovery step was added for progenitor cells before differentiation ex vivo. This results in more robust and reproducible differentiation. Reducing the need for replicates and therefore additional animals.

- Optimisation of ChIP-seq assays to work on 5x10^6 cells (originally 10x10^6), significantly reducing animal use by providing several technical replicates per biological replicate.

  We have also optimised a newly published method for mapping the locations of chromatin binding proteins and histone modifications genome-wide. Where we have previously relied on ChIP-seq, which required approximately 10 million cells per sample/time point, the new method (called CUT&RUN) requires only 100,000 cells and therefore allows us to carry out many more experiments from the same cellular material. This allows results in fewer mice being used.
  Through our collaboration with a commercial partner we are working to minimise the number of fetal liver cells required. Currently this stands at 50,000 cells per assay. This now means that a single fetal liver allows 140 compounds to be tested.
  We are constantly trying to improve experimental protocols to reduce the cell numbers (and therefore mice) that are required to give us the information we need.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Breeding colonies will be maintained at the lowest possible levels and any excess mice will be made available to other users.
Experimental procedures will be updated as appropriate and new technologies will be introduced as they develop to minimise mouse numbers.
We will analyse as many tissues as possible from each mouse.
We will only breed mice as required.
In order to minimise the effects of genetic drift we will only breed for up to ten generations before rederiving lines. Cryo-preservation will be by Sperm freezing wherever possible at an early stage in the breeding process. Embryo freezing will be used only when sperm freezing is not appropriate (e.g. homozygote lines). Any necessary rederivations will be performed by the in house core transgenic service.
All steps in every process will be carefully monitored to minimise numbers.
Experimental procedures will be updated as appropriate and new technologies will be introduced as they develop to minimise mouse numbers.
Blood and tissue samples will be shared across several groups working on this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse models with perturbations of the alpha-globin locus used to investigate gene expression are based on a locus that encodes a terminally regulated structural protein and as such disruption of expression does not

lead to cell fate changes or neoplasms minimising any suffering or distress caused to the mice. In addition, disruption of the locus is asymptomatic when in the heterozygous state and where possible heterozygous experimental animals will be used. Tagging of transcription factors will be checked by in vitro differentiation of mES cells to ensure it does not interfere with normal gene function before generating mouse lines.
In cases where the a protein degradation system is used to acutely deplete TFs, pregnant mothers will be protected from adverse effects of drug induction by paternal inheritance of the protein that effects the protein degradation. Acute depletion of transcription factors is preferable to creating constitutive knock-outs as these models often die early in development from adverse effects in non-erythroid tissues, potentially masking any scientifically informative erythroid phenotype.
We will use the least invasive methods to administer the substances described in this project. We will administer tamoxifen by oral gavage unless this does not yield sufficient recombination in a tissue of interest, in which case injection may be necessary. When administering substances to pregnant females for metabolic labelling we have previously used intraperitoneal injection to achieve the fastest possible delivery of substance to the embryos during the short delivery window (approximately 30m). To minimize the risk of inadvertent injection into the uterus, intraperitoneal injection of pregnant females will be carried out only by the most experienced PILs. The female will be positioned with her head down so that the abdominal contents move away from the injection site. The substances themselves are generally innocuous and are extremely unlikely to cause any distress to mice. In cases where induction of mild anaemia is unavoidable to allow analysis of gene expression this will be kept to a minimum, mice will be monitored and humane endpoints applied appropriately.

Why can’t you use animals that are less sentient?

Although zebrafish and lower vertebrates may be appropriate model systems for studying many developmental processes particularly at the early stages of research, a mammalian model still remains necessary in order to fully understand the effects of many human genes and their disease-associated mutants and other complex physiological systems that mammals share. Where possible we do use embryonic forms, however, for many experiments we need to analyse adult erythropoiesis in liver or spleen cells.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Wherever possible constructs and/or manipulated embryonic stem cells will be produced and tested in an in vitro system before going on to produce new GM lines.
We continue to have a high level of enrichment in our cages to promote natural behaviours and improve general welfare. All cages contain sizzle nest and polycarbonate tunnels as standard: singly housed stud males are given wooden chew toys to prevent boredom and our breeding pairs and pregnant females are also offered mouse smart houses and nestlets.
We continue to use tunnel and /or cupping as a means of handling of mice as promoted by the NCRs. In our experience these mice do get used to this very quickly and are much calmer and easier to handle. We would very much like to see this method being implemented on a wider scale wherever appropriate.
Use of our in vitro fetal liver culture system has increased as an alternative to drug treatment of adult mice in order to obtain haematopoietic cells for analysis. Where drug treatment is necessary we will use best practice with the single use needle procedure.

Where possible we add a companion female to singly caged pregnant females and we have adopted the policies recommended by the Home Office and make sure no aged mice are maintained or used for breeding.
We continue to cryopreserve lines at an early stage in the breeding programme to ensure the line is preserved at an early generation. If it is necessary to use a line for a prolonged period we will rederive before reaching 10 generations to minimise the effects of genetic drift.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the PREPARE and ARRIVE guidelines and the LASA "Guidance on Aseptic Surgery" for advice on best practise when administering substances and also guidance available on the NC3Rs website.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will routinely attend NC3R's meetings, animal welfare meetings where best practices are discussed. The group will keep abreast of the latest literature and read the 3R's newsletters and adopt new methodologies and procedures as they arise.

Home Office

NON-TECHNICAL SUMMARY

199. TOWARDS PREVENTION AND CURE OF HIV INFECTION BY ACTIVE IMMUNIZATION

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

HIV, Virus infections, Preventive vaccination, Therapeutic vaccination

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the project is to make significant contributions towards the development of a safe and

effective HIV vaccine focusing mainly, but not exclusively on induction of protective T-cell responses.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

In 2018, 1.7 million people were newly infected with HIV, 770,000 died of AIDS-related illnesses and an estimated 37.9 million people were living with HIV-1 (PLWH), of whom approximately half received antiretroviral treatment (ART). Prevention largely focuses on behavioural and biomedical interventions such as male circumcision, provision of ART as pre- and post-exposure prophylaxis and mother-to-child transmission, while HIV cure concentrates on long-acting injectable drugs, slow-release implantation devises and vaginal rings. For PLWH, ART saves lives, but it does not cure HIV and has to be maintained for life, which magnifies side effects, stigma and significant economic and logistical challenges particularly in low- and middle-income countries. Given the challenges for widespread implementation of the biomedical measures, an effective vaccine has always been and remains the best solution and likely a key component of any strategy for ending the HIV pandemic.

Although the HIV-1 vaccine field has recently focused almost exclusively on B-cell analysis and induction/introduction of broadly neutralizing antibodies (bnAbs), there is a renewed interest in T-cell vaccines. In humans, there is a large body of data implicating a protective role of T-cells against HIV-1, which was demonstrated directly in an experimental infection of macaques by simian immunodeficiency virus (SIV). Clearly, T-cell responses impose a selective pressure on the virus and their antiviral impact should be harnessed for vaccine protection if only to complement antibodies. The trick is not to induce just any responses, but well targeted protective killer T cells.

What outputs do you think you will see at the end of this project?

The overall aim of the proposed program is to make significant contributions towards the development of a safe and effective HIV vaccine mainly through induction of protective T-cell responses. Early HIV vaccine development is an important, but relatively high-risk area of research, which can be only sustained by the academic sector; following the initial few failed vaccine efficacy trials, big Pharma has reduced its interest, but would become re-engaged if a new strategy showed a real promise of efficacy, particularly if the candidate vaccine was well suited for HIV cure. By the end of this project, we shall extend our understanding of the host-pathogen interactions, gather novel information on protective responses against pathogens and their induction, develop new skills and expand the toolbox of vaccinology.

Who or what will benefit from these outputs, and how?

HIV vaccine will transform lives of millions of people particular those living in low- and middle-income countries. Development of vaccines against human diseases has many features in common.

Demonstration that focusing vaccine-elicited T-cell responses on functionally conserved regions of the proteome can control HIV-1 would encourage similar strategies for fighting other human pathogens. Through thorough investigations of HIV-1 biology and vaccine development, HIV research has significantly contributed to almost every other field of biomedical research. With the renewed focus on infectious diseases, pandemics and demonstrated societal impact pathogens can have on communities and state and even global economies, the time has never been better to extend our understanding of the host-pathogen interactions, gather novel information on protective responses against pathogens and their induction, develop new skills and expand the toolbox of human vaccinology.

How will you look to maximise the outputs of this work?

All results will be presented at international meetings and published in peer-reviewed scientific journals. The proposed research will advance understanding of crucial attributes of protective T-cells against HIV-1 and their induction. Development of vaccines against difficult, highly variable human pathogens is challenging, but the strategy and tools are common; success in controlling the AIDS virus will likely provide a new powerful tool with broader applications for improving public health. Therefore, academics developing prophylactic and therapeutic vaccines against infectious diseases and cancer will benefit from our research. Similar strategies apply to prevention and treatment of animal infections.
Eventually, the HIV programme will contribute to the reduction of the social and economic burden caused by HIV-1/AIDS, a poverty-related disease, by accelerating the development of an effective, safe, accessible, suitable and affordable preventive vaccine against HIV and other viral infection.

Species and numbers of animals expected to be used

- Mice: 5300

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the lowest vertebrate group in the evolutionary tree for which suitable models of immune responses in humans and reagents are available. Adult animals are sufficient to answer all scientific questions in this model before progressing to humans.

Typically, what will be done to an animal used in your project?

An animal is typically administered substances by injections. The route is dependent on the vaccine platform, but is usually either intramuscular or subcutaneous, though other routes may sometimes be required. Experiments can last between three weeks to a year though a typical experiment last one month when a single-prime and single-boost regimen is used.

The animals are always killed by a schedule 1 method for the harvesting of the spleen from which splenocytes are purified for assays.

What are the expected impacts and/or adverse effects for the animals during your project?

Localised short-term pain at the sites of immunisation and blood sampling. In our over 20 years of using the mouse model, we have very rarely encountered adverse effects during the projects as the vectors we use have a long-proven track record for safety.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

I expect 98% of animals to be returned as Mild and 2% as Moderate.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Vaccines have to be tested in living body: The procedures described in this PPL cannot be done using cells, isolated organs or animals kept under general anaesthesia. The vaccine-driven expansion of immune responses and optimization of delivery requires injection of candidate vaccines into a living body. The use of live animals is needed to study tissue distribution/homing of vaccine-generated T cells; there are no alternatives.
Human studies. Every Good Manufacturing Practice vaccine batch is tested for immunogenicity in mice prior to use in humans to confirm that the vaccine is fit for purpose. The batch testing of candidate human vaccines is fully and adequately covered by Protocol 1: we inject animals i.m. by the candidate vaccine, kill the mice 1 week later and assess immunopotency on isolated splenocytes. These are small-batch-size Investigational Medicinal Products for phase 1 and phase 2 Experimental Medicine trials rather than licensed vaccines mass produced by Pharma.

Which non-animal alternatives did you consider for use in this project?

Some very specific questions can be answered using cultured cells, for example defining the small parts of microbes recognized by the immune responses can be performed by expanding specific T-cell clones in culture. But the responses/the immune cells still need to be generated in vivo.

Why were they not suitable?

Some very specific questions can be answered using cultured cells, for example defining the small parts of microbes recognized by the immune responses can be performed by expanding specific T-cell clones in culture. But the responses/immune cells, still need to be generated in vivo.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

Group sizes of animals of individual experiments will vary. For new previously untested vaccines, vaccine combinations and vaccination protocols, the number of animals per group for assessing T-cell immunogenicity is empirically n=5. For challenge experiments and longer-term protocols, this number may be increased empirically. In cases where the vaccine effect or anticipated improvement in a given assay are known from previous results, the number of animals used in a group will be calculated in consultation with a statistician. This will be done on an experiment-by-experiment basis.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

For induction of cell-mediated immunity by vaccination, unvaccinated control groups are typically not included as the background peptide responses in naïve mice are well established and minimal. Control groups will be needed ONLY for experiments determining protection against the surrogate virus challenge.
In an effort to reduce numbers of mice used for vaccination studies, we have now implemented blood sampling as our standard method of immune monitoring. This allows us to follow individual mouse responses throughout an immunization experiment and thus obtain data from multiple time points from one mouse. The main limitation is the blood volume/cell numbers recovered from a living animal.
Validated potency tests for clinical trial vaccines will be carried out in groups of 5 BALB/c mice using H2Dd-restricted epitope included in the immunogens. Based on the past variability of the assay, five, four or three animals fulfilling potency criteria give us 98%, 91% or 71% confidence (p=0.05), respectively, that the vaccines are fit for use.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In our experiments, the group sizes of animals will vary. For new previously untested vaccines and vaccine combinations, the number of animals per group for assessing T-cell immunogenicity is empirically n=5. For challenge experiments and longer-term protocols, this number may increase. In cases where the vaccine effect is known from previous results, the number of animals used in a group may decrease and will be calculated in consultation with a statistician to achieve at least 80% power to discriminate between compared groups ($p<0.05$). This will be done on an experiment-by-experiment basis.
The number of mice used in these studies will be kept to a minimum to answer the scientific questions based on statistical calculations and reproducibility. We shall be using inbred mouse strains, which have a homogenous genetic background that decreases variation in the data, we shall be able to use smaller numbers of animals to obtain good data. Furthermore, whenever possible experiments will be designed to overlap and allow use of tissues from the same animals for multiple experiments answering different questions.
Overall, our experiments are very basic and straightforward. I do not immediately foresee any potential for a novel reduction.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This animal license authorizes the use of mice for experimental testing and development of HIV vaccines. These vaccines will be typically administered to animals using the intramuscular route. As described in the protocols, animal suffering will be minimized by establishing and using the minimum dose necessary to achieve desired levels of immune responses, minimizing the number of vaccine injections, using predominantly of the most applicable route of vaccine delivery for humans, which is the intramuscular needle injection, and for peptide and

proteins, employing adjuvants safe and acceptable for use in humans, including newborn babies. All vaccine dosings are carried out aseptically,

Why can't you use animals that are less sentient?

The aim of our research program is to develop efficacious vaccines. As such, we need an animal model with a good immune system that allows us to test if our vaccine candidates are immunogenic over time. Furthermore, we have developed our toolbox in the strains of mice we use, which maximizes the information gained using minimum number of animals. Animal that are terminally anaesthetised are also inappropriate, as we need to study the durability of adaptive immunity. This is simply not possible for a terminally anaesthetised animal.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We use sterile yellow tips inserted onto the syringe needle to control depth of needle insertion into the muscle. This reduces the risk of the needle damaging tissue as well as provides consistency in immunisation. We will continue to ensure that PIL holders are well-trained in the lab using models or teaching aids, where possible, before progressing to work on live animals.
The best means to reduce pain for the animals is to administer the procedure skilfully and, where possible, administer it under general anaesthesia. To this end, the PILs working are this PPL are overseen by an experience senior scientist who endeavours to work together with each less experienced PIL holder until they are signed off for a specific procedure.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We follow guidance on the administration of substances and aseptic techniques.
We take advice from the NC3Rs as part of our experiment design and planning. We endeavour to the employ the method with the lowest cost in terms of harm/pain to the animal.
We discuss experimental designs and publication requirements with colleagues, peer-reviewers and editors. All PPL and PIL holders attend the termly Animal welfare meeting, where all stakeholders from different groups and institutes share information.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The employing institution has a 3Rs officer who regularly disseminates advances in reduction, replacement, refinement practices with regards to the species of animals we need to use. This information as well as that given at the compulsory termly meetings of the users of the animal facilities is discussed in depth and adopted as standard practices.

NON-TECHNICAL SUMMARY

200. Toxicology of Pharmaceuticals

Project duration

5 years 0 months

Project purpose

- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Toxicology, Safety, Regulatory

Animal types	Life stages
Mice	juvenile, adult, aged, embryo, neonate, pregnant
Rats	juvenile, adult, aged, embryo, neonate, pregnant
Rabbits	adult, pregnant, neonate, embryo, juvenile
Pigs	juvenile
Beagles	juvenile, adult
Cynomolgus macaques	juvenile, adult

| Animal types | Life stages |

Minipigs	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of the project is to evaluate the safety of various types of potential new human drugs when given to test animals. The work is required for new drugs, for the safety of the human volunteers and patients who will take the drugs, and it is designed to meet the requirements of regulatory bodies in Europe and elsewhere, who must agree to the sale and use of drugs. **A retrospective assessment of these aims will be due by 09 April 2026**

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

As well as assuring the safety of human volunteers and patients, the successful conduct of tests will help bring to market those materials which are safe and are subsequently shown to be effective in the treatment or prevention of human diseases. Without these studies, progression of new medicines to early human studies and to patients could not occur in the current regulatory framework.

What outputs do you think you will see at the end of this project?

Data collected will be information on how animals are affected by potential new medicines. This will include efforts to identify systems within the body or particular organs of the body that may be affected by short term or accumulated exposure to the new medicines. Outputs will include simple measures like changes in behaviour, food consumption, growth rate and weight retention or loss. Samples will commonly be taken, particularly of blood, but also other excretions such as urine to assess any changes over time, as well as to assess how much of a medicine has been absorbed or excreted. Post mortem examination can demonstrate change in function or structure of body organs, including examination at a microscopic level. Some studies will be to check if there is any effect on ability of animals to breed, or any effect on the development of the young in the uterus.

The data will be collected to the standards required by government regulators in the UK, Europe and elsewhere, for identifying and excluding inappropriate medicines due to safety concerns, and enabling further development of successful medicines.

Improved methods of conduct of specific data collection processes may be developed during the course of the project.

Who or what will benefit from these outputs, and how?

Our clients, typically commercial drug companies, will benefit from the provision of high quality data. This will help them in their work to develop new and better medicines, to discontinue development of inappropriate medicines or to understand and manage the risks of new medicines given to people. Work on this project may also provide data to inform ongoing human clinical trials.

Enabling development of successful medicines will benefit society through diagnosis, treatment or prevention of disease.
Identification of adverse effects can prevent future harms to human volunteers or patients by resulting changes to medicine development programmes.
The wider scientific community may benefit from publication of refined approaches to animal use.

How will you look to maximise the outputs of this work?

Our organisation has colleagues with extensive experience of such work in different parts of the world. Collaborations and information exchange with others within the organisation helps to identify and spread information on successful and unsuccessful approaches.
Collaboration with clients (knowledge gained on products).
On-going collaborations with NC3Rs on various aspects of regulatory safety studies, over many years.
Presenting outputs at scientific conferences and contributing to publications in the scientific literature where relevant.

Species and numbers of animals expected to be used

- Mice: 20000
- Rats: 45000
- Rabbits: 4000
- Beagles: 4000
- Cynomolgus macaques: 3500
- Minipigs: 900
- Pigs: 30

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Many scientific studies have been conducted to demonstrate that the types of animals to be used in the project will provide results which reflect the likely effects in humans. The way in which each new medicine works in the body will be known, and the animal type(s) to be used will be chosen based on an understanding that the medicine will work in a similar way.
The stage of life of the animals to be tested reflects the age/stage of life of people who would receive the

medicines.
Another big advantage of using the listed animal types is that these animal types may be recommended by specific guidelines on how to do this work, and the results of tests are known to be acceptable to the government agencies responsible for authorising use of the medicines in human volunteers and patients. Development of new medicines cannot currently be achieved without this approval by government agencies in the UK, elsewhere in Europe and in other parts of the world.

Typically, what will be done to an animal used in your project?

Animals will be given a potential new human medicine by the same method that people would be exposed to them - most commonly by mouth, but may be by injection, application to the skin, or by inhalation. Inhalation of materials generally requires that animals are accustomed to close restraint in a purpose-made device while breathing the medicine, and/or wear a mask while breathing the medicine. If applying medicines to the skin, some form of covering or temporary restraint is required, to stop the animal or cage-mates interfering with it. Dosing of the medicines is for at least as long as people would be asked to take a medicine. A small number of studies involve giving the medicine to rodents for an estimate of their lifetime, to check if it might cause cancer. A small number of studies involve surgery, to allow dosing of medicines intravenously for an extended period daily, or continuously. Surgery may also be conducted to take tissue samples, to assess a change in effect over time or to allow collection of information such as ECGs without restraint of animals. All surgery is conducted under anaesthesia and with use of post-surgical pain relief, under veterinary guidance.
Other samples such as blood samples are commonly taken to assess any effect and/or to assess how much of the medicine is absorbed. Behavioural tests may be conducted to check for effects. Other specific examinations may be undertaken, including examination of the eyes. Some studies are to assess if the material has an effect on the unborn, or on the development of young animals.
Animals will usually be used once only, and then will be humanely killed to check for effects in the body, including by examining the tissues microscopically.

What are the expected impacts and/or adverse effects for the animals during your project?

The process of dosing animals or taking samples can cause a degree of discomfort during conduct, particularly if animals have to be restrained to enable the work. Behaviour and health may be affected by the materials being given, and reduced health can be measured, e.g. by reduction in food consumption, weight loss, changes in blood results. Some studies may have effects on the ability to breed or on development of the young. In lifetime studies, adverse effects are usually those seen in ageing animals, such as reducing function of the body's organs, resulting in reducing quality of life over time.
Surgery can cause some discomfort in the immediate post-surgical period, but this is prevented or minimised by use of appropriate anaesthetics drugs and pain relief.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The vast majority of animals which may experience harms as described above are expected to be considered as mild severity. This includes 85% or more rodents and 70% or more non-rodents expected to be used in the project. It is expected that about 80% of animals to be used in the project will be rodents.

Most other animals may experience harms categorised as moderate. Severe outcomes are not anticipated in most studies; about 1% to 1.5% of rodents may be used in a severe protocol for testing of anti-cancer medicines intended for use in patients with late-stage cancer. Some of these animals may experience harms which are categorised as severe, including lack of appetite, significant weight loss, diarrhoea; such animals would be

humanely killed. Some animals may experience no apparent harms.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed

A retrospective assessment of these predicted harms will be due by 09 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Non-animal methods are routinely used in some aspects of the development programme for new human drugs, but they are currently not able to sufficiently predict effects on whole body systems or to provide information on how much of a medicine is absorbed. It is not currently possible to acquire all of the information on how the body systems such as the heart, brain, liver and kidneys may be affected by new medicines, without using animals. This information is essential, to protect human volunteers and patients. The protocols described in this project are conducted according to internationally-agreed guidelines, and are expected to be performed before government authorities will authorise giving new experimental medicines to people.

Which non-animal alternatives did you consider for use in this project?

The organisation does conduct various non-animal tests as part of the development programme for new medicines, but as noted above, it is still considered essential by scientists and government regulators, to also do work using animals, which this project describes.

Why were they not suitable?

There currently remains general scientific agreement, and agreement of government regulators, that to protect human volunteers and patients, non-animal alternatives do not, as yet, provide enough information to replace all animal studies.

A retrospective assessment of replacement will be due by 09 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimates are based on analysis of use of animals in an existing licence authorising work for the same purpose, combined with anticipated need for use to a similar extent.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

There are various guidelines issued by government regulators on how to conduct the various study types described in the licence. While giving general information on study design, most of these do not give specific information on the numbers of animals to be used in a study. Sufficient, but minimum numbers are expected to be selected. In the case of reproduction toxicity studies, specific information on animal numbers is provided. Where there is no definitive regulatory guidance on numbers of animals, the applicant and colleagues will use their extensive experience of related programmes, taking account of statistical significance and scientific advice to use sufficient animals for studies to provide robust results, known to be acceptable to government regulators. In general, longer-term studies will use larger group sizes of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot studies will be used to investigate the potential of new designs or processes to improve outcomes, before being used in larger numbers of animals. Initial screening studies, using small numbers of animals, are designed to identify and eliminate materials with undesirable results, and so reduce the numbers of animal which are then used in the studies required by government regulators. Short-term studies are conducted, and results assessed, before starting longer-terms studies in the same programme, to ensure the need for the follow-on study, and to help maximise the study design opportunities.
A retrospective assessment of reduction will be due by 09 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Dosing of potential new medicines is by the same way as they would be given to people; most commonly by mouth, but including various injection methods, dosing by inhalation and by application to the skin. The methods

used are generally very well established and commonly used by experienced staff at the establishment. Volumes of drugs to be given are in line with published guidance on minimising discomfort, and/or are known to cause minimal discomfort based on extensive experience at the site. Any novel volumes would be tested to confirm lack of discomfort before further use; he Animal Welfare and Ethical Review Body must approve any such requests. The amount of a drug, and the amount of time dosing is continued, depend on how much and how long people might be expected to take a drug.
Blood sampling is a common need. We follow published guidance on methods and suitable volumes which can be taken while minimising harms to animals.
Restraint or confinement of animals is occasionally needed to allow conduct of dosing or sampling processes. Methods used are those with which staff have extensive experience, and the duration of time is minimised wherever possible while allowing completion of the process so that tasks do not generally have to be repeated.
Surgery is conducted with expert veterinary involvement in the creation of suitable regimes for anaesthesia and post-surgical pain relief.

Why can't you use animals that are less sentient?

The species used are selected based on known standards of outcome which will answer the scientific questions. They are also known industry and regulatory standards which will meet expectations of government regulators internationally. The particular species chosen for a programme may also allow comparison with other data which as been generated using the same species with the same medicine, or similar medicines, to assess which might be the best for people to take.
Response to tests is assessed over a time period which would make continued anaesthesia impractical in almost all cases, and would interfere with the outcome in some circumstances.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Refinement of on-going procedures is commonly discussed and explored within the animal technical, veterinary and scientific groups, and also as and when any concerns are identified; for example additional assessments may be included based on initial outcomes.
The surgery and anaesthesia/pain relief protocols used in the programme undergo regular and routine assessment and refinement to improve outcomes. Habituation of animals to restraint is a routine process, and the schedule can be amended in response to outcomes for individual animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Dose volume and blood volume limits agreed with the animal welfare and ethical review body are based on the 2001 publication of Diehl *et al*: A good practice guide to the administration of substances and removal of blood, including routes and volumes.
Welfare end-points are developed in general line with publications on the topic, including the NC3Rs document from 2010 on dose level selection for regulatory toxicology studies.
Non-human primate housing is in compliance with the NC3Rs document on this topic from 2017.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Both our clients and our colleagues working in the same type of work in other countries, are collaborators who can bring ideas as to how to improve how to conduct our animal studies. Various staff at the establishment have been involved with working groups of the UK National Centre for the 3Rs (NC3Rs), over many years. Staff at the site routinely review published papers in the scientific press, some of which

propose refined approaches to conduct of work.

A retrospective assessment of refinement will be due by 09 April 2026
The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

201.Tracking Salmonid Smolts and adults to establish in river survival rates and coastal movements

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals (e)
- Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work

Key words

Sea trout, Salmon, Acoustic tags, Marine distribution, Survival

Animal types	Life stages
Other fish species	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To better understand salmon and sea trout migration and provide data on in river and marine movements, including the potential and actual effect of man-made structures in coastal and river environments

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Fish which migrate into freshwater to spawn, such as salmonids, may have to migrate past coastal and in-river developments to complete their life cycle. Developments such as weirs, barrages, tidal lagoons or major abstractions have the potential to impact on survival of both juvenile and adult stages.
This can be particularly important for species such as Atlantic Salmon (*Salmom salar L.*), sea trout (*Salmo trutta L.*) or twaite shad (*Alosa fallax*), which spawn multiple times and may therefore be subject to cumulative impacts. The lack of data on migration patterns of these species, and hence potential impact, has impaired the ability of developers to assess impacts and propose suitable mitigation, compromising marine licence applications and potentially putting the fish populations at risk.
This project will track up to 300 sea trout smolts, up to 200 sea trout adults, and up to 100 salmon smolts tagged with acoustic tags. The tags regularly emit a coded acoustic pulse which can be detected and decoded by fixed passive receivers, enabling individual movements to be followed. Fish will be tagged in freshwater, and their migration to sea followed, to develop quantitative survival, migration and availability data for a specific coastal location. It will also look at the impact of a major in river structure at head of tide. The project will provide specific data for an important coastal development area, and contribute to the development of a wider understanding of in river survival, coastal and marine phase movements, and distribution of sea trout.

What outputs do you think you will see at the end of this project?

1. Quantitative data on distribution and residence times of salmon and sea trout in the immediate study area.
2. Qualitative data on coastal distribution and migration paths in a wider area.
3. River and sea survival / return data for sea trout
4. Evidence describing migration past a structure at the tidal interface (some limited data exists already at this site, but this study will significantly improve knowledge).

A final project report will be published and made publicly available. The more important results will be published in peer reviewed journals.

Who or what will benefit from these outputs, and how?

Lack of data on key marine species, including migratory fish, is recognised as a strategic information gap by both regulators and industry (see the ORJIP report, 2017).
Developers and regulators will be provided with valuable data as the study progresses; migration data and

survival would be analysed and reported on an annual basis. Information specific to the area will benefit local regulation and inform evaluation of current and future development proposals. The information will therefore provide both short and long term value. Results describing migration and behaviour patterns in inshore areas will have wider utility and will benefit assessments by regulators elsewhere in the UK. The value regulators place on this data is reflected in financial commitments (tag and receiver purchase) to help support the work.
Local angling associations are keen that evidence is developed to ensure that both the fish population and fishery are protected through the regulatory process for marine developments. They have provided/are providing practical assistance with our fieldwork, including fish capture.
We would also expect to provide information regularly during the course of the project to the wider scientific community through conference papers and publications.

How will you look to maximise the outputs of this work?

We expect to produce reports, conference papers and peer reviewed publication.
We are already working closely and collaborating with UK regulators, governing bodies, conservation authorities and Trusts.

Species and numbers of animals expected to be used

- : Up to 600 fish

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Sea trout migrate to sea as smolts, returning to spawn as adults. During these migrations they may be killed or their migration success compromised by various natural and human activities, including natural factors such as predation and disease, and man-made problems such as the presence of barriers (weirs and barrages), pollution, marine and in-river developments.
In the natural state, sea trout normally spawn multiple times, unlike salmon, where only a small percentage survive spawning. As such the impact of human activities can be multiplied through their lives, as losses may compound with each migratory phase.
At the current time sea trout populations in many parts of the UK are at historically low levels. However much less is known about sea trout than salmon, particularly their movements in the marine environment. This study aims to look at sea trout survival rates at different life stages, and will focus on the impact of specific man made developments and development proposals. This is important information for managing and protecting sea trout populations.

Typically, what will be done to an animal used in your project?

Fish will be captured using nets or traps specifically designed to avoid damage. They will be anaesthetised and tagged with an acoustic tag through an incision approximately 1cm long (or less). The incision will be closed with a dissolvable suture and covered with a suitable covering to initially prevent the wound from infection during initial healing.
Juvenile fish will then be transferred to a well aerated recovery tank and monitored for normal behaviour (holding their position and actively swimming). Adult fish will be held facing into the water stream until they are able to hold position and actively swim upstream.

Once the fish are recovered from anaesthesia they will be released to continue normal lives.

What are the expected impacts and/or adverse effects for the animals during your project?

Experience has shown that fish rapidly recover from anaesthesia and surgery and are not expected to suffer any lasting long term harm as a result of the procedures under this protocol being carried out.
The procedures carried out in these protocols will be done under general anaesthetic and therefore fish will be subjected to no more than mild stress as a result of capture and handling. There may be some mild post-operative discomfort, but experience of staff carrying out the work will ensure that juvenile fish are only released once they are behaving in a normal manner within the release tank, or for adults, when they are able to swim upstream against the flow.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the severity to be moderate for all fish tagged. The tagging approach is intended to minimise discomfort or damage to the fish.
What will happen to animals at the end of this project?

- Set free

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The project aims are to look at the behaviour and distribution of Atlantic salmon (*Salmo salar L.*) and sea trout (*Salmo trutta L.*) in the wild in order to gain information to manage and protect the species in the context of specific development areas. There are no practical alternatives to generate this data.

Which non-animal alternatives did you consider for use in this project?

Theoretical modelling has already been utilised to look at potential distribution and movement in the study area. This has identified the species most at risk from developments and these are the subject of these studies.

Why were they not suitable?

In the absence of migration studies and actual movement data for sea trout in the study area, there is no basis to validate these models and their predictions.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may

include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We need to use sufficient fish to provide robust estimates of survival at different life stages to inform models which can then be used to predict impacts without the requirement for further experiments using live fish. Sea trout life cycles are more complex with multiple spawning returns common and a sea complex age structure. For this reason we aim to tag more sea trout (up to 500 in total). For salmon, where we are tagging smolts and looking at emigration through a more limited area, we would aim to tag up to 100 fish, over two years. Our initial estimate is therefore that this *could* require tagging up to 600 fish to generate robust data.
In practice the key factor in determining the number of fish required will be survival at different life stages. The numbers given above are maximum numbers and design and actual numbers will be set on a 'pilot study' basis and informed by past results as the project evolves.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have undertaken a small pilot study to provide proof of concept, develop sites, skills and procedures and provide some initial data to inform year 1 tagging requirements. Each phase of work will be reviewed to inform estimates of required sample sizes at the next stage and to minimise unnecessary capture and tagging.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Pilot study as above; developing computer models which can be used in subsequent studies to reduce requirements for similar work.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Both salmon and sea trout are economically important for recreational fisheries; they are also important conservation species, widely recognised as a measure of the health of river systems. Marine developments are routinely required to demonstrate that they will not impact salmonids, yet the data to do this are highly limited. For tidal developments, modelling has demonstrated that sea trout are a particular concern.
The capture and tagging of methods we are using with acoustic and radio tags are well established. The methods we are using are designed to allow the fish to return as rapidly as possible to normal behaviour with minimal long term effects.

Why can’t you use animals that are less sentient?

Our objective is to understand observe behaviour and distribution of sea trout and salmon under natural conditions, including at sea. This cannot be achieved by other means.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Capture method

The trap we are using for adults has a large holding area and will be fished at least twice a day. For smolts the Fyke nets we are using a design with a large soft meshed cod end designed to minimise damage to the fish. We will remove smolts from the nets at regular intervals during the night.

Choice of tags

We are using the smallest tags available consistent with the objectives of the project, including tag life and tracking in the marine environment. The tags we are using are specifically designed by the supplier (VEMCO) for work with the species and life stages we are using. They are tough and smooth to minimise any issues if ingested by a predator.

Tagging and recovery procedures

The anaesthesia technique we are using for both smolts and adults ensures water circulation throughout the procedure.
When tagging during dark hours (smolts) light will be kept to a minimum to reduce stress. Aseptic surgery techniques and single use scalpel blades and suture needles will minimise risk of infections.
Each incision will be covered with a suitable temporary wound barrier to provide a temporary barrier, reducing discomfort and providing protection from infection. Sutures will be checked prior to transfer into recovery and holding tanks.
Smolts will be monitored and only be released in groups when exhibiting normal swimming behaviours. Adults will only be released when they are able to swim upstream and maintain position against the flow, and will be released into a quiet deep pool where they can shelter in lower flows until ready to swim away.

Smolts will be released in groups to maintain shoaling behaviour.

Humane end-points and limits of severity

If internal damage to organs were to occur during surgery, the fish would not be allowed to recover and would be euthanized by a schedule 1 method.
If fish fail to recover from anaesthesia they will be euthanized by a schedule 1 method

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

There are a number of published studies using these tags and techniques. However methods evolve continuously and we have taken best practice advice from regulators, other scientists, Non-Governmental Organisations working in this field and our NVS. All the above are undertaking current licenced work with these species and our approach and protocols seek to take the best from each, consistent with our objectives.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continually review the literature. We will attend conferences, such as the recent SAMARCH workshop, which brought together salmonid tracking researchers. We will continue to network with others to share and learn from further developments, both as research understanding of the field develops and to improve our

tagging methods to minimise any potential adverse effects. Where appropriate we will update our protocols and methods.

Home Office

NON-TECHNICAL SUMMARY

202. Training in complex surgical procedures

Project duration

1 years 0 months

Project purpose

- (f) Higher education or training for the acquisition, maintenance or improvement of vocational skills.

Key words

No answer provided

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project will train surgeons in advanced, therapeutic, minimally invasive, surgical procedures.
A retrospective assessment of these aims will be due by 05 February 2022

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

In many cases minimally invasive (keyhole) surgical procedures are significantly better for patients than open procedures as they are associated with less post-operative adhesions, less time in hospital, faster recovery, less pain, easier post-operative care and much faster return to active life. Consequently, many new minimally invasive procedures are being developed to replace larger, open procedures - particularly in response to the Governments new screening programmes for bowel cancer and aortic aneurysm among others. These screening programmes are identifying 30-40% more patients requiring surgical intervention for their conditions and the number of surgeons qualified in the new procedures is very limited. Un- or insufficiently trained use of these new procedures results in unacceptable death rates and long term side effects. We aim to teach surgeons these new, complex procedures, in terminally anaesthetised animals, to ensure rapid competency and safety. These courses will ensure an adequate supply of appropriately trained surgeons who will be able to fulfil the needs of our increasing numbers of patients using new minimally invasive procedures safely and effectively.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project? 51 pigs

and 8 sheep over the course of the licence

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

As all protocols are non-recovery, and animals are given an anaesthetic overdose whilst under anaesthesia, no adverse effects are envisaged. Also, at the end of the procedures, all possible tissue and organs are harvested for use in other studies as well as for use in other training courses.
A retrospective assessment of these predicted harms will be due by 05 February 2022

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

As yet, there are no simulators that truly represent the full physiological state necessary to teach these procedures. Current simulators are unable to replicate the blood and lymph flow of tissues and are also not able to replicate tissue responses to stimuli, muscular activity in bowel, effects of surgery affected by temperature, or tissue changes relative to procedures. We will endeavour to develop better simulators as these courses progress.

A retrospective assessment of replacement will be due by 05 February 2022

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how you will assure the use of minimum numbers of animals.

By carrying out a number of procedures in one animal we can reduce the number needed and, as all animals will be deeply and terminally anaesthetised, there will be no suffering or adverse effects. Using 2 animals per 3 or 6 surgeons depending on the course also reduces the number of animals needed.

A retrospective assessment of reduction will be due by 05 February 2022

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The pig and sheep have been chosen for these courses as we need to represent the same size and physiology as humans, in particular with regard to blood system, lymph system, tissue response and general anatomy. Principally, animals are terminally anaesthetised and therefore insentient throughout.
They are carefully monitored using staff trained, skilled and experienced in ensuring effective prolonged anaesthesia in these species.

A retrospective assessment of refinement will be due by 05 February 2022

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

203.Training in Murine Polio Intraspinal Inoculations

Project duration

5 years 0 months

Project purpose

- (f) Higher education and training

Key words

Training, Polio, Vaccine, Batch release, Research and development

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of the plan of work is to enable a team of prospective and existing practitioners to develop and maintain manual skill in the inoculation of substances into discrete areas of the mouse spinal cord with sufficient accuracy and reliability to satisfy established World Health Organization (WHO) criteria for the polio vaccine safety test using transgenic mice expressing the human poliovirus receptor.
A retrospective assessment of these aims will be due by 27 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Skills gained and maintained as a direct result of the procedures applied in this project will be utilised in the successful conduct of definitive the transgenic mouse polio vaccine safety test (Tgm test). The most immediate benefit of the proposed training programme will be that it will be possible to retain a pool of appropriately qualified and competent practitioners able to perform the Tgm test in-house.
The benefits arising are:

1. Implementation and use of the Tgm test will continue to significantly reduce the use of nonhuman primates for batch-release testing of monovalent poliovirus vaccine bulks both in UK (if still required) and in Europe.

2. The Tgm test is now included in the European Pharmacopoeia (EP) and there have been strong ethical, practical and financial imperatives upon the vaccine manufacturers to take up the test as they are increasingly doing. The lack of an Official Medicines Control Laboratories (OMCL) in Europe adequately qualified and competent to complete the test or comment on its execution would severely compromise the public acceptability of the test within Europe.

3. The WHO will continue to have access to a suitably qualified reference laboratory to which matters of global health significance relating to neurovirulence of poliomyelitis vaccines can be referred.

4. The parameters detected by the Tgm test compared to other possible assays will be better established giving greater confidence in its reliability and meaning for product safety.

5. New strains to be used for live-attenuated oral polio vaccine (OPV) and inactivated polio vaccine (IPV) production and antivirals will be evaluated early in their development giving some confidence in their safety and likely protective efficacy before their use in human subjects.

6. Ability to oversee training programs and advise new manufacturers, national control laboratories, and contract research organizations (CROs) globally in the testing procedures which is imperative to the quality control of new vaccine production and testing of clinical trial materials from new vaccine trials.

Failure to obtain this licence application would compromise the ability to train new staff or retrain existing staff if there is a break in their execution of the test of sufficient duration, leading too loss of skill. With inability to perform the test, in the medium to long term (3-10 years), this would significantly affect the UK's, Europe's and the World's ability to effectively control the release of OPVs. It will also halt the development of new improved vaccine seeds for OPV/IPV production.

How will course attendees use their knowledge or skills in their future careers?

Staff completing this training will then move on to performing work under the main testing licence that covers the intraspinal inoculations required for the WHO Tgm test. This is a very unique skill and requires a high level of dexterity. Being able to perform these procedures means that they can perform quality control testing for polio vaccines and also be involved in testing new vaccine candidates for the polio eradication initiative.

What are the principal learning outcomes from the course?

The objective is to inoculate the dye into the grey matter of the spinal cord. This training stage is considered complete when the inoculator reaches >90% success rate in three consecutive tests of at least 30 animals each.

How are these learning outcomes important to the people on the course?

Progression to the next stage cannot occur until this step is completed.

Who or what will benefit from the transfer of knowledge, or acquisition of skills that this course will deliver?

1. The World Health Organization uses designated laboratories to provide training in this test globally.
2. European national authorities and medicine regulators rely on this animal model for the OPV safety testing for quality control of vaccines manufactured in Europe.
3. New manufacturers requiring safety testing for new vaccines in development.
4. Clinical trial programmes using this test to test material from the trials. These tests provide data on how successful the trials are and can inform new vaccine development. New novel vaccine strains are being developed for all three polio serotypes, clinical trials for these are currently on-going and they are set to run for a least the next 5 years.

How will you look to maximise the outputs of this work?

An annual workshop with all laboratories performing the test globally is held annually. This is an open forum for all laboratories to discuss issues and achievements in the testing and encourages consistency in the test methodology. This opportunity gives the opportunity to discuss refinements in the test methodology and animal welfare.

Species and numbers of animals expected to be used

- Mice: 4000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice including genetically altered are used. Transgenic mice with the human polio virus receptor are used in the main testing licence. Genetically altered mice surplus from this main testing licence can be used for this project. For training with the ink inoculations mice are not required to be used within a certain age range although only adults are used, both males and females can be utilised depending on availability.

Typically, what will be done to an animal used in your project?

1. Surgical exposure of the injection site. (AC).

2. Intraspinal injection of substances (inert pigment). (AC).

3. Animals will be killed by a Schedule 1 method.

Experience with previously trained inoculators indicates that training speed will vary. Therefore, inoculators will be monitored throughout this important phase of the training, with particular attention in the initial sessions in order to quickly identify trainees who will have difficulty developing the necessary skill: inoculation results will be assessed after each training session. As long as an inoculator is making steady progress towards the target success rate of 90%, training will continue. If progress is poor a full review of the training schedule and results will be initiated, and the trainee may be withdrawn from the programme. Any such review of poor progress will ideally be done early in the programme (typically after about 6 sessions).

As the role of the co-inoculator is simpler, progress is expected to be more rapid though would still normally require on average 3 sessions over 2-3 months, and “loss” of skill less likely. However, progress will still be monitored in the same way as for the inoculator.

What are the expected impacts and/or adverse effects for the animals during your project?

The procedure is non-recovery so any adverse effects would be related to anaesthesia only and minimised by following best practice and veterinary advice, any animals showing any deviation from the norm that is not immediately rectified by adjustment of anaesthesia level will be killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Expected severity is non-recovery. Only mice are used is this procedure.

What will happen to animals at the end of this project?

- Killed

A retrospective assessment of these predicted harms will be due by 27 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The initial training in identifying the anatomical landmarks can be carried out by looking at pictures and diagrams and watching experienced operators and videos. The initial training in making the skin incision can be obtained on cadavers
The aim is to train the prospective operator(s) to develop the required manual skills to make the inoculation into the correct region of the spinal cord, i.e. into the grey matter. Correct inoculation has been shown to correlate well with two reactions in the test animals: First, a twitch in one or both of the hind limbs as the needle reaches the grey matter of the spinal cord. Second, as the inoculation is made, a distinct tremor/spasm is produced in one or both of the hind-limbs.

Why can't your aim be met by observing or by participating in ongoing research or clinical procedures?

The purpose of this of this project is to train new staff in a procedure in a manual skill which cannot be learnt from just observing. Participation in ongoing procedures is not an option as the operator needs to reach a certain level of skill prior to participation in such procedures.

In a wider context, there are current research and development efforts to replace the WHO Tgm test with molecular assays using next generation sequencing analysis of polio vaccine products. While these methods might take some time to be fully established and validated, replacement of the WHO Tgm test with molecular methods will help reduce the need for this licence in the long-term.

A retrospective assessment of replacement will be due by 27 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

There are a number of assumptions that can be made which aid in setting totals for the 5 year life of the licence:

- Given the nature of changes to currently trained operators, it is reasonable to assume the need to train up to 2 new operators in 5 years (to maintain the current figure of 4 fully trained operators). These will train in both roles. Up to 100 mice are likely to be needed to train for the co-inoculator role. From previous experience, up to 1000 mice will be needed to train for the inoculator role. (2200 mice for 5 years).
- Required annual proficiency testing will require a minimum of 40 mice per trained operator per year. (800 mice for 5 years).
- Each of the 4 trained operators may require up to 2 additional ink sessions annually to retain/regain proficiency. Each session would require a minimum of 40 mice each. (1600 mice for 5 years). With current testing levels this option would probably not be required. However, testing frequencies may change during the life of the licence, making this contingency option necessary
- A conservative estimate for 5 years based on these assumptions suggests 4000 mice will be required (with

a reasonable margin of error factored in).

What in silico or ex vivo techniques will you use during training?

Some aspects of initial training such as identifying the anatomical landmarks and making the skin incision can be carried out by looking at pictures and videos or using cadavers. New methods such as ultrasound guidance have been considered to augment the training process.

Will these techniques reduce animal numbers? If so, how?

The trainers will make sure the trainee is aware of the requirements of the procedures and is as knowledgeable as possible about the requirements prior to performing the procedure. This awareness should reduce the numbers required to be used once performing the manual training themselves.

What other measures will you use to minimise the number of animals you plan to use in your project?

The process is repeated until a satisfactory percentage positive score is reached. This has taken 750 to 1000 mice under the previous training licence. In contrast the training previously carried out required over 1500 mice for each trainee because of irregular intervals in training associated with the need to liaise with another site. Training therefore reduces the total number of animals used.
Having full control of the training process means that potential trainees can be selected based on genuine experience of proficiency in Regulated Procedures and can be monitored closely and constantly by experienced operators to determine genuine rate of progress. Training can be planned carefully to maximise success in a reasonable time frame. Unnecessary repetition of aspects of training can be avoided.
We also use animals surplus from other protocols.

A retrospective assessment of reduction will be due by 27 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mouse model is used including genetically altered, these are the methods used:

1. Surgical exposure of the injection site. (AC).

2. Intraspinal injection of substances (inert pigment). (AC).

3. Animals will be killed by a Schedule 1 method.

This is a non-recovery severity procedure so that opportunities for further refinement are limited to good induction and maintenance of general anaesthesia. It is not necessary for animals to recover from the anaesthesia and they are killed immediately following the inoculation. The vertebral column and spinal cord are then dissected out to allow for precise assessment of the accuracy of inoculation by viewing the distribution pattern of the dye.

Why can’t you use animals that are less sentient?

The main reason for using mice in this training PPL is to prepare for the use of genetically altered mice in the polio studies. Mice are necessary because the main animal model, makes use of genetically modified mice that are susceptible to poliovirus. Our experience, supported through discussion with other organisations performing this test, strongly indicates that it is not possible to observe these required reactions on non-sentient (freshly-killed) animals. In order to elicit the reactions, it is essential that the animals are alive and correctly anaesthetised, but it is not necessary for animals to recover from the anaesthesia - they are killed immediately following the inoculation. The vertebral column and spinal cord are then dissected out to allow assessment of the accuracy of inoculation.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is a non-recovery severity procedure so that opportunities for further refinement are limited to good induction and maintenance of general anaesthesia. However, the programme of training and competency is maintained to ensure that the full number of animals under the full protocol is kept to a minimum. In the absence of this training, more animals would be used as tests might fail and need repeating due to suboptimal inoculation. Suffering could also escalate for a test because staff competency would not be as high.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

As this training licence is aimed at preparing for the main licence, we carry out the surgical procedures aseptically and to the same high standards. Therefore, and although there is no post-op care, we follow the general LASA guidance: Guiding Principles for Preparing for and Undertaking Aseptic Surgery. Training protocols were optimised under WHO supervision through experience in different laboratories and discussions in training workshops.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Staff attend conferences on these subjects and are continually researching new methods. The applicant’s expert knowledge in this area and he himself keeping abreast of any new developments. Annual meetings are organised for this forum where presentations are given on the 3Rs and how they have been implemented.
A retrospective assessment of refinement will be due by 27 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

204. Translational assessment of cognition in laboratory rodents

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Mouse, Behaviour, Touchscreen, Pharmacology

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The development of effective treatments for devastating mental health conditions such as Alzheimer's disease and schizophrenia is a very high priority. This process however is very complex and associated with a high rate of failure, with drugs found to be effective in laboratory models such as mice often showing no significant benefit

when tested in patients.
An issue that has been highlighted as a potential contributor to this failure rate is the often marked differences between the assessments used to evaluate the effect of a drug on the nervous system in mice (such as swimming in a pool to find the location of a platform) and the analogous assessment used in humans (which might include asking a person to remember a series of words).
The overarching objective of this project is to contribute to efforts to close this so-called 'translational gap' between preclinical research and clinical trials by increasing the similarity between the cognitive assessments used in laboratory mice and humans.
This will be achieved by developing new behavioural assessments for mice that require them to view and respond to images presented on a touchscreen device to earn palatable rewards such as sugar pellets or milkshake. These assessments will be designed to target specific elements of mental health, such as memory, decision making and emotional state. Previous research has shown that it is possible to evaluate some elements of mental health in humans using similar touchscreen tasks and this project intends to expand the number of cognitive features that can be assessed in this way.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This project will generate a number of new behavioural assays for use in laboratory mice that will have much higher similarity to analogous assessments that can be used in humans than are currently available. This will substantially increase the likelihood that a drug that has been shown to improve the function of the nervous system in a mouse will have a similar effect in humans. This will help to reduce the failure rate in clinical trials by potentially eliminating the use of drugs that ultimately will be ineffective in human patients and may also reduce the number of preclinical studies involving animals that are performed to collect the data required to justify entering a new drug into a clinical trial initially.
Expanding the utility of the touchscreen assessment system in mice will also increase the reliability of these experiments as all data is collected automatically by computers and is not reliant on investigators scoring the behavioural performance of mice 'by hand' which can be very challenging to do consistently. The development of 'standard' automated measures of behavioural performance will also make comparison of the touchscreen data collected by different investigators more straightforward than it currently is and eliminate the possibility that inconsistent results are due to differences in assessment method, but rather are due to a genuine biological difference that should be investigated and may reveal important insights.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

This project will involve laboratory mice and over a 5-year period we anticipate that 1500 animals will be involved in this programme of work.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the

likely/expected level of severity? What will happen to the animals at the end?

The focus of this project is the development of non-invasive, low stress behavioural assays in which mice are required to view and decide on a behavioural output in response to simple visual stimuli (such as black and white shapes/patterns) displayed on a touchscreen. These assays will avoid the use of aversive stimuli and situations that mice find stressful such as physical restraint. Therefore, the behavioural procedures which form the basis of this project will be of mild severity.
A proportion of the animals involved in this project will be administered pharmaceutical compounds as part of the process of validating the behavioural tasks. This may require injections which should cause no more than momentary discomfort in the mice. The compounds injected will generally have a wellunderstood mode of action and have previously been administered to mice by other investigators. Therefore, doses will be selected to minimise the potential for non-specific or adverse side effects to occur. Following administration of a compound, mice will be closely monitored for any evidence of adverse effects.
This project may also involve some of the extensive range of genetically altered mouse strains now available. For example, animals that carry alterations in genes known to be associated with particular neurotransmitter systems thought to have a role in supporting the behaviour a particular assay measures will enable confirmation of this association. Similarly, mice altered to carry genetic mutations known to be associated with mental illnesses will determine if an assay designed to measure a particular cognitive characteristic known to be impacted in a particular mental illness is capable of doing so. The mouse strains selected will be those that have already been well-studied by other investigators such that their characteristics and capacity for behaviour will be well-understood. In addition, any strains associated with degenerative conditions (such as Huntington's disease) will only be involved in studies designed to finish well in advance of the age at which the animals are known to develop characteristics with negative health effects, such as movement problems. Such animals will therefore be humanely culled using approved methods well in advance of any potential adverse effects on their health and welfare occurring as a result of their degenerative condition.
To maintain stable levels of behavioural performance, it may be necessary to control the amount of food provided to the mice to motivate them to earn a food reward in the touchscreen tasks. Mild caloric restriction has been shown to have a number of physiological benefits in both humans and animals. Nonetheless, mice experiencing food restriction will be weighed regularly and monitored for signs of ill health. Food restricted animals would be expected to maintain between approximately 85 and 95% of their weight as measured when free fed, and should an animal be found to weigh between 80 and 85% of this value they will immediately be provided additional food and checked to ensure their weight has increased. If an animal is found with a weight below 80% it will be humanely culled using an approved method. At the end of experiments, animals will be humanely culled using approved methods and where necessary the brain and other tissues will be collected for further analysis.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

This project requires access to a complete nervous system with the ability to dynamically select between the full repertoire of cognitive processes and behavioural outputs. It is currently not possible to effectively study complex cognitive processes using *in vitro* methods or computational modelling approaches. Similarly, as the objective of this project is to devise assessments for use in mice, which remain an integral element of the preclinical drug development process, this work cannot be completed in humans.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We are committed to involving the smallest number of animals required to maximise the likelihood of detecting biologically meaningful results in our studies. All experiments will be planned and statistically modelled in advance to ensure the appropriate number of animals is included.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The mouse is the least sentient species capable of supporting the sophisticated behavioural outputs targeted in this programme of work. The mouse and human brain share a number of structural similarities and the mouse has also been shown to be able to perform many of the same cognitive processes present in humans, making it the ideal model system. Equally, a large number of genetically modified mouse strains are available which will enable investigation of the neurobiological mechanisms supporting the behaviour we are studying. A large repository of data concerning the administration of a wide variety of pharmacological compounds to mice also exists which will ensure appropriate doses are used in our studies.
It is anticipated that the majority of procedures performed as part of this project will be of mild severity and cause only momentary discomfort. Animals will be closely monitored throughout for any signs of ill health or distress and humanely culled if necessary.
In addition, studies involving mice genetically altered to exhibit features associated with degenerative diseases (e.g. Huntington's disease) will be completed well in advance of the age at which such animals are known to experience negative health effects (e.g. movement problems), such that these animals will be humanely culled well before their degenerative condition has an impact on their welfare.

NON-TECHNICAL SUMMARY

205.Treating a range of pathophysiological retinal insults with gene therapies

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Gene Therapy, AAV, Prevention of vision loss

Animal types	Life stages
Mice	adult
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of this Project Licence (PPL) is to design and test novel gene therapies to treat a variety of eye diseases. Both cell culture systems and rodent disease models will be used to measure gene therapy effectiveness and safety. From the previous PPL, we made several gene therapies to treat glaucoma, a disease that causes permanent visual loss. We will now expand our treatments to other retinal diseases that have an unmet clinical need. These include diabetic macular oedema and both dry and wet-form age related macular degeneration (AMD). Over the tenure of the licence we expect to patent a further four products. The expectation is that one or more of these gene therapies will be progressed into clinical studies.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

In 2010, the global cost of vision care was estimated to be £2.5 trillion for the 733 million people living with low vision and blindness. Eye disorders constitute one of the costliest health considerations worldwide and there remains a high unmet medical need to treat common eye diseases. Current treatments require frequent application, such as daily eye drops to lower eye pressure in glaucoma, or monthly back of the eye injections for AMD. This can cause ocular scarring, in addition to discomfort and inconvenience. Gene therapies involve a single, one-off injection which should protect patient vision many years.

What outputs do you think you will see at the end of this project?

The team are hoping to publish all notable results in high-quality, peer-reviewed journals to inform peers of their successes. Data will also be presented annually at conferences. Key results will also be incorporated into product patents and used in documents for regulatory filing which will support novel products being advanced into clinical trials.

Who or what will benefit from these outputs, and how?

The scientific community will benefit from scientific publications (expectation of 2/year) over the course of the project. The team are also confident of generating at least two novel product concepts within the timeline of the project. It is expected that these products will outperform current market leading therapies for vision loss. Longer term outputs would include clinical trials and approval for patients. Initially, the gene therapies would benefit more affluent countries (due to initial high costs, but also due to the higher proportion of patients suffering from diabetic and age-related eye pathologies). Over time, costs will considerably reduce, and treatments will benefit less affluent countries.

How will you look to maximise the outputs of this work?

We will be publishing data from this PPL in notable peer reviewed journals and presenting results at research conferences. A key output is to patent the constructs so that the treatments can be protected and progressed towards clinical trials so that benefits reach patients.

Species and numbers of animals expected to be used

- Mice: 3000
- Rats: 1100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

This project uses both adult mice and rats, the majority of which are not genetically altered. The team has extensive experience with both species and the development and testing of gene therapies for the eye. Rodent eyes are anatomically similar to humans, and treatments that are effective in rodents often translate well to human clinical trials. Certain experiments and equipment work better in mice, whilst rat eyes, being larger, allow a more accurate gene therapy dosing regime to be examined.
Young animals would not be suitable for this project, as the retina is less susceptible to damage and the diseases we are investigating are often age related.

Typically, what will be done to an animal used in your project?

All experiments involve injecting a gene therapy into the eyes, usually on one occasion and only whilst the animal is anaesthetised so that it is unaware of the procedure and feels no discomfort. The gene therapies are then given several weeks to reach maximum expression levels before an injury is performed to model a disease. This typically involves the injection of a chemical or protein, a surgical procedure, or the pathology may develop with age in a genetically altered animal. Again, these injuries occur with appropriate anaesthetic and pain relief. During the disease progression various in-life examinations are performed to measure the animal's vision and judge the success of the treatment. These tests are similar to what take place in an eye clinic or at the optician using miniatured rodent equipment. These assessments do not cause any pain but allow extra information to be gathered throughout an experiment.
Animals might also have blood samples taken during the disease progression and after treatment. Blood sampling is more common in the diabetic models to confirm the pathology and ensure sugars in the blood are elevated to a level that can cause visual loss. Sometimes tears or ocular fluids are collected to assess the ocular environment.
At the end of the experiment, animals are killed humanely, and ocular tissues collected and processed.

What are the expected impacts and/or adverse effects for the animals during your project?

Most procedures will not have any adverse effects. The team have performed eye injections and in-life imaging for several years with high success rates and few complications.

Some injuries to the eye can cause temporary swelling and tenderness, which resolves over time. Increased monitoring occurs during, and shortly, after these steps and any animals displaying discomfort or inflammation are treated with appropriate pain relief. Vision in the injured eye should decrease over time to model what happens in human disease. For surgical procedures, the injury is limited to one eye and for genetic strains visual loss occurs slowly over several months. By the time the experiment is terminated, visual loss is expected to be around 50%. For reference, patients often lose 50% of their vision prior to being diagnosed, so this level of vision loss is not expected to impact animal behaviour. Additionally, the gene therapy treatments are expected to preserve sight and reduce any signs of disease within the eye.

The diabetic models will have the greatest impact in relation to adverse effects because the pathology affects the entire animal, not just the eye. Some unavoidable weight loss and possible abnormal behaviour is expected. This is required to match the clinical condition whereby diabetes is a chronic condition and retinal damage occurs gradually over time. I have chosen four different diabetic injury models to mimic different aspects of the disease, allowing me to remove protocols if they are considered less relevant or offer to higher cost to benefit ratio.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

C57BL/6 (a wildtype mouse strain) – mild (50%) moderate (50%)
B6.Cg-Tg(THY-1 YFP) 16Jrs/J (a non-harmful mouse strain that has some fluorescently labelled retinal cells) – mild (60%) moderate (40%) db/db (a genetic diabetic mouse stain) – moderate (100%)

Ins2Akita (a genetic diabetic mouse stain) – moderate (100%)
Wistar, Sprague-Dawley, Lister Hooded (wildtype rat strains) – mild (50%) moderate (50%)

mild = pain or suffering experienced by an animal is low and for less than one day. The animal returns to its normal state within a short period of time.
moderate = animals may experience short-term pain to the eye (i.e. from a surgical procedure), or prolonged impairment to typical behaviour (i.e. a diabetic animal which may become less mobile over time).

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The eye is a complex organ which cannot be accurately examined outside of a living organism. Therefore, animals are required to understand the pathophysiology associated with common eye diseases and ways to prevent blindness.

Which non-animal alternatives did you consider for use in this project?

Where possible, gene therapies are examined in cell culture systems for their ability to transfect and express therapeutic proteins to levels that can influence disease pathways. The use of purified primary retinal cells and retinal organoids (tiny, self-organized three-dimensional tissue cultures) will be investigated over the PPL tenure to limit in-life animal usage.
The group already uses rodent and human retinal explants to study mechanisms relevant to ocular disease. We use these tissues to examine markers and optimise processing protocols and the team have received 3R funding in the past for its non-animal alternative approaches.

Why were they not suitable?

Cell culture systems cannot predict overall efficacy (preventing, attenuating, or stopping pathology). Isolated cells are also not appropriate to examine any immune responses to the gene therapy or evidence of toxicity.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Pilot studies are carried out to calculate appropriate experiment group sizes for full studies. These often involve 3-6 animals to examine reproducibility, safety and to allow further optimisation. Controls are included for all studies and a reference treatment (one which is known to be effective) is often included to benchmark our gene therapies.
For diabetic studies, we have based the estimated number of animals required from scientific literature to obtain statistically and biologically meaningful data. 10-15 animals per group seems appropriate when doing longitudinal experiments due to genetic variability and disease onset.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Statistical advice was sourced from a Biostatistician and experiment study plans are designed to follow appropriate guidelines for animal welfare (Planning Research and Experimental Procedures on Animals: Recommendations for Excellence (PREPARE)) and publication (Animal Research: Reporting of In Vivo Experiments (ARRIVE)). These guidelines help to minimise unnecessary studies, maximise information published and improve reproducibility. Using both eyes of an animal, for non-injury procedures and transgenic animals, also greatly reduces animal numbers and maximises data collection.
Any new surgery, and any new Procedure Individual Licence (PIL) holder will undertake preliminary experiments to generate data relevant to the technique and research question. Similarly, doses will be calculated from effective non-toxic concentrations in tissue culture studies to minimise dose ranges needed to be tested in animals.

To ensure accuracy of data, we also use masked experimentation for almost all studies whereby each animal is given a number and the processing scientist does not know what procedures or treatments each animal has received. In-life results are then not revealed until after the data has been obtained.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

To minimise variability, and therefore total number of animals, procedures will be performed on animals of the same strain. Where possible, functional and behavioural tests will be carried out to support anatomical results (e.g. performing retinal vasculature imaging whilst the animal is alive, before supporting these changes with histological retinal sections). The team will also use ocular fluids, bloods and eye tissues to maximise the

amount of data generated per animal.
The team will also provide excess organs and tissues to other researchers.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Injury models:

Laser treatment to reduce aqueous outflow - An established model of injury in rats. This model has a high degree of success and is an effective model of glaucoma. Suffering is minimal and complications are alleviated by keeping the eyes lubricated and performing the procedure with pre-defined and optimised laser settings.

Laser treatment to Bruch's membrane - A new technique to the group but one of the most established techniques in the literature to induce damage to the retinal vasculature. Laser spots are directed onto the retina at the back of the eye and the rate at which blood vessels reform and repair are measured. Suffering and distress will be minimal as the injury is self-contained and only applied to one eye.

Microbead intraocular injections – The injection of tiny magnetic beads into the front of the eye (known as the anterior chamber) blocks aqueous drainage channels and causes a gradual rise in IOP. This technique is relatively easy to perform, and eyes and animals remain healthy. There is minimal pain using this model and it allows for post intervention treatment with gene therapies, better reflecting treating of patients with glaucoma.

Crushing of the optic nerve - the optic nerve crush procedure is well established in our team and causes a reproducible level of damage. The optic nerve (which transmits visual information from the eye to the brain) is exposed behind the eye and crushed with forceps for a few seconds. The nerve is then released, the tissues moved back into place and the injury site heals on its own. The technique is relatively challenging, particularly on mice, but the data is essential for assessing neuroprotective gene therapies. Animal group sizes are also small for optic nerve crush studies, due to the consistent level of injury, making it a useful model for testing multiple therapies against one another.

Diabetic animal models:

Ins2Akita mice are a diabetic strain of mouse that lose vision slowly over 6-9 months due to leaky blood vessels in the eye. We will try to use these animals at the earlier end of the disease progression when adverse effects are less likely.

Streptozotocin (STZ) is a toxin that damages cells of the pancreas, reducing insulin levels and therefore resulting in increased blood sugar levels. Similar to the Ins2Akita, blood vessels become leaky in the eye releasing inflammatory cells which can reduce vision. The STZ model induces diabetes as early as 3 days post treatment and can be used in both mice and rats making it favourable when progressing gene therapies to other species.

It is likely only two diabetic models will be required to show efficacy. These will be selected after preliminary testing for suitability and the models that display the least adverse effects or complications will be progressed on the licence.

To avoid adverse effects, all invasive surgical procedures will be carried out according to the Laboratory Animal Science Association (LASA) Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

Why can't you use animals that are less sentient?

Due to the complexity of the eye, and as many of the diseases we are aiming to cure occur in adult and aged patients, we need to use appropriate models. We require the use of mammals due to the similarity in the visual system and the length of time for a treatment to express or a disease to progress means procedures under terminal anaesthesia are not applicable. The injury models and gene therapies being designed are relevant to human disease and therefore have a high likelihood of transitioning to patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We've introduced a scoring system (1-10) for all procedure with anything lower than 7 having additional checks post-surgery. These animals will be examined thoroughly throughout the study for evidence of ocular damage and given post-operative antibiotics if required. We will also monitor the weight and behaviour of diabetic animals throughout studies to better understand the pathology and to intervene as early as possible. Each researcher will keep hold of these records and use them to improve their experiments. From experience, researcher scores consistently increase from 5's and 6's to 8's and 9's when performing surgeries on a regular basis.
A health assessment score sheet has also been created to identify complications linked to surgery or diabetic strain to help researchers and animal technicians agree on a correct course of action based on a multitude of scores and criteria.

The group will also have a picture monitoring catalogue detailing what to expect post-surgery and possible adverse expects. The team also train routinely on cadavers which allows them to perfect their surgeries and techniques before beginning pilot studies. This reduces variability whilst helping reduce animal usage through failed procedures.
A shared spreadsheet will be maintained within the group which details the course of all animals through all procedures performed. This spreadsheet will record each animal, every procedure performed on that animal, the actual severity reached, additional comments to the study and how the tissues were used and stored. This system has worked very well in the past.
Over the tenure of the licence, we will also employ an experienced animal technician to oversee procedures and work closely with the animal facility technicians. Maintaining active communication with the facility animal technicians is vital and will allow us to immediately identify problems. In the past, I have also given presentations to the animal facility staff and managers about the nature of our experiments and studies. This helps the facility staff understand what we are doing and why certain adverse effects can arise and why others are not expected.
Animals will also be housed in groups to enable social interaction and grooming. From experience, rarely do our

animals fight after surgery and open wounds are not expected. We have experienced minimal signs of stress or discomfort from similar procedures in the past and expect a good quality of life for the animals on this licence.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Publications will follow the ARRIVE and PREPARE guidelines using the 'Animal Research: Reporting In Vivo Experiments' template. LASA publications will also be referred to in addition to any other best practice guidance articles on surgery and procedures.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will be applying for 3R funding throughout the tenure of the project which requires constantly keeping up to date with 3R advancements. We also seek to collaborate on several 3R projects allowing us to learn and implement new ways to replace, refine and reduce animal usage.
Information will also be periodically checked from www.ubs.admin.cam.ac.uk/3rs/3rs-search-tool, www.animalcare.ubc.ca/animal-care-committee/sops-policies-and-guidelines and www.arvo.org/About/policies/statement-for-the-use-of-animals-in-ophthalmic-and-vision-research/ that provides detailed guidelines for working with animals for eye related research.

NON-TECHNICAL SUMMARY

206. Treatment of abnormal retinal development

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to demonstrate, using albinism as an example, how to develop precision medicine pathways to prevent any child who has inherited a retinal form of blindness from losing their sight.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Inherited eye disease is one of the most common causes of childhood blindness, affecting circa 420,000 children worldwide. Oculocutaneous albinism (OCA) is an example of an inherited eye disease that illustrates why the control of blindness in children is a high priority within the World Health Organisation's VISION 2020 — The Right to Sight programme. Albinism affects up to 1 in 1000 people and is characterised by pigment deficiency of the skin, hair and/or eyes, abnormalities of retinal development and visual impairment. The average best-corrected visual acuity (VA) in OCA is below the UK eyesight standard for driving. Moreover, there are significant effects on school performance, employment and quality of life and most patients are registered as sight impaired in the UK. Despite significant advances in understanding the molecular basis of inherited eye diseases e.g. albinism, there remains a paucity of effective treatment options. This project aims to remedy this deficit.

What outputs do you think you will see at the end of this project?

By the end of the project we hope to have established:

1. The optimal L-DOPA (Levodopa) dosage parameters that can safely obtain maximum rescue of visual function in oculocutaneous albinism (OCA), in preparation for a future randomised controlled trial (within the next 5 to 10 years).

2. Provide new insights into the mechanisms underlying abnormal retinal development in albinism, potentially identifying novel pathways to interrogate in future work.

3. Development of additional novel therapies for albinism and other inherited retinal diseases. This will lead to phase 1/2 randomised controlled trials (within the next 10 years) and establish proof of concept for developing effective precision therapies for other inherited retinal diseases.

In addition, the adoption of a longitudinal study design using non-invasive investigative techniques such as electroretinograms (ERG), optical coherence tomography (OCT) and OptoMotry™ to demonstrate improvements in retinal development & visual function in response to an intervention in a murine model has not been done previously. If this is successful, it may serve as a model for other vision scientists working on drug development studies and has the added advantage of reducing the numbers of animals needed to demonstrate a significant result.

The information from this project, including the study protocols, will be made freely available via publication in peer-reviewed journals, in order to benefit other researchers (e.g. paediatric ophthalmologists and physicians) who are involved in the development and assessment of novel therapeutics which target abnormal retinal development in early childhood.

Who or what will benefit from these outputs, and how?

By the end of the project we hope to have established:
The optimal L-DOPA (Levodopa) dosage parameters that can safely obtain maximum rescue of visual function in OCA, in preparation for a future randomised controlled trial (within the next 5 to 10 years).
Provide new insights into the mechanisms underlying abnormal retinal development in albinism, potentially identifying novel pathways to interrogate in future work.
Developed additional potential treatments for albinism and other inherited retinal diseases. This will lead to phase 1/2 randomised controlled trials (within the next 10 years) and establish proof of concept for developing effective precision therapies for other inherited retinal diseases.
In addition, the adoption of a longitudinal study design using non-invasive investigative techniques such as electroretinograms (EGG), optical coherence tomography (OCT) and OptoMotry™ to demonstrate improvements in retinal development & visual function in response to an intervention in a murine model has not been done previously. If this is successful, it may serve as a model for other vision scientists working on drug development studies and has the added advantage of reducing the numbers of animals needed to demonstrate a significant result.
The information from this project, including the study protocols, will be made freely available via publication in peer-reviewed journals, in order to benefit other researchers (e.g. paediatric ophthalmologists and physicians) who are involved in the development and assessment of novel therapeutics which target abnormal retinal development in early childhood.

How will you look to maximise the outputs of this work?

Public Engagement & Education

Our approach towards developing an effective treatment for albinism serves as an excellent example of how clinical observations at bedside can be taken back into the laboratory for more detailed mechanistic investigations and novel therapeutics development which can then be translated back into clinical practice. This is a good story which we will disseminate to the public through outreach activities, press releases etc. Those affected by the condition (sufferers and parents) will be especially interested, and we will make efforts to reach this audience. We will communicate the progress of our study to the patient community on a regular basis in conjunction with our patient and public involvement (PPI) study group. The results will be presented to the patients by liaising with patient focus groups, attendance at open days, where patients, parents and carers will be informed of the progress of the study. The results will be publicised in patient newsletters and other resources. We will also utilise social media resources such as Facebook and Twitter feeds to disseminate up-to-date information about the study.
Communication of findings to the scientific community will be disseminated by presentations at national and international conferences in addition to publications in peer reviewed high impact ophthalmological and medical journals. In addition to publication, the results will also be communicated on relevant server lists. Progress of the study and results will be regularly disseminated at ongoing teaching events and public lectures.

Species and numbers of animals expected to be used

- Mice: (1) Normal pigmented control mice: 130, (2) Mice with ocular cutaneous albinism (OCA) type 1: 430, (3) Mice with the ocular albinism (OA) subtype: 230, (4) Reporter Mice (i.e. mice who have been genetically modified so that specific cell-types in the retina are labelled, for the purposes of monitoring the dynamic processes that take place during retinal development): 100.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of

the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We have demonstrated that eye development and vision in oculocutaneous albinism (OCA) can be improved through L-DOPA (Levodopa) supplementation, if administered during the critical period of neuroplasticity (i.e. younger than 18 months of age). Unfortunately, L-DOPA (Levodopa) is unlikely to be effective in ocular albinism (OA), as it normally acts through the OA1 receptor to regulate eye development. This receptor does not work correctly in OA.
Targeted treatment(s) are needed that are not age-dependent, or dependent on an intact OA1 receptor. Pigment epithelial derived growth factor (PEDF) treatment is of interest, as PEDF acts after the OA1 receptor to regulate eye development. Another option is to expand the critical treatment period into adulthood, using ciliary neurotrophic factor (CNTF) for which proof of concept has been demonstrated in other retinal conditions.

Before these and other potential treatments can be developed and translated into clinical practice, we need to prove that they can safely improve eye development and eyesight in infant (L-DOPA
(Levodopa) & PEDF) and adult (CNTF) mice with human albinism. We will also need to compare each of these treatments, under the same conditions so that we can identify which one is the best treatment.

Typically, what will be done to an animal used in your project?

A typical mouse will receive a treatment, which may be dissolved in their drinking water, given as an eye drop or a single injection into the eye (like the injections given to humans to treat age-related macular degeneration). This mouse's eye development and eyesight then needs to be checked and followed over time. The eye development can be checked using a non-invasive retinal scanner called an optical coherence tomography (OCT). The mouse optical coherence tomography (OCT) is an adapted version of the human optical coherence tomography (OCT), which allows us to take highly detailed images of the retina. In order to measure eyesight, we will use electroretinography (ERG), which measures the electrical activity being generated by the retina in response to light, a bit like how an EEG measures brain activity. The mouse will have a maximum of six optical coherence tomography
(OCT) and electroretinography (ERG) examinations at: 4 weeks, 5 weeks, 6 weeks, 2 months, 3 months & 4 months of age, so that we can monitor how their retina and eyesight develops over time. These examinations will be carried out, after we have put the mouse to sleep using a small injection of anaesthetic. This is to minimise any possible distress of discomfort that the mouse may experience.
Like infants who like to follow stripes and patterns, mice also have the same reflex. We can use this reflex to check how well the mouse is seeing when they are awake. In order to do this, the mouse stands on a central platform. Black and white stripes of varying thicknesses are rotated around the mouse. If they see the stripes, they move their heads to follow it. The finer the stripe that the mouse follows, the better their eyesight. We will do this test twice at 2 and 4 months of age.
Mice may experience some side effects from the treatment that they are getting. This can include changes in their normal behaviour, anxiety, memory problems and muscle weakness and coordination problems. If mice are suspected have having these side effects, they will undergo some additional assessments at 7, 11 and 15 weeks of age. This will include observing their normal behaviour in their home cages (home cage activity), examining their normal tendency to explore by placing a novel object into their environment (novel object exploration test) and assessing their anxiety levels by observing their tendency to avoid open spaces (open field arena) or avoid falling off of an elevated platform (elevated plus maze). Muscle strength will be measuring the time it takes a mouse to fall of an inverted square of wire mesh held 40-50 cm over a padded surface (Kondziela's inverted screen test). Coordination will be testing by recording how long a mouse can stay on a rotating rod, rather than falling onto a padded platform 30-50 cm below (Rotarod test). Memory testing will only be conducted once at 15 to 16 weeks of age and will involve either the novel object exploration test or the radial maze test. With the novel object exploration test, the mouse will first have several sessions over two day to explore and become familiar with a novel object. Following this a second novel object is introduced, and

provided the mouse has remembered the first object, they should spend more time exploring the second object. The radial maze test involves training the mice for 4 days to locate food pellets in baited arms of the maze. Following this, they will undergo several trials over a number of days, in which the maze will have specific arms that are baited, that are fixed for each trial. Their ability to remember which arms are baited can then be assessed based on the number of arm entries required to locate to acquire all of the food pellets.

What are the expected impacts and/or adverse effects for the animals during your project?

The individual procedures planned in this project are expected to cause no more than mild transient pain or distress and no lasting harm to the majority of the animals.
It is possible that some mice may experience side effects from their medication, which can manifest as loss of appetite and weight, dehydration, lethargy or hyperactivity, twitching, trembling, agitation, sleep disturbances. This is expected to be a rare occurrence and to date, we have observed no side effects in the animals that we have treated with human-equivalent doses of L-DOPA (Levodopa). In the rare event that this occurs, affected mice will quickly receive routine medical treatment appropriate to the presenting symptoms. Any animal that is in chronic pain or distress, which cannot be relieved, will be immediately euthanised.
Behavioural and neurological tests may cause temporary (a few minutes) distress to animals, however, to limit/avoid such distress, mice will be allowed to adapt to the environment prior to testing.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severity for 90% of the animals in this project is expected to be moderate, as each treated mouse will have up to six separate examinations under anaesthetic throughout their lifetime. The remaining 10% (i.e. animals not undergoing several repeated examinations over time) are expected to be mild or sub threshold.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animal use in this project is necessary for two specific reasons:

1. In order to establish L-DOPA (Levodopa), PEDF, CNTF as valid treatment options for infants, young children and adults with albinism it is necessary to identify with as much precision as possible the therapeutic timing window and optimal dosages in a genetically well characterised model at specific time-points. In humans, albinism is a genetically mixed group of conditions, making it extremely difficult to diagnose the specific genetic subtype at an early age, and limiting the precision with which the potential therapeutic window can be determined. In addition, proof of concept for each of these potential treatments needs to be demonstrated prior to proceeding to human clinical trials.

2. To provide post-mortem ocular tissue for investigation of the molecular and cellular mechanisms of L-DOPA (Levodopa) mediated rescue of retinal development and function in albinism, and to determine potential novel targets for future treatment studies.

Which non-animal alternatives did you consider for use in this project?

Ex-vivo tissue and cell
line cultures.
Why were they not suitable?

Demonstration of improvements in both retinal morphology and visual function in albinism in response to potential treatments cannot be achieved using in-vitro cell culture & expression techniques or protein functional studies in ex-vivo tissue and cell line cultures.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to determine the appropriate sample size & minimise the numbers of animals needed for this project; a power calculation was performed based on previously reported electroretinogram data in this murine model. In comparison to controls, a sample size of n=10 in each group will identify a difference in a-wave and b-wave amplitudes of approximately 24% and 26%, respectively (where alpha=0.05 and power=90%).
Histology: Retinas stained with H&E will be used to count nuclei. Previous studies which focused on cell counts of the outer nuclear layer nuclei used an n=4 retinas per group..
Transmission Electron Microscopy (TEM): Previous studies from the literature suggest that the optimum number for TEM studies of retinal synapses require analysis of a minimum of 10 slices, from a minimum of 3 mice per group. However, because these experiments cannot be performed blinded, we will be using a slightly increased number (n=5) to ensure unbiased results.

Immunofluorescence and Proximity Ligand Assay: These are qualitative studies, where there is no standard deviation. Eyes will be collected from the same mice used for other studies, as TEM, histology or protein/genetic studies, therefore, there will be a minimum n=4 eyes/group that will be available for confocal imaging.

Cell sorting: Previous studies sorting retinal cell types suggested that 4 mice retinas yielded 1.5– 2.5×106 rod photoreceptors in a volume varying between 4-10 ml. Considering that mammalian cells normally have a content of RNA around 10-30pg, 4 mouse retinas will have between 15 and 75µg of RNA. Depending on the experiment where cells will be sorted, the sample size will vary.
Transcriptomics: Samples will be run by RNAseq; paired end 2x75bp at 30 million reads (on average per sample). Typically, retinal transcriptomics are run with an n=3 of samples that will, depending on the system, come from one mouse or a pool of retinas. The minimum amount of RNA required is 1µg. Taking into consideration the calculations above, retinas can be sorted individually to prepare transcriptomics samples, therefore needing 3 mice/group.

Protein studies (WB/ELISA): As it has been previously described for retinal development studies of protein by western blot, I will use n=3 retinas per homogenate and 3 different homogenates per group.
Genetic studies (PCR): Previous studies have indicated that it is necessary to have 3 biological replicates to perform statistical analyses. As we do not know a priori the genes that will be analysed (dependent on the transcriptomics results), I will plan an n=5 mice/group to ensure unbiased results for different depths of the candidate genes.

OCT: In our previous study (unpublished own data), the response within each subject group was normally distributed with standard deviation of 3. If the true difference in the experimental and control is 5, we will need to study 7 experimental subjects and 7 control subjects (alpha=0.05 and power=80%).
OptoMotry™: We have used data from preliminary experiments to obtain an estimate of the standard deviation of 0.55. Based on this, a sample size of 5 mice/group will detect a difference of at least 25% between groups (alpha=0.05 and power=80%).
In all cases, we have also included a margin of 10% in the numbers provided and rounded the figures up to the nearest 10.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The design of individual experiments will be optimised to ensure that the maximum amount of data is obtained from the minimum amount of resources. A randomised block design will be used to determine treatment allocation and a mixed cross-sectional & longitudinal study design has been planned which will minimise the number of animals needed for this project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The work in this protocol can be maximised by interrogating the underlying cellular and molecular mechanisms responsible for the recovery of retinal function, in the male OCA mice. These mice are currently not being used in this study, for the longitudinal in-vivo assessments of retinal structure and function in response to potential treatments. The underlying cellular and molecular mechanisms responsible for L-DOPA (Levodopa) mediated recovery of retinal function in albinism are unclear. Understanding the molecular and cellular mechanisms of Levodopa mediated rescue of visual function in Albinism is the key to developing novel therapeutics for the visual problems associated with albinism. Therefore, a subset of male mice will be culled at different ages/time points throughout the treatment protocol for the purposes of interrogating the molecular and cellular effects of L-DOPA (Levodopa), PEDF and other potential treatments on ocular and cortical development and morphology in albinism, thus ensuring maximum output from all available tissue.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

For this study, we have chosen the only genetically well characterised animal model of albinism in which preliminary data exists for the use of oral L-DOPA (Levodopa) (including drug dosages and formulation) in safely rescuing retinal function – the C57BL/6J-c2J murine model of OCA1. This making them an ideal model for longitudinal monitoring of in vivo retinal development response to different therapeutic candidates.
In order to determine treatment efficacy, we plan to use longitudinal electroretinography (ERG), optical coherence tomography (optical coherence tomography (OCT)) and OptoMotry™ assessments of retinal, development, structure and function. Baseline electroretinogram values have been established as a measure of visual function in both control and albino mice. Optical coherence tomography (OCT) imaging of the mouse retina has been used successfully to identify morphological changes in degenerative retinal diseases and has

been shown to be comparable to histological quantification. Electroretinography (ERG) and optical coherence tomography (OCT) are both non-invasive and well established examination techniques, that can be carried out sequentially under the same general anaesthetic. This minimises any potential pain or distress experienced by the mice. OptoMotry™ visual function examinations is also a well-established technique, where we observe the mouse's response to a visual stimulus consisting of rotating set of black and white stripes. This is carried out in awake mice, is non-invasive and may cause temporary (a few minutes) distress to animals until they become accustomed to the test environment. This results in less distress than traditional Morris water maze visual assessments, which carries a risk of drowning and hypothermia.
In order to assess neurodevelopment, we have chosen to use well established non-invasive tests that can be conducted in awake mice, including observation of home-cage activity, novel object exploration (exploratory behaviour) open field activity and elevated plus maze (anxiety related behaviour). For muscle strength (Kondziela's inverted screen test) and coordination (rotarod) we have also selected two well-established, non-invasive and short tests that can be performed in awake animals, Apart from observation of home-cage activity (60 minutes), all of these tests can be conducted in 5 minutes or less, thus minimising any potential distress or discomfort experienced by the animals, and facilitating longitudinal assessments. For memory testing we have selected the novel objective exploration test or the radial arm test as the best options for assessing memory, as these have been validated, with established protocols and will result in less distress than Morris water maze memory assessments, which carries a risk of drowning and hypothermia.

Why can't you use animals that are less sentient?

In order to determine treatment efficacy, we need to perform longitudinal electroretinography (ERG), optical coherence tomography (OCT) and OptoMotry™ assessments of retinal, development, structure and function. These tests can only be performed in animals to whom we can:

1. Administer oral, topical or systemic medications

2. Perform longitudinal electroretinography (ERG), optical coherence tomography (OCT) and OptoMotry™ assessments

The tests have been specifically designed and optimised for mice and requires animals that have reached a sufficient stage of maturity and sentience for the tests to be performed safely and reliably.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In order to minimise the numbers of mice needed & any possible distress, the functional & anatomical effects of administering L-DOPA (Levodopa) to mice at different ages on retinal development will be determined by performing longitudinal, non-invasive electroretinography (ERG) & optical coherence tomography (OCT) examinations under general anaesthesia. Animal suffering will be minimised in accordance with ASPA guidance. All animals undergoing any form of examination will be studied for a maximum of 30 minutes per session and will be given appropriate rest periods between examinations. Local (such as lignocaine) and general anaesthetic (including ketamine and isoflurane) will be administered for surgical procedures followed by systemic analgesia. Mice undergoing surgery will be given an appropriate rest period before further study, typically one week according, or when animal resumes normal behaviour (eating and drinking) according to established protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will conduct all our experiments in accordance with the most recent guidance from the NC3Rs and the ARRIVE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Throughout the project, we plan to stay informed about advances in the 3R's using a combination of the resources at the available at the NC3R's website: https://www.nc3rs.org.uk/3rs-resources and the NC3Rs monthly newsletter.
In order to implement these advances effectively, we plan to:

1. Disseminate them to all members of the team
2. Incorporate them into our training
3. Embed them where possible into our local experimental guidelines and protocols.

NON-TECHNICAL SUMMARY

207. Tuberculosis infection and treatment model for active tuberculosis

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Tuberculosis, Mouse model, Therapy

Animal types	Life stages
Mice	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to test drugs or drug regimens using Cornell tuberculosis treatment model to examine their activities against the TB causing bacterium, *Mycobacterium tuberculosis* in actively growing and persistent forms which co-exist in the organs of animals with active TB infections.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Tuberculosis caused by the bacterium called *Mycobacterium tuberculosis* kills nearly 1.8 million people every year worldwide. One of the important characteristics of the disease is that the bacterium has an unusual ability to survive for extended periods of time in human body despite human immunity and anti-TB drug treatment.
It has been estimated that about 2 billion people, equal to one-third of the world's total population, are infected with the bacterium in whom it causes unnoticeable latent infections that lead to a 5-10% lifetime risk of active disease. Current tuberculosis treatment needs at least 6 months with four drugs to cure the patients. This long-term treatment is extremely difficult to implement especially in developing countries. Poor patient compliance will lead to treatment failure, high disease relapse and promote anti-TB drug resistance. We desperately need new drug regimens which can shorten the treatment duration and prevent TB relapse.

What outputs do you think you will see at the end of this project?

The novel drug regimens tested in this study will provide novel information on their bactericidal and sterilising activities against active TB for the clinical studies in patients
The research has its novelty which will be disseminated to the wilder scientific community by high impact publications and in national and international conferences.

Who or what will benefit from these outputs, and how?

Patients will directly benefit from the research project as novel drug therapy will shorten treatment duration and prevent disease relapse. The activities of the drugs against *M. tuberculosis* have been shown in test tube experiments, therefore the therapeutic efficacy to kill the bugs in animals will be observed at early stage of the project which contribute or predict further impact on disease treatment.
The findings of the projects will be rapidly published in high impact journals which introduce new field, novel treatment strategy, novel therapeutic drugs to advance academic understanding and research in the infection and treatment fields.
This information will advance academic knowledge and UK competitiveness. In the public sector, the work will most directly impact on the academic research community and healthcare professionals who care for patients with infectious diseases such as tuberculosis. Findings in the project will also benefit veterinary professionals and the treatment of the disease in animals and livestock.

How will you look to maximise the outputs of this work?

The findings in this project will be published in high impact journals and disseminated via national and international conferences. The scientific and commercial communities will be made aware of all positive and negative results or approaches to avoid unnecessary duplication of the findings using animals.
The results produced in this project will enable us to collaborate with academic research sectors and establish international collaborative networks that exchange ideas, skills, and jointly produce publications which will reinforce the dissemination of new knowledge produced in the project.
This will also enable us to collaborate with clinicians in the hospital and clinical settings to fully understand the pharmacokinetics and pharmacodynamics of the drug regimens and the management of TB patients with the new drug regimens.
The research outcomes from this project will enable us to apply for further grant supports to advance the findings of the project.

Species and numbers of animals expected to be used

- Mice: 2500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are chosen because most of the standard refined infection and treatment models are using mice and most of the knowledge, experiences and scientific data come from mouse infectious models. Mice are the closest compatible animals to predict and reproduce the effects of antimicrobials potentially applicable for human usage. The infection models we proposed are well characterized by infection dose, route and disease progression. Adult mice will be used as they have matured immunity against bacterial infection. Also, adult mice have fully developed organs such as liver that is an important organ for drug metabolism.

Typically, what will be done to an animal used in your project?

Mice will be infected with TB bacteria via injection or inhalation to induce diseases in their organs such as lungs or spleens. The diseases progress normally takes 2 to 10 weeks. Treatment with anti-TB drugs will be given to the animals orally or by injection (a similar way to those are given to patients) at 2 to 10 weeks after M. tuberculosis infection to reduce the bacterial numbers in the infected organs. The treatment will be 5 days per week for up to 20 weeks. At the end of the treatment, the remaining mice will be given corticosteroids for 8 weeks to check disease relapse as a result of the treatment outcome. The experiment will be terminated. The duration from infection of the animals to completion of the experiment is within 44.5 weeks. Blood sampling to check the drug serum levels will be performed via superficial veins or cardiac puncture which will only ever be conducted under terminal anaesthesia.

What are the expected impacts and/or adverse effects for the animals during your project?

Mice normally do not show clinical symptoms if we infected mice with a low or medium dose of the bacteria. We will control the inoculation size and duration of infection before treatment is started which only allow bacteria to grow in the lungs or other organs of mice but do not induce clinical signs. The medicines used to treat TB will not cause side effects to harm the animals. Side-effects of corticosteroids in this model are immune-suppression which can result in clinical infection from other bacteria. We will give the animals antibiotics to prevent other bacterial infections. The steroid also induces reactivation of dormant TB which may transfer to active TB. The animals will be closely observed, if animals show any of the adverse effects, they will be humanly killed.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected maximal severity will be moderate which will be monitored and controlled using scoring system. The intervention procedures given to the mice individually are mild, for example, IV, IP injection or oral dosing. However, repeated oral gavage may have a cumulative effect to cause discomfort. In this model, approximately 80% of the time, mice are treated with anti-TB drugs or steroid via oral dosing.
The low and intermediate doses of bacterial infection to the mice are mild. However, at the follow-up period when steroid is given and no anti-TB drugs are administrated to the mice, mice may develop active infections due to disease relapse, one-third of mice at the end of the experiment may experience moderate severity

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

One of the most important steps in preclinical studies of anti-TB drug discovery and development is to test the activities of drugs or drug regimens using animal models. Nearly all the antimicrobial agents have been tested using animal models before studied in human trials. The activities of the anti-TB drugs against TB causing bacteria have been tested in our test tube experiments and their toxicity has been examined using animal or human cell cultures. However, the environment in a live animal is much more complex than that in a test tube or a cell culture. This means that it is necessary and important to study the bacterial colonization and the drug activities in living animals to assess the effectiveness of the treatments. Therefore, whole animals are needed.

Which non-animal alternatives did you consider for use in this project?

The activities of the antibiotics or drugs against TB causing bacteria have been tested in our test tube experiments and their toxicity has been examined using animal or human cell cultures. The anti-TB drugs have been used clinically in patients.
Cytotoxicity assays using mammalian cell lines, Ames test for mutagenesis, comparative in vitro metabolism with human, rat, minipig hepatocytes and the HerG test have been considered as alternatives.
Minimum Inhibitory Concentration, Minimum Bactericidal Concentration, Minimum Stationarycidal concentration, Minimum Dormicidal concentration have been considered as measures of efficacy of antimicrobial. Drug solubility, stability, tissue penetration, metabolism, excretion, formulation can be tested in vitro.

Human samples such as sputum can be used as part of alternative to animals.

Why were they not suitable?

These in vitro tests have limitations in predictive power when compared to the whole animal. There are factors in the whole animal which cannot be mimicked in vitro. For example, simple cytotoxicity assays have been used with partial success to predict animal and human toxicity and to estimate starting concentrations for animal toxicity studies. But the pathways leading to drug toxicity are very different between cell lines and whole animals. Cell-based assays typically lack metabolic competence and often miss chemicals that require bio-activation in a whole animal. They also fail to provide data on some of the most important toxic mechanisms, for example those involve organ- or cell-type specific physiology.
Although Minimum Inhibitory Concentration of an anti-TB drug in particular, is used to predict drug efficacy in humans, the pharmacokinetics and pharmacodynamics are very different in a whole animal. Also, bacterial colonization and growth in human organs and tissues are very different from those in the test tubes, therefore results obtained from in vitro studies cannot often directly predict biological responses of organisms to drug exposure in the animal. Therefore, whole animals are needed.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

In order to evaluate the efficacy of the TB drug regimens, bacterial numbers in the infected organs will be

examined at different intervals for 14 to 20 weeks after treatment is started. The bacterial numbers will be monitored as colony-forming units on agar plates and most probable numbers in the liquid medium. For each treatment group, these bacterial numbers will normally be taken from the infected organs from 4 animals at early time points and 6 to 8 animals at the late time points. After completion of the treatment, about 20 animals will be kept for 8 weeks to examine TB relapse. These numbers of animals used in each time point are derived from power calculations which optimize the numbers of animals required to obtain the maximal study outcome with minimal numbers of animals. Based on data from 22 previous treatment arms performed in the TB model, a range of linear elimination rates from -0.16 to -1.07 log CFU/wk have been observed with an average standard deviation of 0.23. With a sample size of 60 animals per treatment arm and an alpha of 0.05, a difference in elimination rate of 0.19 will be detected with greater than 90% power. For the TB model, we will use 500 mice/year with about 7 treatment arms and one control. For the 5 years, the maximal of 2500 mice will be used.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Experimental designs and methods of analysis of the results have been discussed with professional statisticians and with those who have experience in the field. The design of individual experiments will usually involve factorial designs, which maximize the information obtained from the minimum numbers of animals.

We will also use the NC3R's Experimental Design Assistant online tool to design our experiments to ensure we will use the minimal numbers of mice to produce significant scientific results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will select the effective drugs with no toxicity using well-defined in vitro tests before applying them to animals to reduce the number of animals used. For any new drugs being tested in the infection models, pilot studies will be carried out with small numbers of animals to assess the activities of the new drugs.
We will employ computer modelling using the data derived from our previous studies to evaluate the drug efficacy using the numbers of the animal used in the studies. Model-based clinical development of antimicrobial and drug combinations has been used in our previous studies. We will continue to employ those methods to optimise the number of animals used in the study to provide us with the maximal scientific outcome.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Tuberculosis infection and treatment model will be used in this project to test anti-TB drug activities against *Mycobacterium tuberculosis* that causes tuberculosis.
The TB mouse model was established more than 60 years ago. The current TB drugs used to treat human TB were firstly tested using this model. During these years, the model has been refined in different research groups around the world which produced the optimal scientific outcome with the least adverse effects to the animals. In this model, mice are infected with the bacterium that causes TB, the immune response of the animals against TB will be established at 2 or 3 weeks after infection, that can inhibit TB bacterial growth but will not eliminate the bacterium. The infected mice will be treated with TB drugs, that will reduce the bacterial numbers in the infected organs and control the infection.

Why can’t you use animals that are less sentient?

Mice are chosen because most of the standard refined infection and treatment models are using mice and most of the knowledge, experiences and scientific data come from mouse infectious models. Mice are the closest compatible animals to predict and reproduce effects of antimicrobial potentially applicable for human usage. The infection and treatment model we propose is well characterized with infection dose, route, disease progression and treatment management. Also, mice are less sentient to tuberculosis showing a strong immunity against TB bacteria.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

To reduce adverse effects, animals will be closely monitored throughout the experiments and will be provided with environmental enrichment such as fluid and warming pad to reduce discomfort. It is proposed to utilise optimal experimental techniques with minimal intervention performed by well-trained persons. Infections will be rapidly controlled by providing treatment to the animals with anti-TB drug therapy. The experiments will be terminated at the earliest possible stage when a satisfactory scientific outcome is produced. All these measures will reduce distress and suffering to the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The ARRIVE guidelines
Guidance on the operation of the Animals (Scientific Procedures) Act 1986 (Home Office)
The Harm–Benefit Analysis Process (Home Office)
LASA Good Practice Guidelines (Administration of Substances and Collection of Blood Samples) will be followed for dosing and blood collection

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Receiving newsletters, information, and guidance on the latest knowledge to improve laboratory animal welfare with the National Centre for the Replacement, Refinement, and Reduction of Animals in Research (NC3Rs). Also, to use NC3Rs experimental design to ensure our methods and findings are robust and reproducible.
Having regular meetings and discussions with the local animal Establishment and close liaison with the Named Information Officer.
Attending the internal and external training courses available to learn and obtain updated information about the advances of the 3Rs in animal research.

Home Office

NON-TECHNICAL SUMMARY

208. Uncovering Novel Targets for Pulmonary Arterial Hypertension

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Pulmonary hypertension, Therapy, Pharmacology, G protein-coupled receptors

Animal types	Life stages
Mice	adult, embryo, neonate, juvenile, pregnant
Rats	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim of our research is to advance the understanding of pulmonary arterial hypertension and uncover new drug targets for the disease.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is currently no cure for pulmonary arterial hypertension and current treatments, such as phosphodiesterase 5 inhibitors, calcium channel blockers, prostacyclin receptor agonists and endothelin receptor antagonists, which have little effect on disease prognosis, can cost over
£300,000/year/patient. The only way to completely reverse pulmonary arterial hypertension is a lung or heart/lung transplant. Understanding the triggers of the disease and uncovering new drugs for pulmonary arterial hypertension is essential.

What outputs do you think you will see at the end of this project?

We have identified novel proteins, such as G protein-coupled receptors, which are significantly increased in the blood vessels of patients with pulmonary arterial hypertension compared to patients with normal pulmonary pressure. G protein-coupled receptors and their downstream pathways are excellent drug targets: >30% of current approved drugs target GPCRs, a number of which are used to treat pulmonary arterial hypertension. The research, although basic science in nature, is aimed at providing a greater understanding of pulmonary arterial hypertension and validating novel drug targets for the disease that have not been previously been described. The results generated from the studies will have wide implications for the field of research in pulmonary arterial hypertension and be published in peer reviewed high impact journals, presented at national/international conferences and by engagement with the public and patient groups. Furthermore, increasing the understanding of PAH could lead to additional understanding of other lung pathologies such as COPD, HIV infection, connective tissue disease and congenital heart disease.

Who or what will benefit from these outputs, and how?

In the short-term, researchers (both in nationally and internationally) will be able to incorporate this new target into current models of pulmonary arterial hypertension. It is envisaged that validating novel G protein-coupled receptor targets will lead to interaction with major drug companies to develop screens for drugs or humanized antibodies directed to these proteins that could inhibit its activity, which if successful will generate valuable tools for clinical research. The insights into disease pathogenesis will also help the medical community understand the disease process. It is hoped that the main beneficiary one-day, in approximately 5-10 years, from this work will be patients with pulmonary arterial hypertension, who currently have no curative treatment available.

Once potential therapeutic agents are identified it is anticipated that they will be tested in-vivo. Such invivo experiments will provide evidence for the clinical utility of these agents for pulmonary arterial hypertension and intends to lead to novel therapies for the disease, although full preclinical testing may be required. Since existing drugs target GPCRs and phosphodiesterase, depending on the targets we uncover preclinical testing would already have been carried out, therefore drugs could fast track to the clinic.
Fast track to clinic is important as although pulmonary arterial hypertension (PAH) is relatively rare (approximately 3000 cases in the UK), it has a poor prognosis and current treatments costs up to £300,000/year/ patient. Currently used drugs for PAH are insufficient. PAH most often occurs in young women and, if left untreated, the life expectancy is just two years from diagnosis.

How will you look to maximise the outputs of this work?

In order to maximise the outputs from our proposed work we will continue to publish our findings, both positive and negative (which is now standard practice in a number of journals such as Scientific Reports), on our website (to a lay audience), at national/international conferences and in open access peer reviewed journals. We already have a number of active collaborations in the field that will facility dissemination of our findings to the community.

Species and numbers of animals expected to be used

- Mice: 4500
- Rats: 2250

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The experimental protocols used to model pulmonary arterial hypertension are based upon well-established methods optimized to minimize animal suffering. Mice and rats between 2 months of age or older (younger animals or neonates do not show measurable remodelling of the pulmonary artery) have been shown to be highly effective model organisms to study pulmonary arterial hypertension and have validated the use of now approved drugs and helped uncover novels finding regarding the pathophysiology of the disease. Rats are required to be used in the monocrotaline-induced pulmonary hypertension, as mice are resistant to pulmonary remodelling associated with this plant alkaloid.

Typically, what will be done to an animal used in your project?

Genetically modified mice will be generated to assess the function of importance of genes thought to influence the development/pathology of lung disease, in particular PAH.
Pulmonary arterial hypertension will be induced in either GA mice or normal mice and rats by either housing the animals in a hypobaric/hypoxic chamber for 21 days chamber (similar to living at high altitude) with or without SU5416, a VEGF receptor antagonist administered by injection once weekly for 3 weeks. Alternatively PAH will be inducted in rats by a single injection of monocrotaline with PAH developing over within 14 days. Some animals will undergo ECHO MRI scanning normally on up to 2 separate occasions. Blood sampling will allow us to detect changes in hormones, endogenous ligands, circulating mediators and drug and metabolities (max 4 times per animal). PAH is characterised by remodelling of the pulmonary artery and right ventricular hypertrophy. Potential therapeutic agents or biological manipulations (e.g. genetic alterations) will be performed during these protocols to investigate if natural, synthetic substances or genetic alteration can blunt/reverse/prevent the remodelling of the pulmonary circulation and right ventricular hypertrophy. Therapeutic agents will be administered by the most appropriate route of administration/ exposure using the most suitable regime. Routes of administration may include injection via subcutaneous, intravenous, intraperitoneal, and oral routes including gavage or the addition of substances in the diet or water. If a reversal experiment is being undertaken, after pulmonary hypertension has developed (21 days or 14 days) animals will be housed for a further 21 days.

What are the expected impacts and/or adverse effects for the animals during your project?

The work will involve animals developing pulmonary hypertension. Animals housed in the hypoxic chamber show no adverse effects. The monocrotaline induced pulmonary arterial hypertension, in some cases, may induce clinical signs of pulmonary or cardiac failure in rats. These symptoms only occur in approximately 20% of animals and if seen the animals will be euthanized. Even if euthanized early the tissue from these animals will still be collected and used in experiments as they have developed the PAH.
Genetically modified mice, mice and rats developing PAH using other methods, undergoing ECHO MRI scanning, receiving potential therapeutic agents and/or blood sampling are not expected to show any adverse effects.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The majority of the planned experiments have a mild severity. Animals housed in the hypoxic chamber show no adverse effects. The monocrotaline induced pulmonary hypertension, in some cases, may induce clinical signs of pulmonary or cardiac failure. These symptoms only occur in small number of animals and if seen the animals will

be euthanized once an appropriate humane end point has been identified (Cardiac failure occurs in 20%). We have 4500 mice and 2250 rats on the licence, so 6750 animals in total. Moderate - 20% of protocol 2 animals (250) show moderate signs that's 50/6750 so less than 1% of all animals. < 3% of rats 50/2250.

Mild – the rest.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Since pulmonary arterial hypertension is a complex multifactorial and multicellular disease we need to use animal models to fully understand the pathophysiology and triggers of the disease and the potential benefits and possible side effects of any of the targets and therapeutic agents we investigate. The experimental protocols used to model pulmonary arterial hypertension are based upon well-established methods optimized to minimize animal suffering. Mice and rats have been shown to be highly effective model organisms to study pulmonary arterial hypertension, since the remodelling of the lung and right ventricular hypertrophy are comparable with that seen in the human disease. These models have validated the use of now approved drugs and helped uncover novel finding regarding the pathophysiology of the disease. By consulting FRAME, the Journal of Alternatives to Animal Experimentation, NC3Rs, Norecopa and other resources we have confirmed that, at this point in time, no other viable alternative models are currently available for pulmonary arterial hypertension.

Which non-animal alternatives did you consider for use in this project?

Where possible, our laboratory performs experiments using cultured human pulmonary artery smooth muscle cells, endothelial cells and fibroblasts isolated from patients with normal pulmonary pressures and those with pulmonary arterial hypertension or commercially available cell line to help dissect the molecular mechanisms that contribute to the development of the disease. All novel targets and therapeutic agents are validated in human cultured cells before commencing any animal studies. We have considered cell culture and organelles and will routinely carry out extensive literature searches (including N3CRs, the Journal of Alternatives to Animal Experimentation, CRACKIT, Norecopa, FRAME etc) throughout the project in an effort to continually improve and refine our experimental techniques to identify appropriate in vitro replacements for these animal studies.

Why were they not suitable?

Since pulmonary arterial hypertension is a complex multifactorial and multicellular disease it cannot be fully modelled using cells isolated from the pulmonary artery and grown in culture. Cells isolated from patients with normal pulmonary pressures and those with pulmonary arterial hypertension are also a limited resource in the research community and have a finite life span in culture.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse. How have you estimated the numbers of animals you will use?

Animal numbers will be determined so as the minimal number of animals will be used to produce meaningful data.

To estimate numbers we take into consideration the size of the effect we are interested in (right ventricular hypertrophy and pulmonary remodelling), the number of responses we intend to measure and the number of targets or drugs we intend to investigate over the duration of the licence. Appropriate advice will be taken from suitably qualified statisticians within the institution in order that our studies are always undertaken using the minimal number of animals but retaining appropriate statistical rigor
throughout. Previous experiments from our lab (including those from our GA colony) and others using the same animal models or drugs provide useful data on which to base an estimation animal numbers over the 5 years.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Animal numbers will be determined using power calculations so as the minimal number of animals will be used to produce meaningful data. Currently, I have access to a biostatistician for ongoing and future studies and NC3Rs experimental. Design Assistant. Online tool such as NC3R's Experimental Design Assistant will be used to design experiments. At all points we will follow ARRIVE guidelines for all of our experimental set ups.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Clear planning will ensure breeding is closely aligned with the proposed experimental plan. All pilot studies will be performed, followed by vigorous statistical analysis including p-value, effect size and experimental power, in such a way that any data generated can be added to any further study. Control tissue will be obtained from suitable (age/sex/breed) wild type animals through a tissue sharing initiative implemented by a number of PIs. We also ensure optimization of protocols for the high output of viable cells per lung.
Skills of the breeding wing technicians ensure GA colonies are run most efficiently – close monitoring of any changes to phenotype, pre-weaning loss, litter size and general breeding mothering performance constantly being tracked.
All procedures will follow robust SOPs.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The experimental protocols used to model pulmonary arterial hypertension are based upon well-established methods optimized to minimize animal suffering (animal models and phenotyping methods in pulmonary hypertension research. Pulm Circ. 4(1):2-9, 2014
). Both mice (allow for GA) and rats (allow for monocrotaline-induced pulmonary hypertension and extensive remodelling) have been shown to be highly effective model organisms to study pulmonary arterial hypertension and have validated the use of now approved drugs and helped uncover novel and clinically relevant findings regarding the pathophysiology of the disease. In addition, there are several advantages of using mice for understanding pulmonary arterial hypertension, such as the ability to easily manipulate genetic and physiological parameters.

All equipment, which will be used according to standard operating procedures, will be regularly serviced and checked. All procedures will be carried out according to robust SOPs, experienced staff will be involved in all procedures, measures including the timings of the studies. Measures will be taken to ensure animals becoming sick can be identified as soon as possible, sick animals will be humane killed.

Where possible

ear biopsies or hair sampling will be performed for genotyping analysis, instead of blood sampling, as this will give the least harm and stress to mice.
Wherever possible, animals will be group housed in same-sex groups and only singly housed if they demonstrate fighting within a cage.

Why can't you use animals that are less sentient?

Younger animals do not develop measurable pulmonary hypertension due to the small size of their heart and resistance pulmonary arteries. Use of younger animals would limit the number of cells that could be isolated per lung and yield insufficient numbers to carry out the proposed experiments. In the moncrotaline model of pulmonary arterial hypertension mice do not develop pulmonary remodelling, therefore rats are required. Insects and nematodes aren't suitable because they don't have lungs and therefore cannot model human diseases.

Terminally anaesthetised animals can be used for some outputs. For reasons (i.e. the time taken to develop PAH) terminal anesthesia is not practical for all outputs.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Appropriate observational monitoring protocols will be implemented. All staff will be trained and assessed before carrying out any procedures. If any animals show signs of heart failure e.g. 20% of the MTC rat model), the protocol will be immediately stopped and all animals humanely killed. Clinical signs of cardiovascular disease usually occur in the last 48 hrs of the protocol so experiments will be planned so this does not occur over the weekend to allow more frequent monitoring. In the case of our genetically modified animals, if any animals develop a moderate harmful phenotype and signs of suffering they will be immediately humanely killed and advice will be sought promptly from the local Home Office Inspector. Tissues will be harvested wherever possible if animals are euthanized, so meaningful data can still be collected. Ear biopsies will be performed for genotyping analysis, as this currently is the least harmful and stressful method for mice. We will closely monitor the situation for less harmful methods arising. For ECHO MRI treats will be used to guide them in the tubes and prevent stress.

Animals housed in the hypobaric/hypoxic chamber show no adverse effects and animals will be housed within their home cages with their cage mates and enrichment within the chambers. A period of 2 days allows for acclimatization to the hypoxic environment. Monocrotaline induced pulmonary hypertension, in some cases, may induce clinical signs of pulmonary or cardiac failure. These sudden onset symptoms occur in small number of animals (~20%) and if seen the animals will be will be euthanized Even if euthanized early the tissue from these animals will still be collected and used in experiments as they have developed the PAH. It is unclear why a small percentage of animals develop pulmonary or cardiac failure after a single dose of monocrotaline. Weight loss will be monitored to identify if this may predict the adverse effects. Furthermore, experiments will begin on a Thursday to allow close monitoring nearer the end of the 14 days, when these adverse effects usually occur. Since stress can trigger heart failure in the monocrotaline-treated rats, we will try to handle them more often to reduce stress when cages are cleaned or animals moved. Scoring sheets will be used to monitor health and wellbeing of the animals during the protocols.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All experiments will follow ARRIVE (Animal Research: Reporting of In Vivo Experiments) guidelines, which allow for the correct reporting of research using animals, maximising the information published and minimising unnecessary studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will continue to keep up to date with ARRIVE/PREPARE guidelines and receive monthly updates from the NC3Rs on events and publications regarding knowledge exchange and evidence-based changes in policy, practice and regulations. Furthermore, I will attend local training events.

Home Office

NON-TECHNICAL SUMMARY

209.Understanding brain and behaviour during neurological dysfunction in sheep

Project duration

1 years 2 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Huntington's disease, transgenic, sheep, behaviour, naturalistic

Animal types	Life stages
Sheep	adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To identify non-invasive biomarkers of neurological dysfunction that can be used to track the onset and

progression of measurable changes in behaviour and circadian rhythms in a sheep model of Huntington's disease

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

There is a large unmet need in the treatment of neurological diseases such as Huntington's disease (HD). HD is a late onset progressive neurodegenerative disease that causes disease in everybody carrying the gene. The disease affects the brain and causes problems with movement, thinking, planning, and emotional behaviour. Patients typically die 15-25 years after the disease starts. To track the progression of the disease or to determine if treatments are working, we need a way of measuring dysfunction. It is particularly important to focus on the earliest stages of disease, since it is likely that in the future this is when preventative therapies will be started. There is only one licenced treatment available for HD that targets the movement abnormalities. There are none that can prevent the onset or progression of HD.

The HD sheep is a good model for studying the earliest stages of HD since they carry the gene mutation that would cause disease in a human in late childhood. The HD sheep shows no overt signs of disease up to the age of 5 years, but by 5 years show some measurable changes in behaviour and metabolism. We will continue to study a cohort of HD sheep from 6 years onwards. This period moves towards the period that the HD sheep might be expected to show signs that herald the beginning of the disease. If we can identify a biomarker that changes measurably with the course of the disease, this can be used for testing potential therapies, such as gene therapies that are currently under development. For example, if a biomarker is reduced or slowed by a treatment, it shows a therapy is effective; if it gets worse or appears earlier after treatment, then that treatment may have harmful side effects. Unlike small molecule therapies that can be reversed by stopping taking the treatment, gene therapies are delivered directly into the brain. There are antisense oligonucleotide gene therapies currently under development that are being tested for safety. The effect of these will last for months. Other therapies in the pipeline that are awaiting preclinical testing, including some of those delivered via viruses, will last a lifetime. The long term effect of these therapies is not known.

What outputs do you think you will see at the end of this project?

At the end of this project we will have a comprehensive understanding of the natural history of the disease phase that occurs before symptoms appear (presymptomatic) and the beginning of the phase when symptoms may start to appear (phenoconversion period) in the HD sheep. This will add to data that are already available for the HD sheep up to 5 years of age. The expected outcome will be a complete characterisation of neurological changes, that are detectable in the circadian, cognitive, and sleep behavioural domains, in the HD sheep from 6 to 11 years. These new data will be published in peer reviewed scientific journals. This will extend our understanding of the natural history of the HD sheep model to cover the whole period of the HD sheep life when it is likely that they will be used in pre-clinical studies for testing therapies, for example.

Who or what will benefit from these outputs, and how?

A comprehensive characterisation of the HD sheep will allow future users of the model to design experiments aimed at investigating either the safety and efficacy of novel therapies without needing to first characterise the model. This is similar to the situation in 1995 when the first HD mouse was developed but not characterised. Once the natural history of the sheep model is characterised, it will increase the opportunities for using this as a model to understand the mechanisms underlying HD. In particular, knowing the time course over which HD-related changes appear will help future investigators to pinpoint the most relevant time period of study. For example, investigators interested in understanding the parts of the brain that cause loss of motor control in HD would be able to choose to study HD sheep close to the time when movement abnormalities appear.

How will you look to maximise the outputs of this work?

I will collaborate with other scientists by sharing our primary data. Knowledge will be disseminated by publication of data and/or presentation of data via lectures. We routinely publish negative results as well as positive findings. Together such data allow a comprehensive understanding of multiple aspects of the natural history the HD sheep.

Species and numbers of animals expected to be used

- Sheep: Up to 21 adult sheep

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Sheep are particularly suitable animals for this study for the following reasons

1. Adult sheep exhibit complex behaviours that are relevant to HD and that can be measured in the laboratory.

2. Sheep have large brains (that are smaller than a human brain but slightly larger than the brain of an adult Rhesus macaque monkey), with human-like anatomy, including a convoluted (folded) cortex and relevant parts of the brain (such as the striatum that is the first part of the brain to degenerate in HD).

3. Sheep are much easier to manage than monkeys, and unlike monkeys can be kept under naturalistic conditions where they are free to express natural behaviours.

4. Sheep can be safely group housed with their social companions when they are not being used for experiments.

5. Sheep are long-lived and can live for at least 14 years. This give us a much bigger window of opportunity for studying them, particularly compared to mice and rats that typically only live for a couple of years. HD sheep have measurable differences compared to normal sheep by five years of age but live for at least 12 years without overt signs of disease. They are ideal for studying the stage of HD when a patient transitions from looking normal to showing symptoms.

6. Sheep are a less sentient species than non-human primates.

Typically, what will be done to an animal used in your project?

The ability of sheep to learn and remember a task and to navigate a maze will be measured once or twice a year. Eye movement control will be assessed regularly, at least twice a year. They have all been trained to sit in veterinary slings, that will be used for measuring their eye movements since the equipment is delicate. (Eye movements are measured using a specialised camera). The slings are canvas supports that fully support the body of the sheep with its feet off the ground. This makes the sheep very comfortable and calm. The training is required to teach the sheep to stand over the sling so they can be lifted. Some measures of health and well-being will be monitored regularly throughout the year (core body temperature, heart rate). All of these will be measured non-invasively. The sheep will live together in a flock, either in pasture or in pens in barns. If they are housed outdoors, they follow the investigator from the field to the testing area where they wait until it is their turn for testing. Their participation in learning and memory tasks is voluntary, and they can end the task at any time. After testing, they return to their paddock or pen.

What are the expected impacts and/or adverse effects for the animals during your project?

Behavioural testing is non-invasive.
Adverse effects from carrying the HD gene are not expected, since it is already known that HD sheep can live for at least 12 years without showing overt signs of disease.
Because the sheep will be ageing naturally, expected adverse events are associated with this. Age-related changes may include loss of teeth, joint degeneration, slower recovery from accidental injury, stiffness or slowness

of movement. Difficulties in feeding from natural loss of teeth will be overcome by replacing their usual food with one that requires less chewing.
HD patients lose weight as their disease starts, and weight loss associated with the aging or the disease might be expected.
Their ideal body weight is taken as their weight at 4 years (fully grown) when they were acquired, when they all had good body condition scores. Up to 10% of sheep adult body weight might be expected once they become symptomatic.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Normal sheep
Behavioural testing and non-invasive physiology recording will be mild (100%), the effects of aging (50%) will be moderate.
HD sheep
Behavioural testing and non-invasive physiology recording will be mild (100%), the effects of aging and onset of HD (100%) will be moderate.

What will happen to animals at the end of this project?

- Killed
- Kept alive
- Rehomed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Measuring changes in complex behaviours (such as cognitive function, social behaviour, control of eye movement) caused by long-term expression of the HD gene requires an intact awake 'behaving' animal.
Behaviour cannot be measured in tissue culture or by using tissue isolated from an animal.

Which non-animal alternatives did you consider for use in this project?

There is no non-animal alternative for this study.

Why were they not suitable?

N/A

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken

to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Previous behavioural studies that 8-10 sheep will be needed per genotype group. The longitudinal testing means that the animals serve as their own controls.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The experiments planned can be done with this minimal number of animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use all of the sheep we have available.
If we have to kill humanely any of the sheep before the end of the study, we may collect post mortem tissue that could be shared with other groups.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will use a genetically-altered sheep model of HD. This is the only sheep model of HD available.
None of the methods we will use will cause lasting harm to the animals.

Why can't you use animals that are less sentient?

HD mice do not live long enough for the proposed studies to be conducted. Anaesthetised animals cannot perform behavioural tasks.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The methodology for the studies has been designed to minimize welfare harms for the animals. Positive reinforcement will be used in our behavioural tasks, and for most of the tasks. Experienced, familiar handlers will conduct all of the experiments. For experiments where animals are required to be still (e.g. during eye movement measurement) the animals have all been trained using positive reinforcement to sit quietly in veterinary slings.
We will constantly review all procedures before the start of experiments as part of our study plan. We will update our protocols according to new information as it arises where it does not compromise the analysis of data already collected.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We already use the ARRIVE guidelines and will continue to do so. We will design any experiments for which a method does not exist using the PREPARE guidelines.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will attend relevant courses and lectures. We will use our establishment's 3Rs search tool and consult 3Rs websites for relevant advances.

Home Office

NON-TECHNICAL SUMMARY

210. Understanding cancer biology and therapeutic options in preclinical models of cancer.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, therapy, genetic models, transplantation models, metastasis

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim is to carry out fundamental cancer biology and translational research to deepen our understanding of the processes that cause cancer, and to use the most relevant mouse models of cancer to investigate new and improved therapies that will benefit patients.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

Cancer is a major health issue for the population and accounts for more than one quarter of all deaths in the UK while being a significant burden on the NHS. Understanding how cancers arise, grow and spread is paramount to our ability to prevent and treat the disease.

What outputs do you think you will see at the end of this project?

Projects covered by this licence will lead to new knowledge in fundamental cancer research and increase our understanding of how tumours initiate, grow and spread to other organs. In particular we will tease apart how cancers are influenced by their environment and metabolic dependencies.
Our goal is that these projects will identify new pathways for therapeutic intervention and lead to the development of novel anti-cancer therapies.
Work arising from these studies will be published in peer review journals and presented at national and international meetings to disseminate knowledge (to scientists and clinicians). We will also publicise our results to the public at open evenings, social media, and on our website.

Who or what will benefit from these outputs, and how?

The knowledge gained from these studies will be of interest to the scientific community (short term) and cancer clinicians. Ultimately we hope this will lead to new therapeutic approaches benefiting cancer patients (medium to long term). Furthermore, studies and validation in our preclinical mouse models should inform clinical trial design (medium to long term).

How will you look to maximise the outputs of this work?

We will continue to collaborate with national and international colleagues and disseminate this work through publication and social media at the earliest opportunity.

Species and numbers of animals expected to be used

- Mice: 75,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Cancer is a disease that results from gene alterations (mutations and loss of normal genes) and therefore the best

way to model the causes of cancer is to use genetically altered animals in which the same gene changes are recapitulated in the mouse. These genetically altered animals (GAA) are predisposed to developing cancer and act as a tool for us to test the principle of novel therapeutic strategies that could be used for patient benefit. We also use transplantation models whereby we can transplant tumour cells into specific sites of the mouse (e.g. breast cancer cells into the mammary gland) to understand how the tumour, the host environment and therapeutic agents impact upon tumour progression. Cancer is an age-related disease and sometimes we have to age our cancer-prone mouse models (for up to 2 years) to mimic the clinical situation.

Typically, what will be done to an animal used in your project?

Animals with different gene alterations will be bred to achieve test subjects which may be predisposed to cancer. Approximately 70% of the mice will not show any adverse effects relating to their breeding and not undergo any procedures except for ear notching for identification and genetic testing. These will be humanely killed when they are no longer required for breeding. It is unfortunately necessary to breed so many animals to create the right combination of patient relevant gene changes in a few key cohort animals. In the future we hope to be able to circumvent the need to use so many animals but at the moment this is the best way for us to study the causes of cancer.
A proportion of animals (no more than 25%) will develop cancer because of their genetic makeup or because tumour cells have been implanted and allowed to grow. Tumour cells may be implanted into some tissues (such as mammary gland, kidney) using a surgical procedure with appropriate anaesthesia and analgesia. Administration of an inducing agent to switch on/off particular genes may be done which only causes momentary discomfort but reduces off-target effects in other tissues.
Animals will be monitored closely by highly trained staff for well-established clinical signs such as weight loss, swelling of the abdomen, and development of visible or palpable tumours. Some of these animals (15-20%) will be given anti-cancer treatments, changes in their diet, antibodies to reduce certain immune cell types, or cancer causing agents (for example chemicals/irradiation) and the response to these treatments monitored. All animals on treatment will be closely monitored and may be blood sampled to follow changes in biomarkers which should cause only mild handling stress and momentary discomfort or may be imaged by ultrasound, CT scan or for reporter markers. Any animal that displays signs of illness such as weight loss of 20%, immobility or ruffling of the coat will be humanely killed - this depends on the type of cancer but usually within 12 months and never longer than 24 months. At the end of the study all animals will be humanely killed and tissues collected at post-mortem to gather as much information from the study as possible.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will be predisposed to tumour development. We are very familiar with the clinical signs associated with these tumours and all researchers are trained in these models. Any animal exhibiting clinical signs of cancer will be humanely culled at pre-determined end-points of no more than moderate severity.
Anti-cancer treatments can cause gastrointestinal and haematopoetic disturbances as they do in cancer patients. Animals are monitored closely when undergoing such treatments and treatments stopped or animals killed if these effects cause suffering to the animal that cannot be resolved.
Surgical techniques are controlled with anaesthesia and analgesia and any animal who does not fully recover from such a procedure will be humanely killed.
For some of our models we use the FVB/N background strain which has a predisposition to sudden death syndrome (overall in our colonies in the last 18 months =1.1%) and neurological disorders (e.g., hyperactivity, spinning). We will periodically report the incidence if greater than 1% and will continually review the incidence of unexplained deaths. Any animal with hyperactivity or spinning that doesn't resolve (< 30 minutes) or which recurs will be killed by a Schedule 1 method.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals on this project (70%) will have a subthreshold severity meaning they will show no harm. About a quarter of animals (25%) will develop cancer in which 10% will have mild symptom such as small palpable tumours or taken at a timepoint prior to clinical signs manifestation. The remaining 15% will exhibit moderate

clinical signs associated to their cancer burden.
With respect to other procedural burden (e.g. imaging, anti-cancer drug treatment), 20% of animals will experience one or more procedures which will never exceed a moderate severity and where we anticipate 8% will experience a mild procedural severity with 12% experiencing a moderate procedural severity.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Although many aspects of cancer research can be conducted using cell lines, the potential of a putative cancer causing gene and the accumulation of secondary events necessary for a cancer to fully form often needs to be assessed within the context of the whole animal. Furthermore, non-animal alternatives cannot totally model the complexities of cancer development as it is well recognised that the immune system, energy requirements and the tumour micro-environment play an important role in disease progression. Whilst the mouse is still not perfect for modelling a human being, we know that we can get closer to patient relevance using a living mouse model alongside our lab assays.
Most cancer patients die not from their primary tumour but when it spreads to other organs and to model this in the most effective way requires a living organism. Finally we know that cancer cells respond differently in the lab to anti-cancer therapies as they do in the context of the animal and so testing the efficiency of such therapies requires a complete animal system.

Which non-animal alternatives did you consider for use in this project?

Our mouse experiments are an extension of solid lab-based observations and only progress using mice when sufficient rationale is obtained based on *in vitro* cell culture. Where possible we use 3D organoid based systems, patient material and mathematical models alongside our mouse models. Organoids and 3D models are excellent ways to study genetic changes in a cancer cell and how this might affect cell growth and cell survival. We are also developing better ways to assay how cells invade and spread (as a model for cancer metastasis). We use these systems to check selectivity and specificity of a new compound for example, which allows us then to prioritise the best candidates to take forward in a physiological system for validating tumour targeting effects.

Why were they not suitable?

Modelling cancer and how cancers spread to other organs in anything other than a whole animal has obvious limitations. The interactions between the different cell types that make up a cancer (tumour cell, immune cells, blood vessels) is difficult to do in a dish. Patient samples tell us about end stage tumours but to understand what is happening at early stage of disease requires model systems.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

This licence will be used by several different research groups and the numbers reflect the need for many different lines of investigation. Cancer is a disease in which several different gene changes occur and so we have to breed many mice in order to achieve the 'sweet-spot' of gene alterations in any one animal. Numbers are calculated based on our experience using the same models, published literature and advice of our in-house statistical experts.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

When planning our experiments we use pilot studies in the first instance, to inform on how many numbers we require taking advice from our in-house statisticians and using the NC3Rs Experimental Design Assistant or other statistical websites which informs us of our effect size in order to guarantee our studies are meaningful.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We share animals between experimental groups where possible - e.g. when we need normal animals for controls, we can often obtain these from our breeding colonies where they would normally not be needed in a study. We also harvest surplus tissues from experimental cohorts to use these tissues in other studies replacing the need to undertake additional cohorts.
We maximise our breeding strategies to generate the most effective breeders to create the genetics of interest for our studies and we use tumour transplant models where appropriate, which do not require breeding of genetically altered animals and thus use fewer animals in total per study.
We use inbred strains of mice which are nearly identical to each other resulting in less variability between animals and allow us to use fewer animals to achieve a statistically significant result.
To reduce numbers of mouse-based experiments we always perform studies using cell lines or 3D models so that only our strongest hypotheses are tested in the mouse.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We use mouse models with the same genetic changes that are known to cause human cancer – so accurately replicating the human disease. These genetic changes are specifically altered in the tissue of interest so that unrelated effects in other tissues do not occur. All animals are monitored regularly for signs of normal behaviour and are humanely killed if they exhibit moderate adverse symptoms. All staff are expertly trained in these clinical signs. Regular monitoring of mouse welfare allows us to complete studies at the earliest endpoint in which we observe a significant result to prevent unnecessary suffering resulting from high tumour burden.

Why can’t you use animals that are less sentient?

The mouse is a mammal and warm-blooded which shares many features of human physiology and metabolism not found in other cold-blooded species such as flies and worms. Furthermore with the ease of manipulating the genetics of the mouse, this makes the mouse the best model organism to understand the genetic changes observed in cancer.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Animals are housed in a dedicated facility proactive with environmental enrichment and receive anaesthesia and analgesia as appropriate.
All animals are health checked daily in addition to the routine monitoring by the researcher. Where any animal shows abnormal behaviour this animal is placed on enhanced inspection. Study animals are often weighed and tumours measured at regular intervals to detect early clinical signs.
We have written standard operating protocols for all our models with researchers being trained and signed off only when proficient in the clinical signs of the models.
We always refer to previous studies for adverse effects of anti-cancer therapies and when a group is given a treatment for the first time, we initiate the study with a small number of animals (n=3-6) which is closely monitored before extending to a larger number. Where possible we use the least invasive method of drug administration.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We adhere to the Workman Guidelines for the welfare and use of animals in cancer research and regularly review the NC3Rs website.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We continually review our processes and take advice from the Named Veterinary Surgeons, Named Training and Competency Officer, Home Office Inspectors and the NC3Rs website. Our technical staff are very proactive in adopting 3Rs advancements such as non-aversion handling and single-use needles and contribute/attend in-house events such as 'culture of care AWERB' and 3Rs workshops.

Home Office

NON-TECHNICAL SUMMARY

211. Understanding how behaviour modulates neural responses in the visuomotor system

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Brain activity, Vision, Decision-making, Internal state, Motor activity

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We have two overall aims. First, we want to understand how the brain integrates visual information with information about the subject’s behaviour and internal state. Second, we want to understand how the brain uses this integrated information to control decision-making and motor outputs.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration

of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our understanding of how the brain enables us (and non-human animals) to sense the environment, make good decisions, and act accordingly is still very limited. One problem is that a large portion of brain activity cannot be explained by sensory input. For example, the exact same image or video can elicit different activity every time it is seen, even in nerve cells that are in the eye and sense the incoming light.
Using the nerve cells in the early visual system as a model, this project aims to understand:
(1) how activity in nerve cells is influenced by non-sensory factors such as the animal's behaviour or internal state,

(2) which biological mechanisms underlie these influences, and

(3) how the modulation of this sensory brain activity affects brain activity controlling decision-making and motor actions.

This project will lead to a better explanation of the activity in the brain, a better understanding of the computations performed in the brain, and thus a better understanding of the brain's failures in disease.

What outputs do you think you will see at the end of this project?

The main benefit of our research is to increase knowledge about brain function. We currently know little about how the brain works. In our field of research, scientists only recently realized that the visual system, i.e. nerve cells and brain areas that make sense of the visual input, is affected by behavioural state like locomotion and the level of alertness. For example, neurons that reliably respond to a certain visual input like the picture of a black bar on white background respond more or less to this very same stimulus depending on whether the animal is highly alert or tired and drowsy. That even nerve cells in the retina are affected by this modulation is a very recent finding from our previous work. What we do not yet know are the specifics of the behavioural modulation of vision, i.e. whether the processing of certain stimuli is more or less modulated, or whether certain types of cells are more or less prone to modulation by behaviour. We also do not know why the brain modulates visual signals depending on behavioural state, and how does it do so.
The goal of this project is to contribute the following milestones:

- Understanding the effect of the animal's behavioural state like its speed of locomotion or its level of alertness on visual processing
- Understanding the purpose of this modulation regarding the efficiency of visual processing and regarding behavioural performance in tasks that depend on vision

- Understanding how these behavioural effects are mediated

At the end, we will have a better understanding of how behaviour and internal states shape vision.
In addition to new knowledge about the brain, we will also contribute by developing techniques to learn about the brain. We will refine methods to record functional activity of single retinal ganglion cells (neurons that transmit information from the eye to the brain) over a long time period of weeks to months.
The knowledge we gain will be published in peer-reviewed articles. Manuscripts will also be published on a preprint repository so findings are available to public as soon as we deem them ready for publication. We will present findings at conferences and during invited talks.
Datasets of neural recordings and simultaneously recorded behaviour of animals will be published online, and code developed by our group to analyse the data will be made publicly available.

Who or what will benefit from these outputs, and how?

The outputs of this project will directly benefit scientists who study the visual system and the processing of visual information in the brain, and scientists who study decision making based on visual information. In addition, findings on behavioural modulation in visual processing are likely to generalise to other sensory modalities. So, this work may lead to new hypotheses in these fields.
The outputs can also directly benefit scientists working on therapies of eye diseases because we are now able to

record the activity of single retinal ganglion cells in awake animals on a daily basis over a time span of weeks up to several months. This technique could be used by scientists developing therapies to treat retinal degeneration as they can observe the functional changes of retinal ganglion cells throughout their therapeutic treatments. Moreover, the outputs of this project may have indirect benefits for scientists studying visual impairment in relation to diseases that are accompanied by abnormal behaviour. For example, ADHD is thought to involve the malfunctioning of a visual area (superior colliculus) involved in guiding our attention. It is thought that this area is overactive in ADHD patients, and therefore these patients cannot stabilize their attention but get distracted by any new visual stimulus that is perceived. Our goal to better understand of how visual signals in the brain are influenced by behavioural states or by neuromodulators that mediate these states may lead to a better understanding of visual malfunctions in disease. We expect that these benefits will only be seen in the long-term and after this project is concluded.

How will you look to maximise the outputs of this work?

To maximize the outputs of this project, we will closely collaborate with colleagues at our establishment who study the visual system or particular behaviours in mice. We will also promote the publications of our articles and datasets on social media channels like Twitter and via the media office of our establishment.

Species and numbers of animals expected to be used

- Mice: 2,100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Brain architecture of mice and particularly the visuomotor system that we will study is very well conserved across mammals and is thus similar to that of humans. Our findings will thus have a high probability to generalise to other mammals and humans.
Mice use vision in their natural habitat and they can be trained on tasks that require vision. Using mice, we can study visual processing in the brain and how changes in this processing influence behavioural performance.
Many genetic tools exist for mice. These tools enable us to study specific cell types, and measure and manipulate neural activity.
Mice can be kept in animal facilities typically provided at a university setting under conditions that cater their well-being and health.
We will be using adult animals because we are studying fully developed brain function.

Typically, what will be done to an animal used in your project?

Almost all of our mice will be bred in the local animal facilities.
Mice that will be used in experiments (an estimated 20%) usually receive an implant attached to their skull so they can be head restraint. We will gain access to their brain by removing a small part of their skull (about 0.5 – 5 mm in diameter). In some mice, we will induce the genetic expression of certain molecules by injecting viral vectors into the brain or the eye. We may also implant light guides (tens to hundreds of microns in diameter) to optically access deeper parts of the brain. These interventions are necessary to measure neural activity, identify certain cell types, or manipulate neural activity. These procedures are all performed under full anaesthesia and under aseptic conditions, and animals will be treated with analgesia during recovery from the surgery. Several surgeries may be necessary to accomplish our goals, for example if it is better for the animal’s well-being to split one surgery into

two or when genetic expression needs to be induced at certain time points after the animal has been trained, where training necessitates the head restraining implant. No animal will undergo more than 5 surgeries (each lasting more than 10 min).
Mice are then acclimated to head restraint over several days before we perform experiments to record neural activity. These experiments last at most 4 hours a day. Depending on the method of recording, the experiments continue for several days up to several months.
Some animals will be trained to perform a specific task, e.g. they have to choose one of two visual stimuli. To keep the mice motivated to learn and perform the task, their daily water intake will be restricted, and they will be rewarded with water when performing the task correctly. Animals are monitored every day for signs of dehydration, weight loss and abnormal behaviour, and their water intake will be adjusted accordingly.
At the end of the experiments, the animals will be culled or perfused for further histological processing of their brains.

What are the expected impacts and/or adverse effects for the animals during your project?

Animals will undergo surgery under general anaesthesia but are expected to make a rapid and unremarkable recovery from the anaesthetic within two hours. None of the surgical intervention, implants or viral injections is expected to lead to long-term harm.
Head restraint will cause stress to the animal but usually only during the first few sessions when the animal is acclimated. Once the animal is used to the head restraint, most of the time animals do not show signs of stress and behave normally, e.g. they run on a treadmill or they groom themselves.
In some experiments, in which neural activity is recorded, the insertion of the recording probe (a few microns in diameter) may cause temporary pain when the dura, i.e. the skin surrounding the brain, is penetrated.
Under water restriction, mice will most likely experience weight fluctuations and may show signs of dehydration. These effects will be monitored every day and provision of water will be increased as necessary.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

About 95% of the animals (2,000 of 2,100) are expected to undergo Protocol 1 (Breeding) and will experience a severity category of mild.
20% of the animals (420 of 2,100) are expected to undergo Protocol 2 (Measurements and manipulation of neural activity during behaviour), and thus will experience a severity category of moderate.
What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

We will study how the brain processes visual input during different behaviours, and how this visual processing impacts decision making and motor output. No artificial or non-living biological model system can replace the animals we use to perform our studies as we do not know the neural architecture and function that performs visual processing and controls behaviour.

Which non-animal alternatives did you consider for use in this project?

Parts of the brain (e.g. brain slices) and the eye (in particular the retina) can be removed from a dead animal and kept under conditions that allow nerve cells to stay functional. Such experiments are termed “in vitro” studies. These model systems can be used to study circuits of nerve cells and to some degree their function, e.g. which nerve cells are active together.
Artificial neural networks offer the opportunity to simulate biological neural networks.

Why were they not suitable?

In vitro models of populations of living nerve cells lack the input from the rest of the brain and they cannot be studied in relation to the animal’s behaviour, which is an essential goal of this project.
Regarding artificial neural networks, we have too little information about the biological networks in order to reconstruct them artificially. More importantly, we do not understand how nerve cells react and interact during natural behaviour.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Using statistical methods, we have determined how many nerve cells we need to record to answer each of our scientific questions and to draw robust conclusions from our results. Based on our previous experience, we have estimated how many nerve cells we will record from each animal. Both numbers together, i.e. the number of necessary nerve cells and the number of nerve cells recorded per animal, provide an estimate of the number of animals we will need to use for this project.
Several factors complicate the estimation of the numbers of animals though. First, there are uncertainties on the actual number of nerve cells we can record from each animal, as this depends on the quality of the preparation and the recording, as well as individual differences across animals. Second, although we have planned a number of specific experiments that we want to perform, the exploratory nature of our research demands some degree of flexibility in the planning of experiments. In the case of highly unexpected results from one experiment, we may adjust subsequent experiments, which may lead to different numbers of animals needed. In the case of inconsistent results from performed experiments, we will perform further experiments on other animals if it is likely that these experiments will lead to consistent and robust results.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Our experimental technology yields a large number of nerve cells that we are able to record in each animal: (1) we use state-of-the-art technology that allows simultaneous recording of hundreds to thousands of nerve cells; (2) we can perform these recording sessions several times on the same animal, so that every session yields another population of recorded nerve cells.
Our longitudinal experiments on awake animals last from several days to a few months. To gather the largest possible amount of data from each animal, and thus reducing the total amount of animals, we need to pay

particular attention to the health and well-being of each animal. Please, see Refinement for details on this.
When we are investigating functional differences between specific types of nerve cells, we will use several methods of targeting several types within the same animal. For example, we can use a transgenic animal to target one genetically defined cell type. At the same time, we can define other cell types based on the anatomical connection to other brain areas by injecting tracers into several brain areas.
We will constantly review the methods we are employing by following published literature or receiving advice from other experienced researchers in order to increase the effectiveness of our methods. This will reduce the number of failures, for example in targeting specific cell types, and will increase the success rate of experiments.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient use of animals bred both under this licence and under the authority of other licences within the establishment that allow for the breeding and maintenance of mice expressing genetically encoded reporters and effectors of neuronal activity. For example, we will avoid ordering additional wild type experimental animals whenever surplus mice can be obtained locally.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

In our experiments, we will use purpose bred mice, some of which are genetically altered so we can distinguish and target specific types of nerve cells. In comparison to many other mammals, particularly larger animals, mice can be kept in the laboratory under conditions that cater their health and wellbeing very well. The genetic modifications in the mice we are using are not expected to lead to pain or any harm for the mice. All animals will be co-housed with litter mates as mice are social animals. We will only make exceptions to this rule if the animal's health is impacted, e.g. when animals get injured by other cage mates or when animals are too vulnerable due to surgical implants or sutures.
We will perform surgeries to access parts of the animal's brain and to implant a plate that allows us to head restrain the animal. We always use appropriate anaesthetic and analgesic regimes for pain relief during surgery, and surgeries are performed under aseptical conditions. The implant weighs less than 1 g and does not affect behaviour of the animal in a negative way.
We will head restrain the animal during our experiments so we can reliably measure the activity of many neurons while also controlling the animal's sensory input, e.g. via visual displays. We will acclimatize the animal being head restrained step by step, starting by simply handling the animal and then restraining it just for a few minutes. After a few days, the animal is getting used to the procedure and does not show signs of stress anymore.
To record and manipulate brain activity we will use methods of two-photon imaging, electrophysiology, opto- and chemogenetics. Two-photon imaging can be performed on awake animals on a daily basis for weeks and months without any invasive procedures in addition to the initial surgery. The same is true for the manipulation of activity via optogenetics. Manipulation of activity via chemogenetics requires the injection of specific drugs that then only act on previously targeted neurons that express receptors for these drugs. Electrophysiology necessitates the insertion of a probe into the brain to record electrical activity of the neurons. The recording probes we are using are only a few microns in diameter, much thinner than a human hair. The animal might feel mild pain when the probe penetrates the skin surrounding the brain (the dura), but does not feel pain as the probe penetrates the brain itself as there are no pain receptors in the brain.
We will train some of our mice to perform a visual decision task where they have to choose the correct stimulus out of two presented stimuli. We do this to study how the brain processes visual input and it uses this information to

make decisions. To keep mice motivated to learn and perform this task, we restrict their daily water intake as they are rewarded with water when they perform correctly. We monitor the animals every day for signs of dehydration and ill health and increase their water intake accordingly.
Our research depends on the mice being healthy, cooperative, and engaged in the tasks that we trained them to perform, so we have many reasons to avoid any suffering. The measures we take to avoid any unnecessary suffering work: the mice are cooperative and engaged.

Why can't you use animals that are less sentient?

The brain is still developing until early stages of adulthood. Our goal is study processes in a fully developed brain, and we therefore use adult animals. A further advantage of using adult animals is that they do not grow anymore; implants mounted on the head therefore do not need to be adjusted for changing sizes of the skull.
Another goal is to study the influence of various behaviours on the processing of visual inputs. Therefore, we have to work with awake animals.
The function of the brain and its nerve cells is not well understood in most if not all animals. Studies of the brain are therefore necessary and useful in any animal species. We decided to use mammals, in particular mice, rather than species of a different class that may be considered less sentient, because the brain structures we are studying are conserved within mammals including humans but show greater differences across animal classes such as fish or birds.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

- After surgeries, the animals receive analgesic to minimize pain and are monitored closely for at least three days.
- Animals are acclimatised to the head restraint for several days starting with a few minutes of restraint on the first day. Animals are taken off head restraint if they show high levels of stress, and acclimation is continued on a slower rate for these animals.
- Animals under water restriction are closely monitored every day for changes in weight and signs of dehydration and illness. Water is given in higher amounts or ad libitum to restore full health.
- Training of animals on decision tasks is performed step wise starting at an easy level and slowly introducing more difficult conditions. The time point of introducing more difficult conditions is based on the performance of each individual animal. In this way, the animals are learning the task in the shortest time possible.
- Throughout the duration of this project, we will adapt all methods if better strategies become known and available.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will continuously refine our training procedures to follow best practice in this area, which is a very active one at the moment; e.g.,
Guo et al (2014) Procedures for behavioural experiments in head-fixed mice. PLoS One 9: e88678.
Burgess et al (2017) High-Yield Methods for Accurate Two-Alternative Visual Psychophysics in HeadFixed Mice. Cell Reports 20: 2513-2524.
Goltstein et al (2018) Food and water restriction lead to differential learning behaviours in a head-fixed two-choice

visual discrimination task for mice. PLoS One 13: e0204066.
Our participation in the NC3Rs working group mentioned elsewhere, through which we will disseminate any refinements throughout the community, also puts us in an excellent position to hear about and adopt any relevant updates to refinements developed by other researchers.
Surgical procedures will be carried out according to the published LASA Guiding Principles for Preparing for and Undertaking Aseptic Surgery (2017).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will follow several avenues:

- Participation in NC3Rs working group on 'high-yield rodent behaviour', through which we share best practice in this area;
- NC3Rs bulletins and newsletters;
- News and information provided by local NACWO/NTCO/NIO;

Scientific meetings with presentations on mouse behaviour and training.

Home Office

NON-TECHNICAL SUMMARY

212. Understanding how to stimulate the immune system to remove old, senescent cells, from aged tissues

Project duration

5 years 0 months

Project purpose

- (a) Basic research

Key words

Ageing, Telomeres, Telomerase, Immunity, Senescence

Animal types	Life stages
Zebra fish	embryo, juvenile, adult, neonate, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to determine which immune cells and mechanisms we can target to improve the removal of old, senescent cells, from aged tissues, where we know they contribute to chronic diseases of old age. The ultimate aim is to identify new potential therapeutic targets to promote healthy ageing.
Specifically:
Aim 1- Identify key immune cells involved in senescence cell clearance (Years 1-2)
Aim 2- Identify mechanisms involved (Years 1-3)
Aim 3- Test ways to put it right
(Years 4-5)

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A major medical problem associated with ageing is that the different tissues in our bodies become damaged over time. A major reason for this is the accumulation of old or “senescent” cells. It is likely that, as we age, our immune system becomes defective in its ability to clear senescent cells from tissues – if we could understand what goes awry this may provide opportunities to design therapies to support this particular function of our immune system, as we age.

What outputs do you think you will see at the end of this project?

This **first output** from this work is the identification key immune cells involved in clearing old, senescent cells. This is important, as it will allow us to focus our efforts in understanding the mechanisms in these cells that may be dysfunctional with ageing, which will be our **second output**. At this point we should have a high impact publication and disseminate this knowledge to the public and peers via conferences, press releases and public talks.
The **third output** of this work is to test known and also potential new therapeutics to stimulate the immune system to promote the removal of these damaging senescent cells to promote healthy ageing. This knowledge should then be translated into one or two high impact publications and provide proof of principle, pilot data to further develop drug testing in collaboration with Pharma in a future collaborative project. As always, this knowledge will be disseminated to the public and peers via conferences, press releases and public talks.

Who or what will benefit from these outputs, and how?

The knowledge obtained from outcomes 1 and 2 should be public within the five year PPL period. Outcome 3 will likely take a bit more time, but should be made available at year 5 and 7 likely.
The benefits from this project are targeted at the healthcare of the continuously growing ageing population. This

project aims to contribute to a step change in the treatment or even prevention of chronic diseases of ageing, which we know are highly contributed to by the accumulation of these old, senescent cells, in tissues.

This project is part of a wider effort to highlight a new therapeutic strategy to clear senescent cells, using our natural defences, surpassing the non-specific and highly toxic senolytic drug strategy. Such immunotherapeutic strategies will pave the way to a step-change in the treatment of chronic diseases of ageing, with huge health and social impact in the EU.

How will you look to maximise the outputs of this work?

Besides the high impact publications that we hope to obtain from outputs 1-3, we will aim to publish any new significant method (peer-reviewed and open access) that we develop that may help the scientific community tackle the problem of damaging senescent cells in tissues. This is likely to be relevant particularly if we succeed in establishing the state of the art *in vivo* and *ex vivo* live imaging techniques we are aiming to.
I aim to publish all our work in reputable open access journals, freely available to the public.
Furthermore, there are specific journals that aim to publish all sound knew scientific knowledge, even if reporting unsuccessful approaches, to maximise dissemination of knowledge and minimise duplication of work by others.
I have on-going collaborations with other experts in the field who also have close links to Pharma and can help develop any further tests or drugs to maximise the benefits from this work. This is also likely to lead to further joint grant applications, public talks and key note lectures at international conferences.

Species and numbers of animals expected to be used

- Zebra fish: 22,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Zebrafish have a number of additional advantages for these studies, including their near transparency, genetic tractability and extensive genomic resources. My previous work has provided opportunities to develop defined end-points to my ageing protocols that will be employed in this PPL. Fin clipping for genotyping purposes will be performed whenever possible in larvae before independent feeding. Procedures will be tested first in few animals in pilot experiment (up to 3 of each experimental and control group).
I will use animals until old age or genetically altered animals that age faster. Ageing phenotypes are required since we are testing cell interactions in old tissues, testing ways to improve these interactions and see if that has a positive impact on the health of old animals or promote a healthier ageing. I will use genetically modified premature ageing models (previously established) to test the validity of specific molecules as therapeutic target to ameliorate the cell interaction we are studying, in old tissues and 2) Provide a quicker model to display some (but not all) ageing phenotypes that we know mimic natural ageing.
Premature ageing model phenotypes can be divided in early and late. Early phenotypes occur before the half-life of these animals (c.9 months of age), late phenotypes occur nearer the end point of their lives (c. 12-15 months). Because of this, I will use defined end-point criteria, previously characterised by me to determine when to sacrifice the animals to measure specific phenotypes. The time points will generally be 1, 3, 6, 9 and 12 months of age for WT and prematurely aged siblings, which will be extended to 18, 24 and 36/43 months of age in the WT setting. The later time points are important, as there are specific ageing phenotypes such as wasting (equivalent to frailty in old age in humans) , that occur only at these older ages.
Only a maximum of 20% of animals, however, will reach the old age.
We may use larvae forms before 5.2dpf (non-protected) for genotyping, as much as possible, to minimise number of animals required to grow.

Typically, what will be done to an animal used in your project?

Most animals will be used for breeding and generating transgenic and/or mutant lines. Fish will be grown to selected time-points, where they may:

- Be culled for post-mortem analysis of fixed tissues or isolated cells from selected tissues.

- Undergo specific tissue regeneration challenges and culled at selected time points post-procedure for post-mortem analysis of fixed tissues or isolated cells from selected tissues. An example challenge is irradiation. The dose we will be using has previously been shown to induce signs of illness in a maximum of 10% of animals.

- Undergo selected drug treatments aimed at improving tissue regeneration and culled at selected time points post-procedure for post-mortem analysis of fixed tissues or isolated cells from selected tissues.

Fish may also undergo non-invasive behavioural testing, where we film animals swimming, interacting with objects, which will allow us to monitor general health of the animals.

What are the expected impacts and/or adverse effects for the animals during your project?

To understand how the specific cell interaction we are studying is impaired with ageing requires animals to age, whether naturally, or in the presence of mutations that mimic premature ageing syndromes in humans. During the course of their life-span premature ageing will result in weight loss, animals may develop arched backs and cataracts. This, however, will only happen to maximum 20% of the animals used in this project, and for a short amount of time. Note however that death is not an endpoint and fish will still be is able to swim and feed prior to reaching their end-point. To ensure the moderate humane end point is not exceeded, animals will be closely monitored, particularly after the age of 9 months when weight loss is accelerated. All fish will be regularly monitored for their ability to feed, swim, socialise/behave, grow and generally thrive well compared with wild type equivalents. We will use a humane endpoint based on body condition and fish will not be kept for long periods in poor condition.
Moreover, other than in terminally anaesthetised animals dosing and sampling procedures will be undertaken using a combination of volumes, routes and frequencies that of themselves will result in no more than transient discomfort and no lasting harm. Aged fish may be more sensitive to regeneration assays and may not recover from anaesthesia or sometimes, even though they recover, they may display a wound that does not heal properly and will have to be culled. However death should not exceed 10%. For young fish used in regeneration testing, though, it is expected that the rate is lower.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals will be used for breeding and generating transgenic and/or mutant lines (Mild). To understand how the specific cell interaction we are studying is impaired with ageing requires animals to age, whether naturally, or in the presence of mutations that mimic premature ageing syndromes in humans. During the course of their life-span premature ageing will result in weight loss, arched back, cataracts (ageing phenotypes in later time points are considered moderate). This, however, will only happen to maximum 20% of the animals used in this project. Animals will be closely monitored, particularly after the age of 9 months when weight loss is accelerated. Moreover, a small portion of animals (up to 20%) will be imaged under anaesthesia post fin clipping or post skin incision (mild). Larvae may require to be immobilised (embedding in agarose) for study and this would be considered moderate. A small portion of animals will be administered with a gut damaging drug for assessing cell interaction in young vs ageing post tissue challenge (moderate). A small portion of animals will undergo irradiation to stimulate cell senescence (Moderate).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding how the different immune cells interact with different types senescent cells, how this is affected with ageing and how this impacts on the animal's health requires in vivo studies using an animal model. These are processes that depend on the interaction between different types of cells in a tissue and organismal context.

Which non-animal alternatives did you consider for use in this project?

The objectives described above are part of an integrated programme of work, including elements of in vitro and in silico work alongside the in vivo experiments. In vitro cell culture using human immune cells (e.g. neutrophils, macrophages) will be performed in parallel. Where candidate genes can be identified from previous work, or by searches of available databases of genetic information, this will be performed to replace in vivo screens. In addition, most of the candidate genes will be identified from human clinical studies, replacing the zebrafish screens. Where possible larvae forms will be used, whenever a simpler hypothesis is being tested.

Why were they not suitable?

There is only so much we can test in vitro with isolated cells. In particular, the immune cell types likely to be involved in senescence clearance are likely to require interaction with each other to effectively clear senescent cells. This is not possible to reproduce in vitro with current technology. We will be able to ask individual questions with a particular cell type, but we will not be able to determine the impact of the cell-cell interaction for the animal's health.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

I have used data generated from previous PPL to gain insight into the number of animals required per line and protocol. I established this using power calculations, based on
http://www.3rs-reduction.co.uk/html/6__power_and_sample_size.html
.
When the given protocol has not yet been tested by me, I will perform a small pilot study with maximum 3 animals per genotype as a refinement strategy. I have used data from the literature to estimate number of animals required for such new protocols. Overall, data suggest I need a maximum of 16 animals per genotype, per time point to allow statistical interpretation.

Animal Numbers

The previous PPL allowed me to determine that I will need a maximum of 16 animals per assay to determine statistical significance (see example below for gut permeability assay) **.**

I have estimated that I will require 22,500 adult WT, mutant and/or transgenic fish for the total in this PPL over 5 years.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have sufficient pilot data from all studies to perform a priori power calculations to calculate group sizes. We will not initially exceed the predicted group sizes required to detect a 25% difference with 90% power (alpha of 0.05 as per convention), and I have calculated that we need a maximum of 16 animals of each genotype per experiment to detect differences. Based on established calculations using the 3Rs recommendations.
We will increase group sizes only if greater power is required, if the variance is greater than in pilot studies, or where the biological effect to be detected is less than 25%. Whenever possible we will use the same adult fish for in vivo assays, including non-invasive, non-harmful behaviour assays, followed by schedule 1 and in vitro cell culture assays, to try and reduce the number of fish that have to be grown in parallel for the different experiments.
Furthermore, an advantage of working with zebrafish, both as larvae and adults is that we only need one animal to look at all tissues at the same time, on the same slide, which increases the quantity and relevance of the information retrieved per animal. Where possible temporal studies will be performed using the same animal to gather serial data. As part of good laboratory practice, we will write an individual study plan (ISP) for each experiment involving regulated procedures.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Many of the functional assays will be performed in vitro using isolated cells from different tissues of the same animal, allowing large amount of data to be collected from reduced number of animals
To minimise the number of animals grown to an age protected by the Act, we will try and genotype the lines before the age of 5 days post-fertilization, after which they are protected by the Act, to identify unwanted genotypes to reduce the number of adults to grow. For example, embryos may be genotyped through micro-abrasion using the ZEG system.
Opportunities to reduce the number of animals required to develop a new line may be possible as new transgenic technologies are developed (e.g. genome editing). Breeding programmes to develop the new lines and intercrosses will be developed and we will use in-house databases (e.g. labtraks) to aid our efforts to maintain the minimal number of animals per line. Where necessary, gametes are expressed either to maintain fertility or to allow in vitro fertilisation, and numbers are determined by the requirements of maintaining fertility and preserving lines.
Furthermore, whenever possible we will use the same adult fish for in vivo assays, including non-invasive, non-harmful behaviour assays, followed by schedule 1 and in vitro cell culture assays, to try and reduce the number of fish that have to be grown in parallel for the different experiments.
Additionally, using such a small sized animal like the zebrafish allows us to look at all tissues at the same time, on the same slide, which increases the quantity and relevance of the information retrieved per animal. Where possible, temporal studies will be performed using the same animal to gather serial data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

I will use the organism with the lowest neurophysiological sensitivity possible for work of this kind, the zebrafish. The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Zebrafish have a number of additional advantages for these studies, including their near transparency, genetic tractability and extensive genomic resources.
My previous work has provided opportunities to develop most procedures (with the help of NACWOS and the

NVS) used in this PPL and establish defined end-points to my ageing protocols that will be employed in this PPL. Fin clipping for genotyping purposes will be performed whenever possible in larvae before independent feeding (before 5.2dpf (non-protected).
Any new procedures will be tested first in few animals in pilot experiment (up to 3 of each experimental and control group), under NACWO and NVS guidance.

Why can't you use animals that are less sentient?

I will use zebrafish as an ageing model because I have shown that, similarly to humans and in contrast to inbred lab mice strains, removing telomerase from zebrafish leads to premature ageing in the first generation. This means that zebrafish are the animal model with the lowest neurophysiological sensitivity mimicking key aspects of human ageing, required to address the scientific questions in this PPL.
Many of the objectives in this PPL will be addressed by collecting tissues from animals that have been killed at the end of the experiment/study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Zebrafish have a number of additional advantages for these studies, including their near transparency, genetic tractability, extensive genomic resources and small size. My previous work has provided opportunities to develop defined end-points to my ageing protocols that will be employed in this PPL. In particular, my previous PPL allowed me to optimise histology, so I know that the culling methods chosen are ideal for tissue preservation, required to address the scientific questions in this project. Scoring sheets and imaging (photographs) will be used to further refine the end-points. Fin clipping for genotyping purposes will be performed whenever possible in larvae before independent feeding.
Procedures will be tested first in few animals in pilot experiment (up to 3 of each experimental and control group).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the latest relevant literature and in house expertise as well as 3Rs resources and guidelines for zebrafish (https://norecopa.no/media/7384/zebrafish.pdf)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I attend departmental meetings on a regular basis where all researchers, technicians, NACWOs, NVS, NIO and NTCO share relevant information regarding recent advances in the 3Rs. In addition, I will also meet with representatives from organisations such as NC3Rs to keep abreast of the latest developments that can be applied to zebrafish studies.

Home Office

NON-TECHNICAL SUMMARY

213.Understanding mechanisms of immunotherapy and the basis of immune related adverse events (irAEs)

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

No answer provided

Animal types	Life stages
Mice	juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

This project aims to better understand how immunotherapy works and how immune related adverse events (irAEs) are precipitated. irAEs limit the use of otherwise highly potent drugs that result in beneficial clinical outcome for the treatment of immune mediated diseases ranging from cancer to autoimmunity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished. Why is it important to undertake this work?

By addressing the knowledge gaps underpinning the mechanistic basis of immunotherapy and irAEs, we can minimise the risk of certain adverse drug reactions and identify strategies that can be used to reverse them. This will also allow new drug candidates with the potential to cause an irAE to be identified and rejected at an earlier stage of development, rather than progress to patient trials and or wider clinical use.

What outputs do you think you will see at the end of this project?

The primary output of this work relates to new knowledge and information about the mechanisms by which immunotherapy works and the reasons why see adverse effects. This will be achieved through understanding the mechanisms of current immune targets, refinement and development of new treatment and/or reagents based upon a better understanding of the host immune responses involved. We will also publish our findings in peer-reviewed journals, present at scientific conferences and
participate in public outreach activities. Primarily, our data will be of interest to scientists, pharmaceutical companies and clinicians. Principles established during these studies should also be applicable to immunotherapy against infectious diseases for both clinical and veterinary applications.

Who or what will benefit from these outputs, and how?

The ultimate aim is to develop and/or improve treatment options for patients with a range of immune mediated diseases. Potential benefits arise from informed design of combination treatments in which monoclonal antibody (mAb) are given alongside conventional and other emerging modalities including other immunotherapy. Consequently, if applied appropriately, unlike conventional treatment, new immunomodulatory therapies should be more potent, and not be associated with long-lasting toxicity.

Knowledge generated from this project has the potential to benefit patients, clinicians, industry and medicines regulators (long terms, 5years+) by:

- Identifying novel strategies for overcoming tumour immunosuppression with the aim of identifying novel treatment approaches for application in patients.

- Allowing new drug candidates with the potential to cause an irAE to be identified and rejected at an earlier stage of development, rather than progress to patient trials and or wider clinical use.

- Developing novel screening procedures to identify patients that are predisposed to a particular irAEs, and characterising biomarkers that enable the earlier identification of patients experiencing an irAE, thus limiting their exposure to the drug and informing clinical diagnosis and prognosis.

A secondary benefit relates to the training of the next generation of immuno-oncologist and drug safety scientists, who will go on to lead future research in this area and/or occupy decision-making positions in industry/regulation (short term, 3 years).

How will you look to maximise the outputs of this work?

We will publish in peer-reviewed journals, present at scientific conferences and participate in public outreach activities. Primarily, our data will be of interest to scientists, pharmaceutical companies and clinicians. We are open to collaboration with academic researchers and scientists from industry/pharma in terms of sharing reagents and data. The proposed project will cultivate a programme of work that builds significantly on the antecedent research in relation to antibody immunotherapy, and offers the promise of exciting collaborative work where all collaborators will benefit from the extension of knowledge generated from this work.

Species and numbers of animals expected to be used

- Mice: 600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are investigating the in vivo effects of immunotherapy with a view to establish their mechanisms of action and their adverse effects, with therapeutic application in humans. These interactions occur between different immune cells, organs and tissues, and as such cannot be reproduced in vitro. There is a remarkable consistency between the immune cell types and gene expression profiles in mouse and human immune system. Majority of gene expression patterns- conservatively estimated at 80 percent– are the same in mouse and human, and this also suggests a role for transcriptional regulators that may underpin these similarities. Furthermore, the ever-increasing availability of genetically manipulated mice has allowed genetic dissection and meaningful modelling of human disease. Mice will be used for this study since they are the least sentient species of mammal that have the following characteristics: 1. The cellular and molecular interactions of the mouse immune system are broadly similar to those of humans, allowing us to investigate relevant immunological strategies and mechanisms; 2. Individual mice within a given inbred strain are considered genetically ‘identical’, thereby reducing variability and allowing valid conclusions to be drawn from experimental data; 3. Numerous models of tumour and autoimmunity have been established and characterised in mice that are strain specific; 4. Numerous strains of genetically altered mice have been developed, such as those expressing antigens of interest or genes of interest removed. For majority of this project we will be using mice that are 6-12 weeks age, which is when they have a fully developed immune system. For some studies, where we investigate how drugs affect the early development of immune tolerance and immune homeostasis, will use mice that are 4-6 weeks old, where the immune system is not fully developed.

Typically, what will be done to an animal used in your project?

Mice will be administered with substances or combination (immune cells, tumour cells, disease inducing compounds, drugs- monoclonal antibodies, pharmacological inhibitors, small molecule drugs, biologics, disease inducing chemicals) through a variety of routes (subcutaneous, intradermal, intramuscular, intravenous, intraperitoneal, intratumour, mammary pad) to study localised or systemic immune responses. Tumour and autoimmune models can last maximum up to 100 days. To study systemic immune responses, blood may be withdrawn via tail vain on no more than 5 occasions. Animals may also be monitored for tumour and/or other tissue growth or response using non-invasive imaging under general anaesthesia. Animals will be allowed to fully recover between anaesthetics. Throughout the experiment, animals will be monitored daily for signs of tumour growth or other disease and/or treatment associated symptoms as appropriate. All animals will be humanely culled at the end of the experiment. Following this, tissues (spleen, lymph nodes, vital organs) may be harvested from these animals for analysis by a variety of techniques in the lab.

What are the expected impacts and/or adverse effects for the animals during your project?

Administration of substances: Administration of substances or cells and the withdrawal of body fluids will be will result in no more than transient discomfort and no lasting harm- injections causing momentary needle stick pain. Application of topical substances on the skin can result in scratching behaviour, and therefore if necessary their claws may be clipped to reduce scratching. If the skin becomes broken or infected mice will be treated with Baytril or similar, and/or with an antihistamine after consultation with our named vet. In some experiments the injection of antigen and/or immunomodulatory agent may cause a transient adverse reaction, for example those investigating the effect of a treatment on a secondary response, the induction of long-term memory or those requiring treatment with an immunomodulatory mAb which may induce cytokine release. These effects can occur acutely, within a few minutes, or may not develop for several days and are typically characterised varying degrees of by pilo-erection, hunched posture, lack of responsiveness and shallow breathing; in a proportion of mice (say 1 of a group of 6) the reaction may be more severe, with prostration. To alleviate the symptoms, mice are placed on a warming pad, stimulated, and monitored until they recover and can be returned to their cages; this is usually within 1.5 h-2 h. Symptoms remain within the moderate severity limit of the protocol. Once recovered, the mice do not exhibit any further adverse effects.

Fasting: Fasting per se is unlikely to cause any adverse effects in healthy animals, but may increase the likelihood of an individual animal experiencing an unexpected adverse event following substance administration. However, the overall incidence of such events is still expected to be low (<5%). Animals dosed following fasting will be monitored regularly within the first 3 hours post- dosing. Beyond 3 hours, the frequency of monitoring will be judged on previous experience with the specific compound and dose.

Whole-body imaging: No adverse effects have been noted with previous use of the stated imaging techniques, which incorporate a means of maintaining animal body temperature. The severity of repeated imaging sessions is related to repeated anaesthesia, rather than the imaging itself. Frequency and duration limits set out in the BSU Refined Guidelines for Imaging will be observed. For repeated imaging, no animal will undergo anaesthesia/imaging unless it is judged to have recovered from the previous occasion by the personal licensee, or when necessary in consultation with the NVS and/or the NACWO.

Tumour models: The typical animal is given tumour as a suspension of cells in suitable vehicle (e.g. saline, or, for some subcutaneous injections, mixed in a solution of an inert matrix material such as matrigel). Mammary pad injection (up to 100µl) may be used to inoculate breast cancer models; no adverse effects are expected due to injection site. The tumour is then allowed to grow to a reasonable size (see below) at which point the animal is humanely killed. The overriding consideration for humane endpoints must be the health of the animal. Experiments will be terminated before or at the first signs of, tumour associated symptoms, such as anaemia, laboured respiration, bleeding or other discharge from orifices, abdominal distension or incontinence or diarrhoea lasting more than 48 hours. However, health is also monitored by assessing the overall condition and behaviour of the mice (Foltz and UllmanCullere (1999) Lab Animal, Guidelines for Assessing the Health and Condition of Mice), including facial expression (www.nc3rs.org.uk/assessment-pain-using-facial-expressions-laboratory-mice-rats-rabbitsand-macaques). In all cases, the size of tumour(s)will be the minimum to achieve the scientific objective. Our humane endpoints are based on recognised NCRI guidelines described by Workman et al. [2010] Br J Cancer 102:1555). If an animal has reached the humane end-point of disease or is displaying signs of distress/suffering, the technicians will either cull the animal or inform the personal licensee that the animal should be culled immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Only mice are used for this project. Procedures conducted on all animals are expected to yield mild moderate severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Immune modulating agents act upon multiple cell types across different organs and tissues within the body concurrently and this cannot be adequately modelled in vitro at the current time. Similarly, to study the interactions between an ongoing immune response and a growing tumour, or to evaluate immune related adverse effects, there is unfortunately no viable alternative to in vivo modelling using animals.

Which non-animal alternatives did you consider for use in this project?

We are committed to replacing mice where possible and we evaluate immunotherapeutic agents on cell lines in vitro when we can. We have considered in vitro assays using primary cells and 3D organoid modelling, but they do not accurately reflect the complexity of the tumour microenvironment in a natural setting. However, we will use PBMC and end-organ biopsies from patients treated with immunotherapy who developed adverse effects to study immune cell composition and biomarkers of toxicity.

Why were they not suitable?

Although such in vitro assays may provide information in relation to biomarkers of immune toxicities, and correlative measures of immunotherapy effectiveness and risk of adverse events, they will not shed light on the mechanistic basis of immunotherapy and immune toxicities, where immune cells interact within different organs and tissues. Such interaction cannot be modelled in vitro assays.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For all work, we will adopt the general principles outlined by the Academy of Medical Sciences (October 2015), including adoption of appropriately powered and robust experimental designs, detailed protocols and specific analysis plan for all studies, with expert statistical advice from senior statisticians affiliated to the Centre. Experiments are always designed with the fewest animals consistent with obtaining statistically valid results. We are using inbred strains of mice, so within group variability is also reduced. Replicate experiments will be performed to ensure reproducibility and when appropriate such studies may be combined to increase sample size, and when possible, treatments will be tested with more than one strain and/or tumour.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have where possible, planned to evaluate immunotherapeutic agents on cell lines in vitro and considered using primary cells and 3D organoid modelling. We will archive tissues from experimental animals to avoid experimental repeats and account for the influence of variables and address sources of bias to yield robust and reproducible data, ensuring that the data from every animal is utilised to its full potential. We will reduce bias by random allocation and blinding to ensure researchers analysing experimental outcomes are unaware of the treatment received until the final statistical analysis. We have ensured that experiments are well designed, adequately power and analysed correctly which will all help reduce animal use whilst increasing the scientific validity of the results.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will conduct small scale pilot studies before starting a major experiment to ensure that the experiment is logistically efficient and to give some preliminary indication of likely results. All experiments will be carefully pre-planned, and not changed while the experiment is in progress. We will also statistically analyse the data after the completion of each experiment so that the results will aid in planning future experiments. Measurement error will be minimised by careful technique and good instrumentation, and blinding the researcher to treatment allocation. Where multiple inter-relating parameters are to be evaluated, larger factorial experiments are performed to prevent use of excess mice as controls. In recent years significant technological advances have enabled more information to be obtained from one individual mouse than was previously possible (e.g. using multi-parameter flow cytometry and micro-array technology), enabling multiple parameters to be assessed simultaneously from small samples. These technologies thereby facilitate longitudinal studies and reduce the need to cull multiple mice at different time points to sample from the spleen for instance; we aim to fully exploit these new techniques fully where possible. We will also ensure that any tissues collected during/after animal studies are archived and stored appropriately, avoiding unnecessary repetition of experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The typical animal is given cells, tumour cells or substances as a suspension in a suitable inert vehicle (e.g. saline); no adverse effects are expected due to injection site. The tumour is allowed to grow to a reasonable size at which point the animal is humanely killed. Daily inspections are usually carried out by experienced animal technicians familiar with the models. The overriding consideration for humane endpoints is the health of the animal. Experiments will be terminated before or at the first signs of, tumour associated symptoms, such as anaemia, laboured respiration, bleeding or other discharge from orifices, abdominal distension or incontinence or diarrhoea lasting more than 48 hours. Use of
Imiquimod cream to induce autoimmune inflammation of the skin to model human psoriasis is known to be safe with minimal pain and suffering.

Why can’t you use animals that are less sentient?

Mice are the least sentient mammal species with an immune system similar to humans. Mice represent a relevant animal model for these studies and the clinical successes now being reported using immunomodulatory drugs against cancer were dependent on data arising from such murine studies. Numerous mouse cancers have been studied and the availability of genetically altered strains, and commercially available reagents aids this research.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Environmental enrichment, good husbandry and frequent monitoring ensure high welfare standards. All animal experiments will be conducted in a humane manner, with particular consideration for highest standards of animal welfare as well as for the quality of the science. Any animal experimentation within the institution is fully justified, and death will not be an experimental endpoint in any studies, and animals will be humanely culled as soon as the objective of the experiment has been achieved.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will adhere to the guidance issued by relevant authorities including the
Home Office (https://www.gov.uk/guidance/animal-research-technical-advice),
NC3Rs (https://www.nc3rs.org.uk/guidelines) and the
University of Liverpool (https://www.liverpool.ac.uk/research-integrity/animal-research/ legislationgovernance-and-standards/) and report them in accordance with the ARRIVE guidelines (https://www.nc3rs.org.uk/arrive-guidelines).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will keep abreast of literature and guidance from the NC3Rs and Home Office in relation to the framework for performing humane animal research and embed in our studies. We will also work with colleagues to develop viable alternatives such as advanced organoid modelling and computational biology based on latest science and technology as an alternative to animal experiments. We will actively participate in workshops organised by the relevant authorities that provide an update on advances in 3Rs.

Home Office

NON-TECHNICAL SUMMARY

214. Understanding musculoskeletal ageing

Project duration

5 years 0 months
Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs

and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b) **Key words**

bone, cartilage, osteoarthritis, osteoporosis, inflammatory bowel disease

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the mechanisms underlying musculoskeletal health, and pathological ageing

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Musculoskeletal conditions are at the forefront of ageing-related conditions: the World Health Organisation has described them as “leading causes of morbidity and disability, giving rise to enormous healthcare expenditures and loss of work”. Osteoarthritis is one of the most frequent ageing-related musculoskeletal diseases; the World Health Organisation estimates that 10% of men and 18% of women aged over 60 already have symptomatic osteoarthritis. Further, 40% of women over 50 years will suffer an osteoporotic fracture and 1 in 500 people in the UK are affected by ulcerative colitis with up to 41% of these also affected by associated osteoporosis.

Understanding the mechanisms underlying these conditions will provide invaluable insights and will have broad translational potential. It will, therefore, likely lead to long-term patient benefit and societal impact from a contribution to global economic activity. The clinical benefits are likely still distant but they are potentially huge and their healthcare, financial and societal impact is only set to rise in the ageing population.

What outputs do you think you will see at the end of this project?

The outputs generated from this project will contribute and complement ongoing research into musculoskeletal health. The majority of the UK population will be affected by a bone or joint disease as they age. These may include bone loss and fractures characteristic of osteoporosis, osteoarthritis or even cartilage to bone conversion such as in dyschondroplasia. The proposed studies will therefore provide invaluable new knowledge of the mechanisms which lead to these diseases, and ultimately offer new approaches to treat them. Further, it will generate outputs in the form of: (i) peer reviewed publications (expected >10) (ii) invited seminars (iii) oral and poster presentations by group members at scientific conferences (iv) future grant applications for example to the MRC (v) lay articles for magazines (e.g. The Conversation) (vi) public lectures (e.g. Pint of Science). Together, these will benefit immediately the scientific community. In the long-term this basic research which will be extended and refined by others and may lead to drug targets and treatments for many musculoskeletal diseases.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries of this work will comprise academic researchers in multiple biological disciplines, including, but not limited to bone biology, cartilage biology, osteoporosis, osteoarthritis, rare joint diseases, and joint imaging. This research will, therefore, benefit a wide range of researchers across the globe, with whom future collaborations can potentially be formed. These partnerships will encourage and facilitate interdisciplinary research and all parties would benefit from this. In the long-term, this basic research will be extended and refined by others and may lead to drug targets and treatments of many musculoskeletal diseases which will ultimately benefit members of the public suffering with these debilitating diseases.

How will you look to maximise the outputs of this work?

I always strive to maximise the outputs of my research and will continue to do so for this work. I work closely with national and international colleagues where group efforts are made to understand these biological mechanisms underpinning bone and cartilage disease. I will continue to nurture these productive collaborations for this work, as well as look to foster new ones where appropriate. I am fully committed to ensuring that any novel results generated are disseminated as broadly as possible across biomedical academic communities and that data are available for future interrogation. Similarly, I will always look to publish unsuccessful approaches as I believe these are just as important in our pursuit of understanding, and within the musculoskeletal field, journals have often had special issues focused on these studies. Through the work generated by this project, I will also continue to play an active role in the public understanding of science relating to bone and joint diseases, and methods for prevention/management.

Species and numbers of animals expected to be used

- Mice: 3200

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Here we will use mice as the genetic tools and models required for achieving the aims of this project are readily available in this species. Further, mice are required to enable us to examine the 'whole joint' rather than the separate components of the joint. We will be breeding genetically modified mice at all ages, however the protocols we use will be in juvenile, adult and aged mice. This is because we are interested in understanding musculoskeletal health across the life course and in particular, with ageing. It is, therefore, important that we consider our models in the different ages detailed.

Typically, what will be done to an animal used in your project?

Typically, a mouse will undergo induction of a skeletal pathology such as osteoarthritis or inflammatory bowel disease. Before or after this, they may receive an injection of a compound to examine whether this protects against the skeletal pathology. Mice will receive no more than two regulated procedures, and experiments will last no longer than 8 weeks post skeletal induction.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of the protocols in this project will not result in any adverse effects. Some mice will have surgery and, therefore, there is a risk of infection, although we will take every precaution to ensure this does not happen. Similarly, there is a small risk of death from anaestheisa given. Those which develop inflammatory bowel disease may experience weight loss, however, we have previously shown that once the treatment is stopped, mice regain this weight.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The highest severity that a mouse will experience in this project is moderate. The majority of animals will experience a mild severity (approx. 60%).

What will happen to animals at the end of this project?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The aim of this application requires a physiological context, and, therefore, this project will predominantly adopt an *in vivo* approach with mice as the experimental model. Use of mice to provide the 'whole' organ is required to study the objectives so they match as precisely as possible the circumstances in humans. It is also important to note that age-related joint deterioration is a 'whole organ' event; studies that may use models of the joint's constituent

components separately would, therefore, only provide insight into only some aspects of the joint function. Similarly, removing the activity of a gene provides information about what that gene normally does in a physiological (whole body) context and this information cannot be obtained from cell culture models where, for example, cellcell interactions and whole body regulatory pathways are lost. Also, the genetic tools and models required for the studies detailed herein are readily available in this species.

Which non-animal alternatives did you consider for use in this project?

In vitro ("test-tube") and cell culture based alternatives have been, and will be, invaluable to my research and I will always consider them in my experimental design wherever possible. I have fully acknowledged their strengths, reviewed their use for others, but am aware and appreciate their limitations, as detailed below.
Why were they not suitable?

In vitro approaches have a number of recognised limitations. Ultimately, they fall short of providing the integrated, organ-level, physiologically intact environment that animal models provide and, thus, make interpretation of indirect effects of agents on bone impossible to detect. These *in vitro* approaches also fail to produce the range of structural abnormalities in joint architecture that can be seen, and do not represent all *in vivo* tissues.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Numbers are based on my previous work. This was used to estimate the minimum number of rodents required for establishing significant differences between groups.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We will always aim to reduce the numbers of animals we use, and routinely use the NC3Rs' Experimental Design Assistant. Power analyses are always applied in order to identify the minimum number of animals that we need to use in order to answer the specific question being posed. For example, we have established that in our surgical model of osteoarthritis (DMM), a minimum of 6 mice per group is required to secure statistically significant differences. Wherever it is possible we will also exploit contra-lateral limbs as controls in order to reduce the numbers of animals required still further.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will always adopt efficient breeding strategies informed on our previous work and knowledge of the mouse strains we are working with. Pilot studies will always be conducted where appropriate. In our studies, we will also

take repeated measures on the same mice where possible, thereby, enabling serial data acquisition and removing the need for the humane killing of multiple groups of mice at set time-points. This will be further advantaged by our current attempts to acquire funding for an *in vivo* computed tomography scanner which allows imaging of bone micro architecture without the need for humane killing. We have many collaborations with other scientists interested in various other related systems and so maximum use of animal tissues is always made.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project will use mouse models. We have chosen mice because their basic skeletal biology is very similar to humans and the models to be used here e.g. joint loading and DMM model, have been developed for, and are widely used in, mice. Furthermore, there is the advantage of readily available gene edited mouse models and reagents for downstream analyses.

Animal suffering will be limited in our studies by our strict monitoring of severity limits and our use of protocols that do not produce excessive trauma or suffering. Drugs will be administered at non-toxic dosages and if unknown, this will be carefully tested. Our use of surgical approaches will be kept to a minimum and appropriate pain relief during our protocols will be achieved through appropriate levels of analgesia.

Why can’t you use animals that are less sentient?

Here, we will use mice as they are the most suited to be able to answer the biological questions which we pose. The genetic tools and models required for achieving the aims of this project are readily available in this species. Further, mice are required to enable us to examine the 'whole joint' rather than the separate components of the joint, and to take into consideration the whole physiology of the musculoskeletal system which would not be possible in less sentient species such as zebrafish. Species such as zebrafish would also not enable us to understand the effects of loading on the skeleton, and are not easily translatable to humans due to their skeleton developing differently. This project will use juvenile, adult and aged mice because we are interested in understanding
musculoskeletal health across the life course and in particular, with ageing, and hence more immature life stages cannot be used.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We have carefully considered each of the procedures described in this application in order to minimise pain and distress experienced by animals, and to enhance their well-being. Indeed, animal suffering will be limited in our studies by our strict monitoring of severity limits and our use of protocols that do not produce excessive trauma or suffering. Animals will be handled for one week prior to experiments happening to minimise stress, and anaesthesia and analgesia will be used whenever appropriate and possible. Animals will receive extensive post-operative monitoring and care to ensure minimal welfare costs for the animals.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I already have and will continue to refer to the 'Guidance on the
Operation of the
Animals (Scientific
Procedures) Act 1986' and will speak with our NVS and others to ensure that I am kept up to date with the published best practice guidance. I will also consult published guidance such as *'Laboratory Animal Anaesthesia and Surgery'* Paul Flecknell, and the LASA Guiding principles on good practice.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The Bioresources Users' Group (BUG) regularly meet and welcome both internal and external speakers to discuss current advances in the 3Rs. Regular newsletters from the NC3Rs and LASA are also distributed.

Home Office

NON-TECHNICAL SUMMARY

215. Understanding skeletal disease and pathological soft tissue calcification

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Vascular calcification, Bone formation, Therapy

Animal types	Life stages
Mice	neonate, juvenile, adult
Rats	adult, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to improve our understanding of the processes which cause skeletal and vascular disease. It will also investigate the complications which can arise in bone and blood vessels as a result of diseases in other tissues.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Maintaining bone mass is important for healthy ageing; however, the skeleton does not exist in isolation and its function is influenced by other tissues. Consequently, many common diseases (e.g. chronic kidney disease (CKD or kidney failure), diabetes) are associated with significant skeletal problems (e.g. bone loss). Many of these conditions are also characterised by unwanted and harmful soft tissue calcification (e.g. calcification of the blood vessels which is known as vascular calcification). The processes which lead to the development of these skeletal and vascular problems are not fully understood and lack effective treatments. Therefore it is important to improve our understanding of what causes these issues. Ultimately this knowledge may lead to the development of new drugs to treat these common problems.

What outputs do you think you will see at the end of this project?

The studies performed under this licence will increase understanding of the processes that lead to the development of skeletal problems and harmful calcification of the arteries (known as vascular calcification) in several common diseases (e.g. chronic kidney disease (CKD or kidney failure), diabetes). Ultimately this may lead to the identification or development of compounds that can be used to prevent or treat vascular calcification without exerting negative effects on the skeleton. Experimental outputs will therefore include:

1. Publications/conference presentations describing our research findings. This will provide important new information to other researchers in the field about the processes involved. It may also be interest to industrial partners.

2. Refinement of protocols to reduce animal use.

3. Identification of compounds that warrant further investigation as potential treatments for vascular calcification and/or skeletal problems associated with other diseases.

Who or what will benefit from these outputs, and how?

Many of the conditions which lead to skeletal problems and/or vascular calcification are much more common in older people. Given the ageing population, these problems are expected to increase in prevalence and so finding new therapeutics is essential. Vascular calcification, in particular, does not currently have any effective treatments. This means there is a need for research to understand the processes involved and to identify compounds of interest. Due to the time required for drug development processes, translating basic science findings to clinical benefit is likely to take many years.

In the shorter term, the benefits will primarily be for the broader scientific research community. Data generated will be published in a timely manner to ensure effective dissemination to the skeletal and vascular biology fields, as appropriate. Any refinements in protocols was also be shared to ensure that improvements in methodology can be more widely adopted.

How will you look to maximise the outputs of this work?

Findings will be presented at appropriate national and international conferences to ensure rapid dissemination of new knowledge, protocols and refinements to a broader scientific audience. Data will also be shared with new and established collaborators within the field to inform and refine future studies of a similar nature. Once individual projects are complete the results will be written up in a timely manner for publication in a peer-reviewed journal.

To prevent unnecessary repetition of *in vivo* studies we will aim to publish all findings, both positive and negative. Publication of research findings is also disseminated to a general audience via the institution website.

Species and numbers of animals expected to be used

- Mice: 3,600
- Rats: 400

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Protocols 1-3: The ability to switch genes on or off in rodents (mice and rats) has yielded a lot of important information about how tissues work. Study of these animals provides an important research tool that helps to increase our understanding of how diseases develop. There are a number of diseases (e.g. chronic kidney disease (CKD or kidney failure), diabetes) which cause problems in the skeleton and also lead to the development of harmful calcification in the arteries (known as vascular calcification). In some cases, animals will be fed a high fat to mimic a western diet. Using these genetically altered animals in this project will help us to understand the processes which lead to the development of these unwanted effects. Furthermore, studying animals at different life stages provides important information on the impact of ageing on these processes.

Protocols 4 and 5: In order to determine whether potential treatments can prevent disease-induced vascular calcification and skeletal problems it is necessary to use animals with that disease (e.g. CKD). These experiments are performed on adult rodents as the diseases being modelling are typically associated with ageing.

Typically, what will be done to an animal used in your project?

Protocols 1-3: Here, animals with genetic changes will be bred for experimental purposes. Animals will either be used to maintain breeding colonies, to isolate cells or tissues or transferred for use in protocols 4 or 5.
Protocol 4: Here, animals will be fed a modified diet which results in the development of chronic kidney disease (CKD) and the associated skeletal and vascular problems. Animals will be fed this special diet for the duration of the study (up to 12 weeks). During this time, animals will have regular blood tests and be given compounds which could prevent the unwanted consequences of the disease. At the end of the study, all animals will be euthanised and tissues collected for experimental analysis.
Protocol 5: Here, animals will be fed a modified diet which results in the development of the skeletal and vascular problems associated with ageing. Animals will be fed this special diet for the duration of the study (up to 12 weeks). During this time, animals will have regular blood tests and be given compounds which could prevent the unwanted consequences of ageing. At the end of the study, all animals will be euthanised and tissues collected for experimental analysis.

What are the expected impacts and/or adverse effects for the animals during your project?

Protocol 1: The genetic alterations in these animals are not expected to cause any significant adverse effects.
Protocol 2: The genetic alterations in these animals may lead to the development of disease and the associated symptoms. In most cases these effects will worsen with age.
Protocol 3: The genetic alterations in these animals and the feeding of a high fat diet are not expected to cause any significant adverse effects.
Protocol 4: Animals on the modified diet in this protocol will develop kidney failure and the associated adverse

effects which include reduced food intake and weight loss. Since this model reliably mimics the human clinical symptoms of kidney failure adverse effects are likely in all animals. Symptoms are expected to appear within 1-2 weeks of study initiation and will gradually worsen over time; after onset, adverse effects will last until the study ends. Animals will be carefully monitored throughout the study and if symptoms are approaching the limit of severity they will be euthanised via schedule 1 methods and tissues collected for analysis.
Protocol 5: Animals on the modified diet in this protocol are not expected to experience any adverse effects with the exception of transient weight loss.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Protocol 1: The expected severity of this protocol is mild. It is anticipated that all animals will experience this level or a sub-threshold severity.
Protocol 2: The expected severity of this protocol is moderate. It is anticipated that all animals will experience this level or a mild severity.
Protocol 3: The expected severity of this protocol is mild. It is anticipated that all animals will experience this level severity.
Protocol 4: The expected severity of this protocol is moderate. It is anticipated that all animals will experience this severity.
Protocol 5: The expected severity of this protocol is mild. It is anticipated that all animals will experience this severity.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Within the body, there are numerous interactions between the different tissues. As a result a disease in one particular organ/tissue can cause problems in another. This project will investigate how diseases such as chronic kidney disease (i.e. kidney failure) and diabetes cause skeletal problems and harmful calcification of the arteries (vascular calcification). To learn more about these conditions and to find effective therapeutic treatments requires a number of experimental approaches.
In vitro (i.e. in the lab) work using cells obtained from animals can provide important information about how things work. Particularly useful in improving our understanding are cells that are isolated from rodents that have had genes switched on or off. However, one limitation of *in vitro* studies is that they cannot replicate the 3D structure of tissues or model the interactions between different tissues. Therefore, *in vitro* work is most informative when used in combination with whole animal (or *in vivo*) studies. This project will use both methods to address our research objectives.

Which non-animal alternatives did you consider for use in this project?

Where possible we use human vascular cells for lab experiments but human bone cells are very difficult to obtain. Therefore bone cells for study need to be isolated from rodents. At present there are no effective non-animal models that allow the skeletal problems or vascular calcification associated with disease to be studied in the same system.

Why were they not suitable?

Non-animal systems that can reproduce the interactions between bone, blood vessels and other tissues do not exist. Therefore, at present there are no alternatives to whole animal models.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The estimated numbers are based on over 10 years of animal work. Extensive experience in bone and vascular research has provided a detailed understanding about the number of animals required for the different experimental approaches employed. It also takes into account typical inheritance patterns when breeding genetically altered animals and intragroup variability for whole animal *in vivo* work.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The techniques employed in our research are continually being refined to maximise the experimental outputs from the animals used. These changes have been used to inform the experimental design in this project licence. For example, recent refinement of isolation methods means that four distinct cell types can now be obtained from a single animal; this represents a significant reduction in the number of animals needed for *in vitro* work. In addition, improvements in the methods used for *in vivo* studies has reduced the degree of variability between animals. This means that overall the number of animals needed in each experimental group can be reduced.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As mentioned above we have designed our protocols so that four distinct cell types can be isolated from a single animal or group of animals. This is particularly useful when isolating cells from genetically altered animals which may only be available in limited numbers. Furthermore, breeding programs will be designed to limit the generation of animal s which cannot be used for experimental purposes.
Where necessary, pilot studies will be used to test poorly characterised compounds prior to commencing a full study. This will ensure that excess animals do not have to experience or be euthanised due to unforeseen adverse effects.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques

during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Protocols 1 and 2: This work will involve the breeding and maintaining of rodents (many with genetic changes) for research purposes. The majority of these animals are not expected to experience any significant pain or distress.

Protocol 3: This will involve feeding certain animals a high fat diet. This is not expected to have a significant impact on welfare.
Protocol 4: Chronic kidney disease and the associated skeletal and vascular problems can be induced in rodent models via the diet or by surgery. We have opted to use modifications in diet because this method is less invasive, shorter in duration and is more reproducible.
Protocol 5: This method uses a modified diet to allow the study of the vascular and skeletal problems that can develop as a consequence of ageing. This approach has been refined to minimise the adverse effects and reduces the need to use aged animals.
Animal suffering will be limited in all our studies by our strict monitoring of actual severity and severity limits. Our protocols are also designed not to produce excessive trauma or suffering. In all cases, animals will be euthanised if they approach the limit of severity.

Why can't you use animals that are less sentient?

The conditions being investigated are most often associated with ageing and cannot be sufficiently reproduced in animals at an immature life stage. Furthermore, since bone loss and the development vascular calcification take a number of weeks to occur it is not possible to carry out these protocols on terminally anaesthetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Protocols 1-3: All animals will be subjected to regular monitoring to ensure welfare is maintained. If an animal model is new or poorly characterised, levels of monitoring will be increased until the model is characterised.
Protocols 4 and 5: Animals purchased specifically for a study will have a 1-2 week acclimatisation period prior to work starting. Animals will undergo a health check twice a week unless part of a pilot study testing a poorly characterised compound. These animals will be subject to enhanced levels of monitoring. Options for using creatinine levels to refine protocol 4 will also be explored.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

All whole animal *in vivo* studies will follow the ARRIVE guidelines. Administration of compounds will follow the LASA guidelines. Power calculations will be performed prior to every study to confirm that enough animals are included to ensure statistically relevant results.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advancing the 3Rs and ensuring animal welfare are central to our research ethos. Attendance at internal seminars and training courses aimed at promoting and improving best practice as well as external seminars and relevant conferences will ensure that the PPL holder and any PIL holders working under this licence are kept up to date with relevant new developments. Regular contact with international collaborators using similar whole animal

models will ensure that any refinements developed in other research institutions can be quickly incorporated to the studies performed under this licence (subject to appropriate PPL amendments).

Home Office

NON-TECHNICAL SUMMARY

216. Understanding the biology of epithelial cancers

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Cancer, Therapy, Preclinical Modelling

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Epithelial cancers such as bowel, liver or pancreatic cancer account for the majority of diagnosed cases, and commonly respond poorly to treatment. To develop better, treatments which are likely to have a positive effect in patients we need to better understand a number of features of how cancers behave. These include understanding how they form, how they grow and they progress to more dangerous disease. We also need to understand how

cancers differ from normal tissue, and what makes response to any treatment effective. To understand this process in its entirety, our study aims to develop animal models which resemble human cancer as closely as possible, then uses these to understand how cancer develop and grow, and use this to identify key new potential treatments.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Epithelial cancers represent up to 85% of all cancer diagnoses in the UK presently. They also represent a pressing need for new treatments, with little progress in terms of development of new targeted approaches seen over the last 20 years. Using bowel cancer as an example, it is second most common cause of cancer related death in the UK, accounting for 10% of all cancer deaths annually. Patients with late-stage, metastatic disease fare worst, with a 5-year survival rates following diagnosis at stage 4 of around 10%. In this patient group, while surgery is the most effective means of increasing patient survival, only ~15% of patients with metastatic disease are suitable for this. Moreover, given that classical chemotherapies and targeted approaches are often ineffective in bowel cancer, there is a real need to identification and validate new potential targets which might be effective as a treatment and might benefit patients. Key to this process is the generation of animal models which accurately reflect human disease, increasing the likelihood of developing successful treatments.

What outputs do you think you will see at the end of this project?

This work will advance our knowledge of the cellular processes which govern tumour initiation, progression and therapeutic resistance in a setting which is directly translatable to defined patient populations. Ultimately, this work will identify new actionable targets for therapy in epithelial cancer. We will seek to publish all experimental data that arises from this work in order to maximise benefits arising from animal usage.

Who or what will benefit from these outputs, and how?

The identification of novel targets, pathways or process which are relevant to cancer progression and therapeutic resistance in cancer will ultimately lead to patient benefit in the longer term. In the medium term, the identification and validation of changes which are common to specific subtypes cancer, may be a valuable way to identify patients who either will or will not respond to any given treatment.

How will you look to maximise the outputs of this work?

We currently participate in number of large collaborative networks aimed at dissemination of data generated from *in vivo* models of cancer, alongside integration of data generated from these models, as well as human clinical samples and advanced culture systems. The ultimate aim of these collaborative approaches is to make high quality, robust and impactful data available to the wider research community, drive appropriate translation of findings into the clinic, and ultimately benefit patients. We aim to disseminate findings from all research carried out as part of this project through seminar, symposium and conference presentations, both within our establishment and to the wider cancer research community, alongside publication of multiple peer-reviewed manuscripts.

Species and numbers of animals expected to be used

- Mice: 180,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The mouse models described in this project are genetically modified so that they are susceptible to cancer development. We now have a great deal of understanding of the genetics of both mice and human cancer, and

can use this knowledge to design excellent models. Each mouse model is very carefully designed so that adult mice will develop tumours which very closely resemble those seen in human cancer, and go through all of the stages of development seen in patients. We need to use these models systems because human cancer is an incredibly complex disease - tumours are made up not only from tumour cells, but also immune cells, supporting cells and blood vessels, many of which they rely upon for growth, and which can be important in success or failure of treatments. As there are currently no non-animal models which can reproduce these complex tumours accurately, the development of effective and accurate animal models of cancer is vital for the development of effective treatments for patients.

Typically, what will be done to an animal used in your project?

Around 25% of mice produced under this protocol will have a genetic predisposition to develop cancer. Subsequent genetic modification of these experimental mice will be induced using an injectable agent, typically on one occasion only. A proportion of these (50% of experimental mice, 12.5% of the total) will go on to develop cancer as adults and will be humanely killed when they show symptoms of cancer development without the need for additional procedures. In a small number of cases (<5% of experimental mice), in order to study particular key aspects of human disease, including the process of metastasis, surgical techniques may be used to implant tumour cells grown in the laboratory into organs affected by metastatic disease, such as the liver or the colon.

Approximately 50% of cancer-bearing experimental mice (12.5% of total) will be used in preclinical trials, in which they will be administered with treatments designed to potentially benefit human patients.
These treatments can include drugs, which can be administered orally or by injection, or can include radiotherapy using a specially designed small animal radiotherapy machine. In a small number of cases (<5% of experimental mice, <1% of total), modification of the diet of the mouse might be used to better understand the impact of the treatment, or to enhance its effect. Similarly, in a small number of cases (<5% of experimental mice, <1% of total), tumour growth and response to treatment may also be monitored using advanced imaging techniques which are commonly used for human patients in the clinic, such as MRI, ultrasound or CT scanning. This will require mice to be anaesthetised for short periods of time while images are collected.

All experimental animals will be humanely killed and tissue specimens collected for analysis to maximise the data available from every study.

What are the expected impacts and/or adverse effects for the animals during your project?

The majority of mice in this project (75%) will have a subthreshold severity, meaning that they will show no harm, and will undergo no procedures other than earmarking for identification purposes. About a quarter of animals (25%) will have a predisposition to develop cancer, of which a proportion
(approximately 5%) will exhibit no more than mild adverse effects, as they will be sampled at timepoints prior to manifestation of clinical symptoms of ill-health. The remaining animals (20%) will be expected to develop moderate adverse effects associated with tumour development. With respect to procedural burden (e.g. imaging, therapeutic intervention, metabolic labelling), around 20% of animals will experience one or more procedures, which will never exceed a moderate severity.

Under this project, cancer-related genetic changes will be targeted to a tissue of interest, such as the intestine, pancreas, liver or skin, which will result in a specific predisposition to cancer development in that tissue. These animals will then be continually monitored for clinical signs which may indicate tumour growth. These signs can include anaemia, weight loss, swelling of the abdomen and development of palpable or visible tumours. Highly trained staff will monitor for these symptoms, and they are observed to interfere with normal behaviour, reach the limits allowed in the guidelines or have any consequences that are out with the guidelines, mice will be humanely culled and tissues harvested for analysis. Typically mice might exhibit mild clinical signs, which do not impact normal behaviour for around 1-2 weeks, and moderate clinical signs for 24-48 hours before they are humanely killed. Animals which undergo surgical implantation of tumour cells under anaesthetic, may experience transient discomfort (~48hrs), which will be alleviated through administration of pain relief.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

All the animals used in this project will be mice, with the following expected severities -

- 70% mild
- 30% moderate

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Cancer is a very complex disease that involves a number of different cell types, including epithelial cells, immune cells, stromal cells and blood vessels. To date, no *in vitro* system has been developed which can faithfully recapitulate all aspects of this complex nature of a tumour *in vivo*. Moreover, our own recent research in colorectal and pancreatic cancers have demonstrated that the immune and stromal components of genetically engineered mouse of models of cancer both align very closely to those of human cancers, and respond to therapeutic challenge in clinically relevant manner. Similarly emerging research in human clinical samples using single-cell sequencing has demonstrated that many of the characteristics of individual immune cell populations in human tumours are very closely resembled by the populations present in mouse tumours.

Which non-animal alternatives did you consider for use in this project?

In undertaking the research outlined in this project we will make extensive use of advanced organoid culture systems to further our understanding of the genetic and/or epithelial determinants of cancer development and progression. This will include the use of human and murine tumour derived culture systems, and will be highly informative with respect to target discovery and validation. These approaches currently represent the best available alternative to *in vivo* modelling in cancer, and will allow us to replace *in vivo* experiments in a number of circumstances. Indeed, in order to further develop these models, and to generate more accurate *in vitro* models, we are actively developing our organoid culture approaches through co-culture with immune and stromal cell populations.

Why were they not suitable?

While organoid culture methods will be used extensively in our research, they are not capable of recapitulating all aspects of complex tumour biology observed *in vivo.* Critically, many of the features of tumour biology which are lacking in organoid culture systems, such as immune evasion and stromal interactions, are now known to be key features in driving both poor prognosis and resistance to treatment in the clinic.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have generated a suite of highly effective complex genetic models of epithelial cancers, which we are now able to position in relation to human disease. Studies carried out with these model systems to date have been highly effective, providing a strong platform of preclinical data on which to base upcoming clinical trials. A combination of knowledge of the complex genetic nature of these model systems, the animal use which was required to generate these models over the previous 5 years, and the further proposed studies outlined in this application have been used to estimate animal use over the period of this licence.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have used statistical approaches to ensure that we use the minimum number of mice to generate significant results. The majority of mice will be generated in a pure inbred C57BL6/J background, which reduces variation between animals and in turn the number of mice required for cohort studies. This allows us to directly compare controls between different experiments and so we can be precise in the estimation of mouse numbers we need for each experiment. In addition, we can consult with experts in the field. At the end of each experiment, data is compared to previous studies by appropriate statistical methods to reduce mouse numbers.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will seek to minimise animal usage through production of mouse colonies using efficient breeding strategies, often through maintenance of stock animals which carry multiple genetic alterations. Where possible, we will reduce generation of control groups through use of inbred mouse strains, and comparison to historic data from previous experimental cohorts. Where possible, pilot studies will be undertaken to allow for power calculation and subsequent estimation of effect size and appropriate group size.

We have undertaken significant effort over the 5-10 years generating new “ex-vivo” models of intestinal cancers which are grown in the laboratory, in the expectation that adoption of these will allow further reduction in animal use. They allow us to tests efficacy of targets “ex-vivo” and so reduce the number of mice we test with genetic knockout or treat with inhibitors “in-vivo”.

Alongside the generation of organoid cultures, we have also developed approaches over recent years which allow us to orthotopically transplant these lines into syngeneic recipients (intracolonic or intrasplenic), which further reduces the number of mice we would need to breed through complex genetic crosses.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Throughout these studies we will use genetically modified mice. By introducing the same mutations found in human cancer to these mice, we can study the development of cancers that accurately resemble human disease. All animals receive the highest standard of care, and will be provided with environmental and behavioural enrichment.

Where possible we will use targeted genetic modification, which allows introduction of cancer driving mutations to specific tissues in adult mice. This approach will reduce any unwanted adverse effects which might result from untargeted genetic alteration. We will use advanced imaging approaches, similar to those used in patients in the clinic, including ultrasound, endoscopy, and PET/MRI to detect tumours at the earliest point possible. Close monitoring of tumour development (using well documented clinical signs and/or imaging) by highly trained staff will ensure any animal suffering is minimised.

Why can’t you use animals that are less sentient?

Cancer in humans is a very complex disease that involves a number of different cell types, including epithelial cells, immune cells, stromal cells and blood vessels. The use of genetic altered mice to study cancer development allows us to understand this process in a mammalian model which has an intact immune system, and develops cancers which very closely resemble those found in patients.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Robust local standard operating procedures for animal care, monitoring and minimal handling are in place, with enhanced social, environmental and behavioural enrichment provided. Lab members will ensure that all animals receive the highest standard of care, with close monitoring on tumour development (using well documented clinical signs and/or imaging) to ensure animal suffering is kept to a minimum. Where appropriate, for example pre- or post- any invasive or surgical procedures, anaesthesia, analgesia, access to palatable food treats and increased monitored will be implemented.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

For all studies we will adhere to published current best practice, and local guidelines. This includes following published guidance related to undertaking ageing studies in mice (Whitehead et al 2014, Wilkinson et al 2019), or *in vivo* studies of cancer in mice (Workman et al 2010). All experiments will be carried out, and any data published, in adherence to the ARRIVE guidelines (NC3Rs, Kilkenny et al 2010).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the NC3Rs guidelines and monitor refinement where such practices are published (NC3Rs website and elsewhere). In our facility, compulsory monthly user forums are also in place for all personal licence holders, and 3Rs advances are introduced here and implemented across the facility.

NON-TECHNICAL SUMMARY

217. Understanding the genetic basis of hearing and inner ear disorders

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aims of this project are to use genetically modified mice to explore i) the mechanisms of hearing and

vestibular function, ii) the genetic causes of hearing loss and iii) the signals that may lead to the regeneration of new hair cells in the damaged inner ear

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Our senses of hearing and balance depends on specialized sensory 'hair' cells located inside the inner ear. The hair cells are only produced during embryonic life. Their disappearance in adults is the main cause of hearing loss, in particular in the ageing population or after exposure to excessive sound levels. There are also many genetic forms of deafness, which vary in their severity and progression over life. Hearing loss affects more than 10 million people in the UK alone, and the World Health

Organisation estimates 280 million people worldwide suffer disabling hearing impairment. The current treatments for hearing loss are limited to hearing aids or cochlear implants and there is a considerable need for new and improved therapies.

Our understanding of the mechanisms of hearing and deafness has progressed dramatically thanks to genetic studies performed in the laboratory mouse over the past two decades. In the mouse, it is possible to inactivate a specific gene and find out how it affects for example the formation of the inner ear or hearing. In most cases, a gene important for hearing in the mouse turns out to have an equally important role in humans, which has led to progress in the diagnosis and prognosis of genetic forms of deafness. Furthermore, studies in genetically modified mice and recent advances in DNA sequencing technologies are now allowing researchers to identify the genes essential for hair cell formation. This knowledge could open up new venues for therapies: understanding how hair cells form is the first step towards stimulating their regeneration in a damaged inner ear.

In this project, we will use genetically modified mice to explore i) the mechanisms of hearing and vestibular function, ii) the genetic causes of hearing loss and iii) the signals that may lead to the regeneration of new hair cells in the damaged inner ear.

Our work will contribute to a better understanding of the genetic causes of hearing loss and balance disorders. This knowledge will improve our ability to diagnose precisely and predict the progression of these disabilities. By identifying some of the genes essential for hair cell formation and regeneration, it could also help developing new and better therapies for inner ear disorders.

What outputs do you think you will see at the end of this project?

We expect to identify and understand the roles of genes important for inner ear development, function and maintenance. We will also develop new animals models and experimental methods that could be used by other researchers.

Who or what will benefit from these outputs, and how?

In the short-term, the main beneficiaries of this work will be the scientific community at large and the pharmaceutical and biotechnological sectors who will have direct access to our results after publication. Discovering new genes important for hearing could improve the diagnostic of genetic forms of hearing loss, benefiting directly hearing loss sufferers. In the long-term, a better knowledge of the mechanisms of development of the inner ear has also the potential to lead to new gene and pharmacological therapies for hearing loss and vestibular disorders.

How will you look to maximise the outputs of this work?

Our findings will be published in open-access journals to maximize their diffusion. Our groups regularly attend international and national conferences to present their results and have close links to clinicians and charities working directly with hearing loss sufferers. We also participate to a number of outreach events to make the results of our research accessible to the wider public. Finally, we have an extensive network of collaborators in academia and the biomedical sector that will help us to maximise the scientific, clinical and industrial outputs and applications

of this work.

Species and numbers of animals expected to be used

- Mice: 4100

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Our understanding of the mechanisms of hearing and deafness has progressed dramatically thanks to genetic studies performed in the laboratory mouse over the past two decades. In the mouse, it is possible to inactivate a specific gene and find out how it affects for example the formation of the inner ear or hearing. In most cases, a gene important for hearing in the mouse turns out to have an equally important role in humans, which has led to progress in the diagnosis and prognosis of genetic forms of deafness. Furthermore, studies in genetically modified mice and recent advances in DNA sequencing technologies are now allowing researchers to identify the genes essential for hair cell formation. This knowledge could open up new venues for therapies: understanding how hair cells form is the first step towards stimulating their regeneration in a damaged inner ear.

Typically, what will be done to an animal used in your project?

We will breed and maintain different lines of mice carrying either specific mutations or genetic alterations known to result in inner ear impairment (causing hearing or balance disorders), or mice with genetic modifications that are not harmful but facilitate the study of a given inner ear cell type.
Some of the animals will be kept for up to 2 years to study their age-related hearing loss and balance function during ageing. In some experiments, we will inject the mice or supplement their diet with Tamoxifen, a compound that can be used to trigger a specific genetic alteration (e.g. deletion of a gene of interest) at a controlled time point. In other experiments, we will need to inject pregnant mice with mitotic tracers to study the potential impact of a given genetic alteration on cell proliferation in the developing inner ear of their embryos.

What are the expected impacts and/or adverse effects for the animals during your project?

Many of the mutant and genetically modified animals to be bred and maintained show no obvious ill effects in the long term, but these animals will be mildly discomforted by the ear clipping procedure necessary for their identification and genotyping.
In our current lines, the ‘breeders’ in which only one copy of the gene has been affected (heterozygous) are normal and do not experience any particular discomfort. However, some of their offspring’s will have both copies of the gene affected (homozygous) and could develop a severe hearing and/or balance impairment, causing moderate discomfort, as well as other pathologies that vary in their severity and tend to worsen with age. The animals developing such side effects will be culled humanely as early as possible to avoid any unnecessary suffering.
For our studies into the mechanisms of development or the inner ear, homozygous animals are usually culled at embryonic stages or soon after birth, minimizing therefore the level and duration of any discomfort or suffering. Tissue collected from these animals is typically processed for genetic and histological analyses, or alternatively maintained in culture for further experiments.
For the other studies aiming at characterizing auditory function in an adult animal, some homozygous mice may be kept until adult stages. The onset of hearing typically occurs at 2 weeks of age in mice, and animals in which the genetic modification can produce harmful side-effects will be carefully monitored and kept for the absolute minimum amount of time required to assess their hearing or balance function.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect that the majority of the animals (90%) will not experience any discomfort or no discomfort beyond the hearing loss or balance disorders associated to inner ear dysfunction or the transient stress associated to the necessary injection/marking procedures.
A small proportion of animals maintained for ageing studies may develop additional pathologies, such as kidney dysfunction or the spontaneous appearance of tumours, causing potentially moderate harm (10%).

What will happen to animals at the end of this project?

- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Understanding the contribution of a specific gene to inner ear development, function, or maintenance necessitates the use of animals since a fully functioning inner ear cannot be produced in a dish, outside of an animal.

Which non-animal alternatives did you consider for use in this project?

Some alternative now exist to produce inner ear sensory cells in a dish, using in particular embryonic stem cells.

Why were they not suitable?

The inner ear 'organoids' derived from stem cells do not allow the testing of auditory or vestibular function or the study of age-related hearing loss. Furthermore, they do not recapitulate fully the normal development of the inner ear, limiting therefore the type of developmental studies that we can perform in this system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We will use mice carrying either specific mutations or genetic alterations known to result in hearing or balance impairment, or animals with genetic modifications that are not harmful but facilitate the study of a given inner ear cell type. In the course of this 5 year project, we plan to breed and maintain approximately 4100 genetically modified mice. This number is based on our previous experience and that of our collaborators working with genetically modified mice.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Careful considerations were given to the Arrive guidelines and information available through the NC3Rs website using features such as Experimental Design Assistant to ensure that the minimum number of animals are used in this project, while keeping in mind the need to generate robust and reproducible data and providing the best possible welfare for the animals.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

When possible, each animal will be used for multiple analyses post-mortem. We will use wild-type animals from the transgenic colonies as controls to minimize animal outsourcing.
We also expect that our current work with alternative models and experimental techniques (in vitro stem cell systems) will contribute to a reduction of our use of genetically-modified mice in the course of this project.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The mouse has become the preferred model for many studies of the cellular and molecular biology of the auditory system: there are numerous mutant and transgenic strains available and a high conservation of the genes controlling inner ear development and function in mouse and humans. In choosing the genetic models for our studies, we will use when possible conditional and inducible alleles which are less likely to result in harmful defects. For studies involving a genetic modification that may cause early lethality, animals will be monitored daily and culled as early as possible and before any signs of severe suffering.
Why can’t you use animals that are less sentient?

Studying the function of the auditory and vestibular system necessitates animals that have reached an age when the inner ear is fully developed. Likewise, investigating the effects of specific genetic conditions on ageing and maintenance of the auditory system would not be possible without using aged animals. We are using chicken embryos to study the roles of genes that participate to inner ear development, but it is often necessary to validate our findings in a mammalian model such as the mouse to ensure that the function of a given gene is conserved across species.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all protocols relying on the administration of drugs, we will perform pilot studies to establish the minimal dose required and the least stressful mode of administration to minimize animal suffering. The animals maintained for ageing studies will be monitored more regularly after 12 months, and we will choose transgenic models (tissue-specific, inducible or not) and breeding protocols that have the least possible impact on animal welfare.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will consult NC3Rs resources, the ARRive guidelines and specific literature about the maintenance of ageing animals and the use of genetically modified mice (accessed online or provided by collaborators) for refining the design and conduct of our experiments.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will regularly consult the information provided by the NC3Rs (website, newsletter, website) and will be kept informed about the latest advances in the use of genetically modified mice and their alternatives by attending specialist conferences and accessing available resources on this topic (website, publications).

Home Office

NON-TECHNICAL SUMMARY

218. Understanding the interplay between different B cell subsets and the gut in immunodependent diseases

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Arthritis, Autoimmunity, B cells, The gut, Bacteria

Animal types	Life stages
Mice	adult, pregnant, embryo, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand how the gut-microbiota and gut "microenvironment" influence the differentiation of B cells, in

particular of a subset of B cells called regulatory B cells that can control the development of autoimmunity, as well as to understand more widely how the gut and bacteria contribute to the causes and severity of autoimmunity.
A retrospective assessment of these aims will be due by 12 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

This work is important because it has the potential to improve the management of disease in patients with rheumatoid arthritis and systemic lupus erythematosus, firstly by obtaining a greater understanding of the causes and development of these complex diseases, and secondly by providing new microbiota or gut-targeted therapeutic strategies for the treatment of these diseases.

What outputs do you think you will see at the end of this project?

The primary outputs of this project will be publications relating novel basic findings about the outcome of the interaction between gut-bacteria, B cells activation and arthritis. We expect to provide new information on firstly how regulatory B cells develop and how the gut, and the gut bacteria composition influence their development and function in healthy mice, and secondly how changes in gut-bacteria composition observed during the development of arthritis and consequent inflammation in the gut affects their differentiation and the severity of arthritis. In the longer term, we hope our research will have an impact on the way patients suffering from autoimmune conditions are treated. For example, our work will investigate how maintaining gut health (making sure the gut doesn't leak contents into the body) affects the severity of arthritis. The drugs we will use to maintain gut health (either by preventing it from becoming leaky, or by preventing the recirculation of inflamed cells to and from the gut) are currently being tested for their efficacy in gut related diseases and could be repurposed for the treatment of arthritis. Thus, our outputs may include novel treatment strategies.

Who or what will benefit from these outputs, and how?

Academic beneficiaries: Given that the work in our proposed project is looking at basic molecular and immunological interactions of a type of anti-inflammatory white blood cell called regulatory B cells (Bregs), and the potential genes and gut-derived metabolites regulating these interactions in the context of autoimmune disease, the main short-term beneficiaries of our work will be researchers working in the field of immunology, mucosal immunology, rheumatology and autoimmunity.
Industry beneficiaries: As the proposed research is to be carried out in animal models there will be no initial commercially exploitable results. However our results will be used to inform work developing therapies for patients (e.g. cellular therapy using Bregs, or manipulation of the metabolites in the gut to alter arthritis symptoms) that may, at a later point, result in commercially exploitable findings.

Non-academic beneficiaries: In the longer term, we hope our research will have an impact on the way patients suffering from autoimmune conditions are treated. If our hypotheses are confirmed by the experiments proposed under this licence we will be able to transfer this knowledge into patients with autoimmunity. Bregs are vital in restraining excessive inflammation and in regulating immune responses including those developing in autoimmunity and in cancer. Thus, for example, our extensive profiling of murine Bregs may identify molecules or genes that can be used to better define Bregs in both mice and humans. These markers they could then be used to better identify patients with abnormally low, or high, Breg numbers, possibly stratifying patients into correct treatment groups.
Similarly, strategies to enhance butyrate production (butyrate is a metabolite produced by gut bacteria that has been shown to reduce symptoms of arthritis in mice, partially by enhancing Breg function) by gut bacteria may be a non-invasive way of aiding tolerance in patients with inflammatory disorders. Manipulation of gut bacteria directly (via administration of antibiotics or probiotics) may lead to an enrichment of Bregs over pathogenic B cells. In

addition, other biological therapies aimed at restoring potential gut-barrier disruption or recirculation of gut-resident inflammatory cells into the joints could also explored in clinical trials. We anticipate that we need a maximum of 4 years before we are ready to translate some of our results to the clinic.

How will you look to maximise the outputs of this work?

In order to inform these beneficiaries of our work we will present our data at local departmental and divisional meetings as well at national and international meetings, in particular at meetings such as the British Society for Immunology, the British Society for Rheumatology, the European Congress of Immunology and the American College of Rheumatology and Keystone Symposia. We have the opportunity to present our findings at least 2-3 times a year at internal meetings, and we hope to present our data at least once a year at international meetings from the second year of the proposed work. Once completed, we intend to publish our data as open access articles in the highest possible impact journals, so that our findings are available to the widest possible audience, and make our data available on widely used public repositories such as GEO, while programming codes will be published via GitHub.

Species and numbers of animals expected to be used

- Mice: 8500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Unfortunately, at present we are unable to model systemic diseases such as arthritis *in vitro*, as autoimmunity affects multiple organs via complex crosstalk between different cell types. Answers that are more representative of human disease are obtained when we study directly the immunobiology of kidneys, liver, spleen, blood, lymph nodes and joints in diseased mice. This allows us to gain an overview of the potential of therapeutics. Presently we cannot do this either *in vitro* or *in silico*.
Mice and humans are genetically and physiologically very similar. The protein coding regions of the two genomes are on average 85% identical, and as much as 99% for some genes. In terms of the study of autoimmunity, this means that mouse models of disease have similar physiological characteristics and clinical symptoms to their human counterparts. As such, using mice as a model system for human autoimmunity has been proven to be very useful in research.
There is a wealth of experience using mice to measure immune responses. The availability of well described inbred, congenic and genetically altered strains, as well as well described spontaneous and inducible models of autoimmunity makes them currently the most appropriate species in which to carry out this work. In addition, it is now straightforward and affordable to generate genetically altered mice to allow the precise dissection of the contribution of individual molecules to the immune system and disease. Thus, mice provide an excellent experimentally tractable system to investigate autoimmune disease development, immune responses, and therapies.

Typically, what will be done to an animal used in your project?

Typically, a mouse used in our project will be induced to have a type of experimental arthritis. We will then compare the effect of different treatments, or the effect of changing the gut bacteria, on symptoms of arthritis and the activation of the immune system. The mice we use will typically be 7-8 weeks old, with fully adult immune systems, and the duration of experiments will typically be 2 to 3 weeks from first treatment to culling.

To induce arthritis, we typically first give a fully anesthetised (using inhaled anaesthetic) 7-8 week old mouse an injection of the molecule that the immune response is to be directed against to cause arthritis. This molecule will be in emulsion with an oil-based adjuvant, which is a substance that causes the mouse's immune system to recognise that molecule as dangerous, and to become specifically active against it. This injection is in a small

volume (0.05-0.1 ml) and is given just under the skin, in the fatty tissue on the rear of the mouse near the base of the tail. The mouse is then allowed to wake up and is returned to its housing. The mice will be unconscious for less than 5 minutes. This injection can cause some irritation, like a strong reaction to a BCG immunisation, for the first few days until the adjuvant is absorbed.
One week later we will anaesthetise the mouse again and, using a very fine needle, we will inject the same molecule in a very small volume of saline like solution (0.01 ml) directly into one knee. In the other knee we will inject the same volume of saline like solution with no molecule so that we can compare an arthritic knee to a healthy knee in the same mouse. Again, the mice will be unconscious for less than 5 minutes. These injections will cause some discomfort, however the mice are able to walk and feed as soon as they wake up and are returned to the cage.
Over the course of the next week mice will develop swelling in the knee that was injected with the molecule. This swelling starts on the first day and reaches a peak by 3 days, after which the swelling subsides and usually completely disappears by day 7. Although mice will undoubtedly feel discomfort at the inflammation in their knee, it is not sufficient to stop them moving, eating, or grooming. While the mice have arthritis we will measure the degree of swelling of both knees daily using callipers. On day 7 mice will be sacrificed so that we can investigate their immune system cells. Alternatively, we may sacrifice the mice at day 3 to investigate the immune cells at the height of disease.
To test whether different interventions can affect the severity of disease, or the function of cells of the immune system, we will usually begin treating mice before we give the first injection that causes disease. Treatment can be simply adding substances to their drinking water, however more commonly it will be given by oral gavage, or by intraperitoneal or intravenous injection. In oral gavage, a stainless-steel bulb tipped gavage needle, or a flexible cannula or tube, is attached to a syringe and used to deliver the compound into the stomach. For an intraperitoneal injection, a fine needle is used to inject the substance into the peritoneal space. Both these procedures are carried out while the mice are awake and being gently scruffed in one hand. Both procedures cause minimal distress when performed competently and properly, and may be performed daily for the course of the disease. For an intravenous injection the mice will be gently warmed up in a heating box to dilate the vein, which should cause minimal discomfort, and substances or cells injected into a vein in the tail. Generally, we will only give one intravenous injection.

What are the expected impacts and/or adverse effects for the animals during your project?

The major impact from the procedures in our licence will be the joint pain associated with arthritis-like disease. We have three models of inducible arthritis with slightly different durations of disease. Our most commonly used model involves joint swelling that peaks after 3 days and resolves after 7 days. Our second most commonly used model involves joint swelling that peaks after 6 days and resolves by 1518 days. Our third, and least used, inducible arthritis model can have joint swelling that lasts for a month, however we would typically cull these mice before that stage, as soon as we see differences between groups.
We will also use mice that display spontaneous arthritis which more closely models human disease. These mice can show joint swelling from 4 weeks of age that never fully recovers. We will generally cull these mice shortly after the peak of disease once differences between groups have been established (7-8 weeks of age).
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect the majority of animals that undergo arthritis in this licence to experience a moderate level of severity. The majority (~80%) of mice will be used for inducible arthritis protocols and these mice will experience a moderate level of severity or lower.
Mice that develop spontaneous, chronic, arthritis (~20% of mice used) will experience a moderate to severe level of severity due to the size and duration of joint swelling.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 12 April 2026

The PPL holder will be required to disclose:

- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Part of the work in our group is human-based *in vitro* studies using peripheral mononuclear cells and serum from rheumatoid arthritis and systemic lupus erythematosus patients, which always informs our murine work. Unfortunately, at present we are unable to model systemic disease *in vitro*, as autoimmunity affects multiple organs via complex crosstalk between cell subsets, as well as cross talk between different physiological systems such as the mucosa of the gut and the joint. Answers that are more representative of human disease are obtained when we study directly the immunobiology of intestines, kidneys, liver, spleen, blood, lymph nodes and joints in diseased mice. This allows us to gain an overview of the potential of therapeutics. Presently we cannot do this either *in vitro* or *in silico*.

Which non-animal alternatives did you consider for use in this project?

Whenever possible we will use human patient samples and healthy controls to inform our animal work. Unfortunately, the only samples we can reliably obtain from humans are from the blood (peripheral mononuclear cells and serum) and therefore we cannot fully investigate the crosstalk of cells and the interaction between organs throughout the body.
To study the role of the gut in arthritis we have considered using cell lines such as the widely studied Caco-2 cell line, colonic cells that are derived from a colon cancer patient. However, we have found that the small intestine is more affected than the colon during arthritis, and thus the relevance of findings using Caco-2 cells to arthritis is unclear and would need to be confirmed using mice. However, if our future experiments determine that colonic cells are also of interest in arthritis we will, whenever possible, use this as an *in vitro* alternative to mice.

Why were they not suitable?

While human peripheral blood immune cells can be used to investigate very basic interactions between cells, or basic responses of cells to different substances, *in vitro* systems do not reflect the tissue specific behaviour of cells during autoimmunity. Cells recovered from the small intestine, colon, lymph nodes, or spleens contain different populations of white blood cell from those found in blood, and they can behave in quite different ways. In addition, although steps have been taken to try and model the anatomical structures where cells would interact *in vivo*, this work is still at a relatively early stage and the dynamics and duration of how cells may interact with each other *in vivo* in a lymph node, or in the gut, are quite different from how they will interact in liquid growth media in a test tube or well of a plastic plate. Thus, we still need to examine cellular interactions in a system that is biologically relevant to humans.
In terms of addressing basic interactions between white blood cells and the epithelial cells that make up the lining of the gut by using gut cells lines, the major problem is the origin of the cell lines. The majority of intestinal cell lines derive from colonic cancers and do no accurately reflect how the small intestine, the part of the gut that is most immunologically active, would respond. In addition, similarly to work with human white blood cells, growth of colonic cell lines in liquid on plastic does not reflect the anatomical structures these cells would comprise *in vivo*. Moreover, as joint swelling in human arthritis is the result of multiple immune phenomena, there is no specific readout (changes to a particular cell, or levels of a particular molecule) that can act as a surrogate of disease. Thus, to test the effects of a particular intervention on the development of arthritis we need to look at what happens to symptoms of disease in a complex biologically relevant system such as a mouse.

A retrospective assessment of replacement will be due by 12 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The large numbers of mice included in this project reflect the work of the 7 researchers employed in our research group. Careful consideration is given to minimise the number of mice needed to give statistically significant results. These numbers also reflect the fact that we are maintaining ~15 different strains of mice and as such have multiple breeding colonies.
Previous work in our group has provided pilot studies for most of our protocols and we have used them for power calculations. For instance, in the AIA model the power calculations showed that an experiment with at least 3 mice per group can reach statistical significance. We will perform similar calculations for all models in order to reduce the number of mice used overall for each protocol.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The size of the group has been decided after consultation with our departmental statistician and we will continue consultation for optimisation of the experiments throughout the life of the licence.
We will continue to consult with the NC3Rs' Experimental Design Assistant, as well as with the PREPARE guidelines: Planning Research and Experimental Procedures on Animals: Recommendations for Excellence.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We will use pilot studies to provide data for power calculations so that we can use the minimum number of animals necessary per experiment. In particular, when investigating novel treatments, we will use small pilot studies to determine the potential efficacy of the treatment so that no mice get used in the future if the treatment proves unsuccessful.
Where possible, we will combine experiments so that one control group can be used for multiple experiments and to allow for sharing of tissues from the same mouse between researchers.
We will also use inducible models of autoimmunity such as AIA or STA where possible, as these models have 90-100% incidence, minimising the number of animals needed per experiment.
A retrospective assessment of reduction will be due by 12 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques

during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The highly complex nature of human autoimmune diseases requires *in vivo* experimental models, and in order to better understand their heterogeneity we have included multiple murine models.
Arthritis models:

1. Antigen-induced arthritis (AIA) – moderate severity.

AIA animals are injected with methylated bovine serum albumin (mBSA) in complete Freund's adjuvant (CFA) subcutaneously followed one week later by an intra-articular injection of mBSA. This results in a self-remitting mono-articular knee swelling which resolves within 7 days. This will be our main model used for arthritis as it is probably the least severe model of this disease. In addition, AIA only affects one joint and the disease course is very short, both aspects limiting the suffering of the animal. AIA is an acute model of disease rather than a chronic model and therefore we require further arthritis models to investigate the chronicity of arthritis, such as the CIA inducible model or the K/BxA^{g7} mice which develop spontaneous arthritis.

2. Collagen-induced arthritis (CIA) – moderate severity.

CIA animals are immunised with type II collagen in CFA and rarely boosted with type II collagen in incomplete Freund's Adjuvant two weeks later. In contrast to the acute, short-term AIA model that we will use most often, CIA persists for up to a month and affects multiple limbs and joints within the same limb. These features make CIA a closer match to human disease than AIA and will provide us with a more representative system to confirm the potential therapeutics that we can initially test in the AIA model.

We will generate initial data in AIA and use the CIA model for confirmation so as to limit the time that mice experience arthritis.

3. Serum transfer arthritis (STA) – moderate severity.

STA animals are injected with serum from arthritic K/BxA^{g7} mice. This arthritis model is a good combination of the two above protocols as it is relatively short term (resolution by 15-18 days after serum injection) yet it induces inflammation in both rear and front paws, which is similar to human rheumatoid arthritis. Another advantage of this model is that it does not require the use of immunostimulatory adjuvants, such as CFA, which can cause localised discomfort for mice. However, the disadvantage of this model, which gives us the need for the adjuvant-induced models above, is that STA only activates part of the immune system and as such does not fully represent the human disease, which involves most cells in the immune system.

4. K/BxA^{g7} mice – severe classification.

Unlike the inducible models of arthritis, K/BxA^{g7} mice develop a spontaneous arthritis involving a loss of both T and B cell tolerance and production of autoantibody. The K/BxA^{g7} model will complement the AIA, CIA and STA models in our study as its spontaneous nature obviates the need for bacterial adjuvant or any other transferred substance to induce disease.

In terms of duration, K/BxA^{g7} mice will not recover from arthritis and we will humanely kill the mice as soon as we see reproducible differences between treatment groups.
As well as using arthritis models we will perform experiments in lupus and multiple sclerosis models to confirm whether our results are arthritis specific or can be generalised to autoimmunity more widely.
Systemic lupus erythematosus models

1. MRL/*lpr* mice – moderate severity.

This is a well-established spontaneous model of lupus that develops around 8 weeks of age caused by a mutation in a gene that controls cell death (*fas)*. We anticipate the development of autoantibodies and clinical symptoms, notably alopecia, proteinuria and rash, similarly to the clinical features seen in humans. Similarly to the arthritis models above, unfortunately we cannot replicate the complexity of lupus *in vitro* without the interaction of cells and physiological systems. We have used this model extensively and have shown that it is sensitive to changes in the B cell population, the cells we are studying.

2. NZBWF1/J mice - moderate severity.

NZBWF1/J develop an autoimmune disease resembling human systemic lupus erythematosus. Autoimmunity is characterized by high levels of antinuclear antibodies, hemolytic anemia, proteinuria, and progressive immune complex glomerulonephritis. The incidence and severity of symptoms is more pronounced in females. NZBWF1/J mice have been used as a model for autoimmune disease since the early 1960s elucidating not only the complex immunobiological responses and mechanisms but also the genetic basis for the complex multifactorial disease.

Multiple sclerosis model - Experimental autoimmune encephalomyelitis (EAE) – moderate severity.

EAE has been used by a number of research groups to study the role of Bregs in controlling autoimmunity. This model appears to be sensitive to both Breg control and the modulation of gut bacteria. Thus, it will allow us to investigate mechanistic aspects of regulatory B cell function and the role of microbiota in disease induction. Extending our work to a model of a third autoimmune disease will determine whether our findings on B cells, microbiota, or the gut itself are disease specific or whether they may apply across the autoimmune spectrum. EAE can induce total bilateral paralysis in mice, however on average most mice will only experience at most bilateral hind limb paralysis and should experience no pain. Mice showing any signs of front limb paralysis will be humanely culled before the disease can progress. EAE in mouse is the gold standard animal model for human MS as, similarly to human RA, it is mediated by both B and T cells, and induces myelin-specific antibodies.

Why can't you use animals that are less sentient?

Mice and humans are genetically and physiologically very similar. In terms of the study of autoimmunity this means that mouse models of disease have similar physiological characteristics and clinical symptoms to their human counterparts. As such, using mice as a model system for human autoimmunity has been proven to be very useful in research.

Unfortunately, animals at a more immature stage of life, or less sentient animals, are not as genetically or immunologically similar to humans and cannot therefore replicate human clinical symptoms as reliably. Furthermore, our models are carried out over several weeks and thus we cannot use terminally anaesthetised mice.

The availability of well described spontaneous and inducible models of autoimmunity makes mice currently the most appropriate species in which to carry out this work. In addition, it is now straightforward and affordable to generate transgenic mice to allow the precise dissection of the contribution of individual molecules to the immune system and disease. Thus, mice provide an excellent experimentally tractable system to investigate autoimmune disease development, immune responses, and therapies.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

All protocols proposed in this application are well-published models that have been tried and tested to minimise discomfort. Anaesthesia and analgesia will be administered to minimise discomfort where appropriate, and animals will be assessed daily for any signs of distress including piloerection, hunched appearance, lethargy and loss of weight. In all the proposed *in vivo* models, if animals display any signs of distress, advice will be obtained from the named veterinary surgeon and, if distress cannot be alleviated, the animals will be humanely killed. Furthermore, we have chosen specific humane endpoints in order to limit the severity of disease models. Where appropriate, we will carry out pilot experiments to determine earliest endpoints of experiments so as to minimise suffering while generating reproducible data.

For instance, if we want to investigate the presence and function of long lived memory B cells (cells that are generated 2-3 weeks into an immune response) in one of our inducible autoimmunity models we will run initial experiments to determine when memory B cells first arise in that model. We will then design experiments that run just long enough to investigate these cells.

Lastly, all animals will be kept in well maintained, individually ventilated cages with sufficient bedding and nesting

material with good quality food and water, which will also reduce experimental variability caused by environmental stresses. Animals will be monitored for weight loss and signs of toxicity, pain or distress following the mouse grimace scale. In the event of unexpected adverse effects, we will use the humane endpoints written under every protocol.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow the PREPARE guidelines: Planning Research and Experimental Procedures on Animals: Recommendations for Excellence, as well as any other useful material, such as the Experimental Design assistant, from the NC3R website to ensure experiments are conducted in the most refined way. Where applicable we will also follow the refinements of arthritis protocols as outlined in Hawkins et al. *Applying refinement to the use of mice and rats in rheumatoid arthritis research*. Inflammopharmacology. 2015; 23(4): 131–150. (https://www.ncbi.nlm.nih.gov/pmc/articles/PMC4508365/), and have incorporated a number of their refinements into our experimental protocols.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will continue to consult with the NC3Rs website for any advances, as well as with the animal welfare officer, named veterinary surgeon and technicians from the animal facility.

A retrospective assessment of refinement will be due by 12 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

Home Office

NON-TECHNICAL SUMMARY

219. Understanding the mechanisms of ageing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b) **Key words**

ageing, reproduction, cancer, diet

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Ageing is defined as the continuous deterioration of an organism with age manifesting itself in the reduced reproductive output and a diminishing chance of survival. Why we age is still one of the highly debated questions

in biology, and several competing hypotheses exist. One hypothesis postulates that the separation of two major cell lineages - one for growth and maintenance (soma) and one for reproduction (germ line) - is a key factor in organismal ageing. The germ line as the producer of gametes and hence the subsequent generations is virtually immortal. This fact demonstrates that cell lineages may in principle continue forever. However, the tissues in the soma show less resistance to the passing of time and show continuous deterioration in their function and quality with increasing age. In contrast, germ cells show remarkable resistance and keep errors in the genome (mutations) during cell division and deterioration to a minimum. One possibility is that maintaining a cell lineage like the germ line is actually costly and comes at the price of a reduced maintenance in the soma. While a direct energy trade-off between the two is unclear, the importance of the interaction of the germ line and the soma for organismal ageing is indisputable. Nevertheless, very little is known about how the germ line interacts and communicates with the soma. While it is somehow intuitive that damage and stress negatively affecting the soma may also harm the cells in the germ line, it is less clear, how much the condition of the germ line affects the rest of the organism.
The ageing processes including the development of cancer in the soma are thought to be controlled by the germ line but the mechanisms involved are currently poorly understood. In recent years some dietary interventions including intermittent fasting and dietary supplements such as rapamycin have been suggested to be beneficial to slow down somatic ageing and potentially for slowing down the development of age related cancers. In this project we therefore will investigate the importance of germline-soma interaction for organismal ageing as well as the relative important of dietary interventions such as intermittent fasting and rapamycin in the zebrafish.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Understanding the mechanisms of ageing helps us to tackle the societal problems of increasingly ageing populations and understand the causes of age-related diseases such as cancer.

What outputs do you think you will see at the end of this project?

This project will produce some highly novel data on the mechanisms of ageing. Signs of organismal ageing can be observed in the accumulation of mutations (i.e. changes to the genomic code) in different tissues, in alterations of the epigenome (i.e. non-genetoc components of the genome e.g. the methylome) as well as in changes in gene expression in various tissues over a lifetime. In addition, reproductive success is a good indicator of general organismal fitness and declines rapidly with age. We will collect data on mutation rate, methylation rate, gene expression and reproductive output and cancer development in wild-type and cancer mutant fish, with and without germ line as well as with and without dietary interventions such as supplementation or intermittent fasting. All these results will provide information that is directly translatable to similar interventions in humans and other vertebrates and will be of wide interest.

Who or what will benefit from these outputs, and how?

Understanding the mechanisms of ageing and age related diseases such as cancer and how to intervene has far-reaching consequences of our rapidly ageing society. Testing simple interventions such as existing dietary supplements and dietary restriction in treatment of ageing and cancer promises to be of widest possible interest. As one grant reviewer has put it recently: “Who would not want an anti-ageing pill".

How will you look to maximise the outputs of this work?

We will disseminate our results through publications in internationally renowned journals, at national and international workshops, conferences and at events involving the general public and through the press. Our lab has a history of publishing also null-results and we apply an open and communicative policy to share our experiences with other labs, the wider scientific community as well as the general public. We are collaborating with a number of research groups across the globe and will continue to do so.

Species and numbers of animals expected to be used

- Zebra fish: 6600

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We will use the zebrafish as much of the ageing research to date has been performed in invertebrate organisms such as C. elegans and Drosophila flies. These invertebrate organisms differ in key biological aspects from vertebrates which affect the ageing processes in the two in very different ways. In order for studies to be directly translatable to other vertebrates including humans, the use of a vertebrate model is necessary. No other, less sentient vertebrate is better suited than the zebrafish. We will use all life stages, as we study ageing throughout life.

Typically, what will be done to an animal used in your project?

Genetically Altered (GA) fish of well-established mutant strains (cancer mutants and germline-ablation mutants) will be bred and monitored throughout life.
One strain of the project simply aims to collect fish at different ages for follow-up studies in their tissues for signs of ageing and cancer development by histological analyses and sequencing.
The second strain aims to understand how mild dietary interventions such as dietary restriction through intermittent fasting and the supplementary feeding of rapamycin may stall or halt the signs of ageing and related cancer.
For both purposes, fish will mainly be maintained under the different treatment until a maximum age of 24 months.
Fish may be anaesthetised up to five times for the collection of finclips or for skin swabbing. These procedures will occur at a maximum frequency of every six months.

What are the expected impacts and/or adverse effects for the animals during your project?

Fish in this project belong to GA mutant strains which result in germline ablation or the development of cancer phenotypes. All these strains are already established and the phenotypes and onset of phenotypes well established. All fish used in this project will not experience any severity level beyond mild. The GA mutant strains developing cancer phenotypes will be carefully monitored. The onset of cancer in these strains is well known and we will end our experiments at an early stage to collect tissues for sequencing and histological analyses.
The dietary interventions such as dietary restriction and supplementary feeding of rapamycin are expected to improve the overall health of any fish, and more so in mutant strains of the types mentioned above. So if anything, we expect beneficial effects from these treatments.
All other procedures such as anaesthesia, fin clippling, skin swabs and gamete collection are standard procedures that have been practised a lot in our lab.
Anaesthesia is not expected to have any harmful effects. Fish that do not return to normal swimming behaviour within 30 minutes after removal of the anaesthetic will be killed by a schedule 1 method.
Genotyping is generally limited to a skin swap, and where necessary to a finclip. Following fin clipping for genotyping analgesia will be provided to reduce potential pain. Any fish exhibiting any abnormal behaviour following skin swabs or finclips will be killed by a schedule 1 method.
Infections can result from fin clipping (<1%) or from damage to scales or loss of mucous surface from swabbing. The procedure will be carried out using sterile equipment. Fish that develop signs associated with infection will be killed by a schedule 1 method.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

We expect mild severities at all stages and for all protocols as any other categories will be euthanised immediately.
What will happen to animals at the end of this project?

- Kept alive
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complexity and fundamental nature of studying the processes involved inn ageing and the development of ageing related diseases such as cancer currently still requires the use of animals. The reason is that the mechanisms of ageing are not yet fully understood and this project will considerably contribute to our understanding of these mechanisms. Using the zebrafish as the lowest sentient vertebrate model species allows us gathering insights into ageing in vertebrates that are directly translatable to other vertebrates including humans.

Which non-animal alternatives did you consider for use in this project?

Invertebrate model species such as C. elegans and Drosophila fruit-flies are widely used in the study of ageing.

Why were they not suitable?

However, the fact that their somatic tissue no longer grows during adulthood changes the interaction between germline and soma for the process of ageing decisively. It is therefore necessary to study these mechanisms ins a vertebrate, and the zebrafish belongs to a low sentient category.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

These numbers are based on our previous experience with similar protocols. We worked out how many fish we will need to answer our scientific questions and then calculated how many fish will need to be used to generate those experimental fish.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

We have been breeding zebrafish for quite some time and know that a minimum stock population is needed to maintain a healthy population in the lab. Many of the GA lines that we will use are stocked as frozen gametes at zebrafish breeding centres. But in order to use these, we will have to get in the embryos rear them to adulthood and then use the next generation of fish for our experiment.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

We aim to maintain our fish under optimal conditions in the lab and are continuously informing ourselves about improved feeding and maintenance protocols as well as protocols to collect tissue samples for genotyping etc.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All the treatments in the protocols involve mild severity levels. In fact, some of the treatments are expected to have beneficial effects (e.g. dietary intervention). We will end the experiments at the earliest possible time points when cancer pehnotypes, which are the most harmful expected phenotypes start developing. This means we keep even these potentially harmful cancer phenotypes to a minimum.
All other procedures are standard procedures and are only carried out by highly trained staff.

Why can’t you use animals that are less sentient?

Invertebrate model species such as C. elegans or Drosophila fruitlfies lack some of the key biological aspects that are necessary to study the role of the interaction between germ line and some in vertebrates, namely a growing proliferating soma. The zebrafish is in the least sentient vertebrate category.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will carefully monitor all animals generated, bred and maintained under this license. Any animals showing signs of suffering or suboptimal behaviour will be immediately removed and killed under schedule 1 procedures.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We closely follow any guidance by leading institutions in zebrafish breeding and husbandry.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We keep ourselves updated by visiting relevant conferences and taking useful online courses.

NON-TECHNICAL SUMMARY

220. Understanding the replication of and immune responses to coronaviruses in pigs

Project duration

1 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (iii) Improvement of the welfare of animals or of the production conditions for animals reared for agricultural purposes

Key words

coronavirus, respiratory disease, virus replication, immune responses

Animal types	Life stages
Pigs	juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this project is to establish a model of porcine respiratory coronavirus (PRCV) infection in pigs to investigate protective immune responses to infection and vaccination. This model will help understand protective

immune responses to coronaviruses, with relevance to SARS-CoV-2 infection of humans.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The coronavirus responsible for the COVID-19 pandemic, SARS-CoV-2, is a new virus about which very little is known. Animal models are being developed which show susceptibility to infection, however the virus is not known to naturally occur in any of them. Investigating the immune responses to both infection and vaccination of a naturally occurring respiratory coronavirus in pigs, would allow detailed host responses to be defined and help understand the biology of respiratory coronaviruses.

What outputs do you think you will see at the end of this project?

The output from this project will be development of a porcine respiratory coronavirus model which mirrors the pathology seen in COVID-19 / SARS-CoV-2 infection of humans. This model would then be available to study various aspects of vaccinology, immunogenicity and therapeutic interventions as a tool to assist COVID-19 research.

Who or what will benefit from these outputs, and how?

Novel therapeutic and prophylactic anti-viral solutions are urgently required to control the spread of emerging coronaviruses including SARS-CoV-2. An understanding of coronavirus replication and the host responses to coronavirus infection will inform future strategies to protect the human and livestock populations from potential new incursions of novel coronaviruses.

This project aims to develop porcine respiratory coronavirus as an animal model to understand more about how coronaviruses cause disease and the immune responses that are raised against coronaviruses and vaccines in the natural host.

Our studies will benefit researchers working in the fields of molecular virology, virus evolution and particularly, coronavirus research. However, it will also be important to medical researchers investigating antiviral therapies.

How will you look to maximise the outputs of this work?

The data will be shared in open-access data repositories a soon as practicable to allow other researchers to benefit from these results. Knowledge generated by this project will be widely disseminated to the research community as soon as practicable through open-access peer-reviewed journals and presentations at national and international virology conferences, collaborative discussions and interactions with members of the scientific community. Conference attendance will allow the dissemination of results and facilitate collaborative discussions, enhancing potential outputs from the proposed project.

Species and numbers of animals expected to be used

- Pigs: 18

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Pigs are being used as they are the natural host for porcine respiratory coronavirus (PRCV), and this infection has previously been shown to produce very similar lung disease as SARS (and by extension COVID-19). The ages of pigs being used are in line with previously published literature.
Typically, what will be done to an animal used in your project?

The duration of the pilot experiment is likely to be 14 day maximum, and will involve sedating the pig then taking swabs and a blood sample. Whilst sedated, the pig will have virus administered into the nose directly, and into the trachea via the mouth, or virus will be administered by aerosol using a closefitting face mask. The sedation will wear off and the animal will be kept for up to 14 days, and monitored closely at least 2 times a day. Swabs and blood samples will be taken from the animal between being inoculated and being culled at the end of the study. At the end of the study, the pigs will be killed by administering an overdose of anaesthetic.
What are the expected impacts and/or adverse effects for the animals during your project?

Animals will experience mild and transient pain associated with a blood sample being taken, which includes restraint and insertion of a needle through the skin. The same level of discomfort will be experienced by those pigs which are sedated. The effects of PRCV in pigs are mainly either subclinical or mild. The mild signs will be intermittent coughing or a mild elevation in body temperature. Relatively rarely, animals infected with PRCV will have difficulty breathing, become lethargic or anorexic. In this project, any animals which show these more severe signs will be killed if the duration exceeded the endpoints in this licence.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

According to the cumulative literature, 95% of animals are expected to show either no or mild clinical signs. Less than 5% are expected to show moderate clinical signs but one of the objectives in the pilot is to develop the PRCV model and evaluate the clinical signs in pigs.
What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Animals are required to study the immune responses to virus infections.
Which non-animal alternatives did you consider for use in this project?

Cell culture and molecular biology techniques will be used to characterise PRCV in the laboratory before infecting pigs. We will use laboratory techniques to understand the responses of the pigs to infection with PRCV using blood samples and tissue samples taken post mortem.
Why were they not suitable?

It is not possible to analyse immune responses to virus infection without using a host animal because the immune system is very complex.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used

throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of pigs in this pilot study is based on the available literature.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

As this is a pilot study, the design of the experiment is based on the published literature on this subject.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

This pilot study will be used to optimise the number of pigs required for future experiments.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

We will take blood samples from pigs, sedate them to avoid causing distress and infect them with a porcine coronavirus. According to the available literature, most of the pigs will experience mild clinical signs. They will be closely monitored by experienced staff throughout the study. Blood samples will be taken at regular intervals and the pigs will be killed at the end of the study to evaluate the pathology caused by the virus and assess the immune responses in the pigs. The blood samples will not cause lasting distress or harm to the pigs.
Why can’t you use animals that are less sentient?

Pigs are a good model for human respiratory disease due to their size and the shape of their lungs. They are also a natural host of a respiratory coronavirus.
How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

This is a pilot study and the pigs will be monitored closely by experienced staff throughout the experiment. The results of this study will be used to inform future experimental design.
What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will follow guidelines from the NC3Rs.
How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We will consult the AWERB for advice about the 3Rs and participate in the annual 3Rs workshops organised onsite.

Home Office

NON-TECHNICAL SUMMARY

221. Understanding the role of the body clock in behaviour and physiology

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	adult, pregnant, juvenile, neonate, embryo

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The aim of this work is to define how circadian timing systems (our bodies' internal clocks) regulate rhythmic physiology, energy metabolism, and our overall cardiovascular and metabolic health.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The circadian timing system regulates daily rhythms in virtually all aspects of our biology, from sleep/wake timing and eating habits, through to how individual cells of the body produce and use energy. Uncovering how this endogenous clock system works is fundamental to understanding not only our basic biology, but also how our health is impacted by aging and the pressures of modern life (which can undermine the normal function of our body clock). It is becoming increasingly clear that disruption of our circadian clock is detrimental to health and well-being, and has been linked to numerous disease states ranging from cancer to metabolic diseases, including type 2 diabetes and cardiovascular disease. Our work examines this link between the clock and disease states at both a cellular and whole organism level. These studies continue to reveal important events which drive pathology and identify novel approaches to improving human health and well-being.

What outputs do you think you will see at the end of this project?

Major Benefits. The primary outcome and benefit of this project is the advancement in understanding of how the biological timing mechanisms regulate physiology and behaviour. A specific context of our work is in the development of metabolic diseases, such as type 2 diabetes and cardiovascular disease, and how disruption of our bodies' clock system (e.g. through aspects of modern life such as shift work) contributes to these conditions. Thus, a primary output from this work is knowledge creation, which will be delivered through publication in academic journals, conference seminars, and communication with regulatory and advisory committees, the clinical community and wider public.

The potential for this research to benefit human and animal health is high, given the scale of the unmet need in clinical medicine for new ways to deal with metabolic diseases and pathologies associated with circadian dysfunction. Our work will identify key cell types and molecular pathways that initiate and propagate such disease processes. These basic science advances are essential in the long-term for medical breakthrough and therapeutic advancements. Development of therapeutic interventions (both pharmacological and non-pharmacological) which target the circadian rhythm to improve well-being is achievable. For example, outputs from our work have, and will continue to inform on the use of timed feeding, specific light interventions and improvement of behavioural routine to achieve health benefits. Benefits will include the identification of molecular targets at which new pharmaceutical products could be aimed.
The research also benefits the health and welfare of animal in the laboratory, farm and at home by providing better understanding of how environmental conditions impact on the circadian clock, and in turn downstream clock-related physiology.
Additional outputs are likely to include the development of new research methods and protocols. This may be in the form of refining and/or enhancing current methods, or through the development of new tools and approaches. Our data will be made available to other researchers in the scientific community at the earliest appropriate time, and therefore enable further/secondary use of the outputs for scientific discovery.

Who or what will benefit from these outputs, and how?

Our internal body clock is fundamental to our biology, and how we live our lives (e.g. when we eat, sleep, work, stare at computer or phone screens…) can profoundly affect our health. Our work will define new aspects of cardiovascular and metabolic physiology, reveal mechanisms of circadian clock control over physiology, and determine how clock function (and dysfunction) contributes to metabolic disease. The outcomes will inform the scientific community, health care sector, occupational health regulators, and government/industry advisory boards,

and the public in general, in terms of both understanding the potential positive/negative impacts of daily routine on health, but also how light and/or food may be used to alleviate such consequences.

How will you look to maximise the outputs of this work?

We will engage with the wider scientific and clinical community through presentations at major national and international scientific meetings, and via high profile publications. To ensure the outcomes of our basic science research achieve maximum benefit, we will focus on communication and engagement with key stakeholders (healthcare sector, regulators, policy makers), the public, and relevant patient groups. We have a strong commitment to Public Understanding of Science activities, in maintaining public interest and trust in UK research, and informing the public on the latest research findings. **Species and numbers of animals expected to be used**

- Mice: 13500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We use adult mice for the vast majority of studies undertaken within this project. This includes normal control and genetically modified mice. Importantly, the systems that we are studying (the body clock, regulation of energy metabolism, and development of obesity) are well reproduced between mice and humans, and mice are therefore appropriate for this work.

Typically, what will be done to an animal used in your project?

Common procedures (~65% of the mice that we study will undergo one or more of these procedures). **i**) Animals may be monitored for natural behaviours under normal or altered environmental conditions (e.g. alterations in light/dark cycle, modulation of ambient temperature across a natural range, altered patterns of food availability). **ii**) Animal may undergo physiological monitoring and/or imaging using non-invasive specialist equipment. **iii**) Animals may also receive injections or have small blood samples collected. **iv**) Animals may have the amount, composition (e.g. increased fat content) or timing of their food changed.

Rare procedures (~12% of the mice that we study will undergo one or more of these procedures). **i**) Surgery in order to insert a device for physiological monitoring, slow release drug delivery, or to induce a change in gene expression (minor surgery with rapid recover of typically 1-3 days). **ii**) experience changes in ambient temperature (within a naturally occurring range) to assess adaptive metabolism.

In addition to these procedures, mice will be used in this project for breeding, and for provision of cells and tissues for laboratory based studies.

What are the expected impacts and/or adverse effects for the animals during your project?

Much of this work examines normal behaviours and physiological processes in the animals. Therefore, most animals experience only transient and mild adverse impact (e.g. temporary stress, discomfort, and/or weight loss) caused by alterations in their housing environment (e.g. changes in lighting cycle, ambient temperature, timing of food availability) and/or cage type. Removing food access for 1-2 days may lead to more pronounced weight loss, but this is rapidly recovered upon re-feeding.

Some animals used here will also experience transient discomfort and mild pain due to surgical implantation of monitoring devices and/or injections.

Alterations in diet composition may lead to weight gain and obesity. Over time (~4 months in mice), obesity may lead to insulin resistance and low level inflammation, akin to that observed in individuals with type 2 diabetes. This may cause subtle changes in behaviour (e.g. reduced activity), but is not associated with any suffering or distress.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The studies to be undertaken in this project will result in a cumulative impact to the animals that are of a sub-threshold to mild (~60% of animals used) or moderate (~40% of animals used) severity rating.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The diseases we are studying involve the complex interaction between multiple organ systems, and often progress over long periods of time.

Which non-animal alternatives did you consider for use in this project?

We routinely use in vitro (e.g. using cells) and information from human data resources (e.g. UK BioBank). In vitro cell/tissue assays can offer powerful models to test how genetic or pharmacological alteration of cell function may impact on clock or metabolic activity and vice versa, and can inform on the best design of subsequent in vivo animal experiments. The complex neural pathways controlling sleep and metabolism however make it unlikely that such approaches can replace the need to use animals. Human studies are important for informing our work, but cannot replace the need to do mechanistic studies in animals.

Why were they not suitable?

We always explore alternatives to using animals in research, as well as developing methods which allow us to use fewer animals to achieve the same scientific objective. However, since circadian biology and metabolic diseases involve multiple tissue systems acting across the body, it is impossible to wholly mimic this biology in a culture dish or by computer.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

We have extensive experience with these approaches and in running projects of similar scope. Thus, estimates of animal use is based on i) previous work and experience with the methodologies used, the physiological parameters to be studied, and the specific mouse models to be used; ii) the scope and objectives of the current project; and iii) careful consideration of experimental design.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

The projected number of animals used over the 5-year duration of the licence is an estimate. At each stage of the project and within each study conducted, we will ensure that animal use is minimized. We employ careful planning

of experimental design including the use of supporting purpose written software (including the National Centre for the Replacement, Refinement and Reduction of animals in research, Experimental Design Assistant). We have consulted with statisticians in preparation of this licence, and will continue to do so throughout the project.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

In addition to good experimental design, we work to optimise animal use wherever possible. This starts with efficient breeding of transgenic mouse lines. For example, where possible we use 'wave breeding' techniques to minimise age variation and breeding numbers, while achieving adequately powered group sizes. Where new approaches are being employed, we optimise experimental conditions through pilot studies. Wherever possible, we share tissues, data, and results with other research groups to maximise the outcome and use of each animal study.
Moreover, through continuous development of our approaches we seek to reduce the use of animals. For example, our development of novel mouse lines which allow longitudinal measures of gene or protein expression (via bioluminescence) to be collected from individual animals rather than requiring many animals to be studies at numerous discrete time points.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

This project focuses on mammalian physiology with all our studies being conducted in mice. Our scientific objectives require us to examine whole animal physiology in adult animals over both short and long-term time frames. The methods we use are, for the most part, non-invasive or involve only temporary discomfort due to surgical implantation of a monitoring device (e.g. to monitor heart rate). Animals may also be provided with alternative diets (e.g. to drive obesity), but these conditions do not themselves lead to suffering and/or distress. To minimise any impact to the animals, we always end the studies as soon as the study objectives have been met. Our researchers are well trained and experienced in animal behaviour and physiology; this reduces stress to the animals under study, and ensures that animals are well monitored and cared for.
Why can’t you use animals that are less sentient?

We cannot adequately replace these studies with other species (e.g. insects or fish) or with very young (neonate) mice and achieve these objectives. As most of our studies involve long-term assessment, they cannot be conducted in terminally anaethetised animals.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

As we study natural physiological responses and behaviours in the animals, minimising stress, discomfort and other general impacts is critical to our work. We take many steps to minimise adverse impact, including acclimatisation of the animals to our researchers and any test conditions (e.g. new cages) during study. Examples of relatively simple, yet highly effective refinements include using appropriate handling techniques (e.g. tube handling for cage extraction) and use of appropriate home cage enrichment. Where animals do undergo invasive treatments (e.g. surgery to implant monitoring devise), we ensure full recovery of the animals under close monitoring and post-operative care to minimise any suffering (e.g. pain management with analgesics, provision of extra fluids). Where appropriate we will assess whether acute studies can be undertaken under general anaesthetic rather than in conscious mice (e.g. acute ECG assessments). Examples of our past and ongoing refinement of approach include increase efficiency in breeding through the use of conditional and inducible

transgenics (which allow for the activation or deletion of genes in specific cells and tissues at specific times), development of genetic reporters to reduce animal use, transition to advanced technical approaches which provide higher quality of information with less impact to the animals, and development of sophisticated analyses to maximise the data obtained from in vivo studies.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will ensure best-practice through continual assessment of experimental design and study outcomes, relative to the cumulative impact to the animals. We will stay informed about regulatory standards (e.g. LASA and NC3Rs publications) and developments within the scientific community (e.g. publications on standardisation and best practice for metabolic phenotyping of mice).

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

We stay informed about advances in 3R approaches, and will continue to implement these into our work where appropriate. This includes, but is not limited to, staying up to date with NC3Rs recommendations, developments in the literature and scientific community, as well as through our own developing work and discussions with our NVS and NATCO.

Home Office

NON-TECHNICAL SUMMARY

222. Using bioelectronics to study the nervous system and to restore neurological functions.

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.

Key words

Brain, Spine, Nerves, Technology, Disability

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

In the world over 1 billion people are affected by a neurological disability (for example the inability to move a limb or talk, blindness or deafness, etc.), due to either brain/spinal cord injuries, stroke, cancer, etc. Most of these disabilities lack specific and effective treatments and medical efforts are generally placed in supportive care rather than cure.
'Bioelectronics' (small electric devices implanted in the body) offers a valid option to treat many of these diseases by interacting with the body, sensing what is wrong and substituting and restoring lost functions. An example is curing paralysis (inability to move a leg) following a spinal cord injury. Usually the signal to move a leg starts from

our brain, it goes through the spinal cord in our back bone to then reach our leg muscles. However, when our spinal cord is injured after injury to our backbone, it cannot recover, and therefore the signals do not pass through anymore. With 'bioelectronics', we can transfer information directly from the brain to the limbs, bypassing the spinal cord injury, and therefore restoring leg function.
To achieve this important result, we have to study four aspects of the process:
1 – How these devices can control and substitute body functions effectively.

2 – How the devices can sense what is wrong with our body.

3 – How to connect these devices and 'talk' between them to bypass sites of injuries.

4 – How to make these devices stay in the body for a long time without breaking or losing their activity.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

This new type of technology will offer tangible treatment for multiple diseases of the brain, spine and nerves, which are untreatable at present. This includes paralysis, Parkinson's Disease, epilepsy and brain/spinal cord injury. Additionally, these innovative devices will allow us to find out more about diseases of which we do not know much about, so increasing the chance to find new treatments.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

8000 Rats and 3050 Mice Over five
years period

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

A third of the animals in this project license will have an intervention during terminal anaesthesia (animal humanely killed before waking up) and therefore not having any discomfort. These types of interventions are used wherever possible and they are important to collect information used to minimise and optimise intervention in animals which are woken up after the intervention.
The rest of the animals will undergo surgery with recovery (woken up after receiving an intervention), with a moderate discomfort in the immediate post-operative period, during which pain killers will be given. Post-surgery, they may show reduced or altered movements, where they have received a lesion to mimic an aspect of the human disease. These animals may later receive a treatment to repair the lesion, such as neural device implantation, which will assess the effectiveness of bioelectronics to ameliorate the effect of the disease model. Animals are expected to have mild to no lasting adverse effects after they have recovered from the surgery itself. Some animals will undergo mild food restriction to motivate their performance in behavioural tasks which are reward-driven, and they will be carefully monitored to ensure that no sign of dehydration occurs, and any weight loss is kept to less than 10% of their adult body weight. We expect no adverse effects due to the behavioural testing.

At the end of all experiments animals will be killed, and in most cases, tissues taken for more testing in the laboratory.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

This research is only possible because we need to study whole nervous system diseases as we do in patients. Human studies in patient groups are used as much as possible, with functional imaging and post-mortem studies but new therapies to arrest the disease can only be studied using animal models because of the experimental nature of the devices being tried.

Reduction

Explain how you will assure the use of minimum numbers of animals.

We carefully design our experiments such that we maximise the behavioural and tissue data collected from each animal. We use the minimum number of animals required to yield statistically and biologically meaningful data, and we will work towards designing more refined behavioural tests such that the number of animals needed to generate this data can be reduced.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Rats are the best experimental animal for neural interface device development because the brain/spinal cord/nerves are reasonably large, there is sufficient space in the body or under the skin for connectors and interfaces, and the patterns of nerve impulses in response to movement are similar to those in humans.
Mice are used when it is important to use genetically modified animals, particularly in experiments in which we are working out which mechanisms in the immune system are responsible for scarring in response to prostheses.
Our devices will first be developed in vivo in non-recovery testing models and subcutaneous implantation models. These models entail a lower degree of harm for the animals, and ensure that only devices which are working as intended are progressed on to the neural implantation models.
All experiments are done on one side of the animal only, to minimise disability.
Furthermore, rats and mice have a biology of nervous system damage, repair and neuronal growth similar to humans. Rats are also capable of complex behaviour and skilled paw use, making it possible to achieve good behavioural outcomes. Mice are used for some experiments because they can have their DNA manipulated. Their behaviour is almost as good as that of rats.

We minimise suffering by developing and/or using behavioural outcome tests of high resolution that pick-up deficits in fine movement control. Therefore, it is not necessary to make large and disabling injuries. We use well established lesion models that have been extensively used in our lab for a number of years, thus we have achieved a high rate of reproducibility.

NON-TECHNICAL SUMMARY

223. Using mouse models of dementia to understand disease mechanisms

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Mice	embryo, neonate, juvenile, adult, pregnant, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To characterise mouse models of dementia causing diseases to understand underlying cellular and molecular mechanisms. Proof of principle drug, genetic intervention and environmental intervention studies to test the potential of possible therapies to ameliorate dementia-associated phenotypes.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Today about 50 million people world-wide have dementia globally. There is no cure for the diseases that cause dementia and current treatments for disease are largely ineffective. Dementia-causing diseases are increasing in occurrence globally because of rising life-expectancy and they cause a huge societal and economic burden world-wide. Despite identification of some of the genetic changes that cause dementia-resulting disease over the last 3-decades; how these genetic changes result in the molecular and cellular changes that underlie dementia is still not well understood. Thus, further medical research is required to understand how changes in the brain and body cause a decline in the ability of people to think and remember, so new therapies can be developed.

What outputs do you think you will see at the end of this project?

The primary objectives of this project are to provide new and well characterised models of dementia-causing

- diseases, further understanding of the causes of dementia-related phenotypes, to undertake proof-of-
- principle studies of potential therapies for dementia-related phenotypes.
- New models generated on other projects will be characterised in this project to full-fill current gaps in preclinical modelling of dementia-causing diseases, including identification of novel therapeutic targets and the determining the mechanisms underlying biomakers used for early diagnostics.

We aim to define the order in which dementia-relevant phenotypes occur in a series of mouse models of dementia causing disease; including those not previously studied. Specifically, we will undertake in depth phenotyping of 5-10 preclinical mouse models of dementia causing diseases, to provide new understanding of common pathways to dementia, as well as disease specific biology.
Firstly, by the identification of specific genes, changes in genes or chromosomal regions that modulate dementia-related phenotypes. Secondly, by the identification of sub-types of cells in which this genetic variation acts. Thirdly, to determine how environmental and pharmacological interventions can modulate dementia-related phenotypes. These data will lead to the identification of potential targets for therapy and preclinical model biomarkers. These will then need further evaluation in human cellular models (including iPSC and organoids), human post-mortem tissues and were possible in clinical datasets. This work will be undertaken by the project licensee in collaboration with others and also independently by other researchers. This combined knowledge can then be used to develop new treatments to slow or prevent the development of dementia. The complexity of developing new treatments for brain diseases makes it likely that new therapies will not be developed within the 5-years of this project.
These new research findings will be published in the primary literature and also all testing protocols will be made freely available.

Who or what will benefit from these outputs, and how?

In the short-term this project will supply mice and tissues to other researchers, including from genetic crosses, animals that have undergone drug treatment or changes to the environment and new mouse models characterised during this project. This will refine and accelerate the research of these investigators.
In the short-term other researchers will also benefit from outputs in the primary literature; both directly produced from this project and as a result of collaborations with other researchers. We will also deposit primary data onto established data repositories were possible.

This research project will contribute to a refinement of mouse models and an improvement in the value of research outputs using these models within the 5-years of this project. In particular, the detailed characterisation of new mouse models will benefit other researchers. For examples, researchers studying behavioural changes will benefit from the our detailed studied of sensory, motor and metabolism changes which will allow them to refine their research by controlling for these factors in future studies if required. Researchers focusing on molecular, cellular and electrophysiological causes of dementia will be able to use the data from this project to help identify the model that is most appropriate for their research question.
We will also produce data determine the role of specific molecular and cellular causes of behavioural changes associated with dementia. These new pathways can be tested to determine if they can be modified by drug therapies to delay or prevent dementia-associated cognitive and behavioural changes. Thus this basic/translational research projects outputs will benefit dementia patients and their carers' and wider-society in the long-term.

How will you look to maximise the outputs of this work?

We will disseminate all new knowledge internally and externally by publication in the scientific literature. This will include the results of all phenotyping studies that passed internal quality control checks. We will actively collaborate with other leading dementia-diseases mouse model researchers and attend international conferences to further disseminate research findings internationally.
Species and numbers of animals expected to be used

- Mice: 54000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Breeding mouse models of dementia-causing diseases with other models will allow us to link molecular and cellular changes to specific dementia-relevant phenotypes. In particular, we can study the causes of dementia-related apathy/ decline in motivation/depression, executive dysfunction (loss of ability to coordinate and control behaviour) and loss of sub-types of memory in mice, which would not be possible in invertebrate models or *in vitro* systems.
Also, we can study how changing the animal's environment and or genes alters processes in body, that are thought to be important to dementia (such blood pressure or diabetes) and how this might affect dementia. Similarly, we can study how dementia-associated neuropathology affects physiology of the body (such as hearing and sight). Studies in mice also allow the interaction of different dementia causing disease that co-occur in patients (e.g. vascular dementia and AD) to be better understood, and whether these co-morbidities are linked by common mechanisms.
Dementia risk is increased by ageing and thus it necessary for us to undertake our research in mature adults that have a fully developed central nervous system.

Typically, what will be done to an animal used in your project?

Many of the mice on this licence will be used only for breeding. This is due to the complex nature of dementia causing diseases and our aim to understand the genes and cells that affect disease. This requires several steps of breeding to get to a group of mice with the necessary combination of genes that can be studied. We will also maintain breeding lines to ship to collaborators for use on other projects authorized to accept GA lines, with the aim of reducing overall animal use.
Approximately 14,000 mice will undergo a combination of phenotyping tests to characterise preclinical models and

for hypothesis-testing. Each experiment will use a combination of tests over the life-span of the animals, most of which are non-invasive, a small number involved anaesthesia used for immobilisation, for imaging, physiology recordings or the administration of substances to modulate gene expression.
Typically mice are then finally anaesthetised and a terminal bleed or perfusion carried out. All experiments are expected to end by 104 weeks of age, with the majority of mice being culled by 78 weeks of age.

What are the expected impacts and/or adverse effects for the animals during your project?

Genetic alterations in the mice used in this project may lead to the development of dementia-relevant phenotypes. In mice these changes may lead to the increased aggression/fighting, decreased food intake leading to weight loss and altered response to some procedures. For example, impaired wound healing after surgery because of impaired immune system may occur in some lines used in this project. Also these genetic alterations will lead to changes in memory and behaviour that may not be apparent in the home-cage but require additional testing to measure.
Mice undergoing cognitive testing using a food-reward for motivation will have reduced access to food to reduce their body-weight to ~90 % of their free-feeding weight. Studies have shown that in some knock-in mouse models of dementia causing disease, food restriction increases survival, consistent with data for C57BL/6 mice in general. Thus we do not anticipate adverse welfare outcomes associated with food restriction. To improve the validity of our results we will monitor long-term effects of food restriction by assessment of blood glucose before and after food restriction and body mass composition.
For some tests mice will need to undergo anaesthesia (e.g. for surgery for the implantation of devices for remote monitoring, hearing response assessment and for the injection of substances into the brain). All surgery and anaesthetic use in mice carries a risk of mortality and a risk of pain (short-term and long-term), which may differ between genetically altered lines. Injection of substances into the brain carries a risk of rare adverse effects such as inflammation, seizures and a risk of wound reopening. In pups injection of substances requires separation from the mother which increases the risk of maternal rejection of the whole litter.
Blood sampling requires the use of restraint to ensure safe sampling in a controlled manner. This poses the risk of induction of a stress response. The use of assays which minimise the required sample volume will be used and larger volumes of blood will not be sampled when the mice are on restricted food intake protocols.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

10,000 mice on the mild breeding protocol are not expected to suffer any adverse effects and the vast majority will not reach higher than a sub-threshold severity.
On the moderate breeding protocol, it is anticipated that any mice carrying the disease-causing phenotype could exhibit a moderate phenotype. Other genotypes will also be born from these crosses, so approximately 25% of the 30,000 mice may suffer a moderate severity.
14,000 mice on the behavioural phenotyping protocol (P3) are all expected to reach a moderate severity. This is partly due to the phenotype of the mice, in which the genetic alteration could lead to a moderate severity in around 50% of the mice (the other 50% being unaffected controls). However, all mice will reach a moderate severity because of a subset of the phenotyping tests causing moderate suffering, for example overnight fasting for blood sampling or food restriction for the purpose of motivation in food-rewarded tasks. Additionally, the combinatorial effect of repeating mild tests over the life span of the animal, in order to understand the progression of disease, will lead to an overall moderate experience. This combinatorial effect of repeating mild-phenotyping tests may also interact with genetic alterations used in this project to model dementia causing-diseases. Whilst these moderate affects will be short lasting they will increase the maximum severity of all animals on this protocol to moderate.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The primary objectives of this project are to

- link molecular and cellular changes of dementia-causing diseases to dementia-relevant phenotypes (including changes to cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole body physiology),

- understand how environmental changes and pharmacological interventions can modulate dementia-relevant phenotypes.

It is not possible to manipulate the molecular and cellular pathways in people who have dementia in order to determine how these processes impact on cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole body physiology. Thus an animal model must be used.
The wider research community is undertaking significant work analysing clinical and human postmortem datasets from people who had dementia-caused diseases, preclinical work in cell, organoid and invertebrate model systems of dementia-caused diseases.
This project will link with and draw on these experiments to minimise animal use and maximize translation value of the preclinical mouse work in this project. The work in this project cannot be addressed elsewhere using alternative approaches.

Which non-animal alternatives did you consider for use in this project?

Clinical longitudinal studies of people who have dementia
(biomakers including blood, CSF and neuroimaging), genetic and cognitive/behavioural/clinical scoring.
Human post-mortem and brain biopsy studies.
Invertebrate animal models.
Induced pluripotent stem cells (iPSC) and brain organoids
.

Why were they not suitable?

Clinical longitudinal studies of people who have dementia, provide correlative data between an individual's genetics, environment, biomarker (blood or cerebrospinal fluid biochemistry, or brain imaging data) and cognitive and behavioural outcomes. These data-sets can be used to generate hypothesis of the molecular and cellular causes of dementia-associated biology but cannot be used to test how specific factors influence dementia outcome.

Human post-mortem and brain biopsy studies comparing people who had dementia (early and late in disease course) with people who did not have dementia, can be used to determine which cellular and molecular changes occurred in the brain. In some cases clinical and biomarker data from life will also be available for these individuals

and this observational data can be used to hypothesis which cellular and molecular changes resulted in clinical disease. However, these samples cannot be used to test all hypotheses.
Invertebrate (fly models) can be used to study the response of neurons to the proteins that misfolded and aggregate in dementia-causing diseases and to screen for genetic modifiers of these processes. However, they do not have complex behavioural and memory biology and thus it is not possible to study the cellular and molecular processes that result in altered executive function or sub-types of memory in dementia. For example, it is not possible to quantify working memory, motivation or apathy in a fly. Flies also lack key immune brain cells (microglia) and a closed circulatory system (veins and arteries) which have key roles in the development of neurodegenerative disease. These aspects of the biology of dementia cannot be modelled in flies.
Similarly, iPSC and brain organoids cannot currently be used to study cognition, behaviour, metabolism, sensory systems, body fluids, tissues and whole body physiology.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Current estimates are that we will need a sample size of 10 per sex and genotype for each phenotyping experiment (see example power calculations in P3). In next-generation preclinical mouse models of dementia-causing diseases, which will be typically used in this project some key dementia-relevant phenotypes do not develop until mice are 12-18 months of age. In order to ensure we have sufficient sample size at later-time points it is necessary to account for an expected attrition rates of 25% (this includes culling of mice to avoid the phenotyping of lone-housed because of loss of cage-mates. Rehousing of females will be undertaken but will need to be included as a variable in subsequent analysis).
A typical study will include 4 genotypes of mice, thus (4 (genotypes) x 14 (mice) x 2 (sexes)) =112 mice will be required for each experiment on P3. We anticipate undertaking approximately 25 such experiments per year for every year of this project.

At least 2-rounds of breeding will be required to generate the mice required for the experiments outline in P3 and we anticipate providing other researchers with cohorts of mice matched to those studied in P3 for collaborative phenotyping projects. Thus, in total we estimate we will need to breed 40,000 mice for this project.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Power equation calculator will be used for group size calculations for P3 experiments plus attrition rate calculation will also be used to ensure sufficient power is maintained until the end of the longitudinal studies.
The combination of tests in each experiment will be designed to gather the most meaningful data. Tests which can inform each other will be carried out on the same mouse to remove inter-animal variability and increase the power, thereby decreasing the overall sample size and the scientific utility of generated data. This approach will also provide novel scientific insight into the relationship between dementia-relevant phenotypes and help validate new testing approaches such as home-cage assessment. We will also phenotype over the life-span of the animal to improve power and to understand the progression of disease and effect of age.
SOP's have been written and used routinely for previous projects. This standardises the way the data is collected and reduces the variability and therefore the sample size.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Efficient breeding and holding lines as frozen down embryos and sperm will be used to minimise the number of mice being produced for these studies. Genetically modified lines will be sourced from repositories to avoid remaking of lines whenever possible. Any excess stock will be offered to other researchers to minimise wastage. Pilot studies will be undertaken to generate means and standard deviations for work using back-ground strains for which data is not available. Tissues sampled from the animals used in this project will be shared with other researchers and the data produced linked to that generated by the project, to maximise long-term utility.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Some mouse models of diseases that cause dementia frequently develop fits or movement problems. Here we plan to use alternative mouse models that do not develop these problems as much.
Moreover, by collecting data from behaviour tests in mazes at the same time as also monitoring the natural behaviour of the mice in their cages, we will help develop new ways to study the behaviour and learning of mice in their normal environment. In the future we hope that this will make the experiments to understand how mice behave and learn less stressful for them.

Test	Why is this the most refined method?
Ear biopsy	Mice need to be ear clipped for identification and the same piece of tissues is used for genotyping. Genotyping protocols have been optimised to use this very small samples to avoid the need for other samples to be taken.
Induction of expression using of genes.	In most cases this will be done by oral dosing. This is more refined than injection, as transgene whilst it involves restraint there should be no pain. Injection will only be used if oral expression and dosing will not work. These methods can be used to avoid the effect of changed changes in gene expression happening in the young mouse which may stop it growing properly and injection can also reduce the number of mice needed for some experiments.
Tests of behaviour and vision	These involves placing a mouse in an arena or maze and allowing it to explore the area or interact with objects and pictures. Light levels are set so that the mouse can see but are not intended to be anxiety inducing.
Social recognition	Light levels are low to reduce anxiety. In this test another mouse is present in a section of the arena. This mouse is in a small cage to stop any aggression but the scent and sight of it are needed to understand how the mouse behaves to other mice.
Temperature taking	This is done using a rectal probe that should cause no more than transient discomfort. The animal is only lightly restrained and the test is done in the shortest time possible, usually less than one minute.

Light dark box and Elevated plus	This is non-invasive and involves placing a mouse in an arena and allowing it to explore. Light levels are anxiety inducing in some arena of the arena but not others. This is necessary as the test is assessing the preference of the mouse to the darker maze or lighter areas.
ECHO-MRI	This test involves less than one minutes of light restraint whilst body composition is measured. This is more refined that alternative tests which require general anaesthesia and a longer time to gather the data.
Blood sampling	Blood samples are collected to a maximum of 15% total blood volume of the animal, which has shown no adverse effects in previous studies. Samples are taken from the tail vein using a very small cut and mice have local anaesthetic applied to the area twenty minutes before.
Tolerance tests	Blood samples are collected to a maximum of 15% total blood volume. Fasting for this tests is usually 18 hours due to the need to allow animals to use up glucose supplies. However, where possible fasting times will be reduced. This test is more refined than other methods of measuring glucose which require surgery to implant a sampling tube.
Home cage monitoring	This is non-invasive and measured in the home cage. After initial insertion of a microchip this test involves no further pain, suffering or distress to the mouse.
Auditory brainstem	This test is done under general anaesthetic due to the extremely sensitive nature of response the test. Mice are monitored at all times through a window.
Touch-screen tests	In this test the mouse learns a series of pictures on a computer screen and that it receives a food-reward for correct answers. It can be used to test motivation and is less stressful for mice than other motivation tests, such as seeing how long the mouse will swim for before giving-up.

Why can’t you use animals that are less sentient?

Here we want to understand how the diseases that leads to dementia change the bodies biology and which changes cause which dementia symptoms.
Invertebrate (fly models) can be used to study the response of neurons (brain cells) to the proteins that build-up in the brain in dementia. They can also be used to find out which genes are important to this. However, flies have simple behaviour and learning and thus it is not possible to study all dementia symptoms in them. For example humans and mice are able to make plans and think ahead to complete a task and experience emotions that can affect how they behave (such as feeling unmotivated). These types of memory and behaviour are affected in people who have dementia and cannot be studied in a fly. Flies also lack immune brain cells (microglia) which are known to have a very important role in the diseases that cause dementia. The cardiovascular system (heart and blood vessels) of flies significantly differs from that in mammals like humans and mice (being open without veins or arteries). Thus the effect of heart health on dementia cannot be readily studied in a fly but requires a mammal such as a mouse.
This work needs to be undertaken in an adult with an intact nervous system without anaesthesia because we need to measure how disease-causing changes in the brain affect how the animals behave.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Here we aim to collect a wide range of phenotyping data to understand dementia-causing diseases. These data

will also be used to understand the biology that underpins changes to mouse behaviour and will also be used to monitor and improve animal welfare, drawing on a welfare improvements technology development pipeline.
For all tests it is important that the animal has no additional stress, therefore mice are handled calmly and habituated to testing rooms as well as arenas if possible.
For all tests mice are only housed in modified cages or arenas for the minimum time needed to gather meaningful data. Mice undergoing phenotyping tests have increased monitoring and are removed from tests if they appear to be suffering from an adverse stress reaction, or other unexpected adverse effects of the phenotyping tests.
Monitoring of mouse behaviour in the home cage and development of tools to analysis these data will be run in parallel with task-based behaviour tests, with the long-term goal of refining mouse behavioural testing particular for mouse models of dementia-causing diseases.
All surgery will be undertaken in full compliance with Laboratory Animal Science Association aseptic technique guidance to minimise infection risk.
Mice which have had anaesthesia have extra monitoring until fully recovered and extra checks when back in the holding rooms. When general anaesthetics are necessary, the combinations with least adverse effects will be used, for example for all tests inhalation anaesthetics will be used, with the exceptions of ABR and OCT which logistically cannot be carried out with the mouse on a face mask. Pain from tail bleeds is reduced by using local anaesthesia.
Experiments will be designed to balance the overall experience of the mouse and the number of type of tests any one animal against the value of a full understanding of the biology of individual animals and why phenotypes are altered in order to maximise utility of the research data obtained.
Technical refinements will be developed throughout the life-time of the project and disseminated to other researchers at the Institute.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

Routes and volumes for administration of substances are taken from Laboratory Animal Science Association good practice guidelines: administration of substances 1998 (http://www.procedureswithcare.org.uk/lasa_administration.pdf).
Surgery will be undertaken as per the Laboratory Animal Science Association Guiding Principles for Preparing for and Undertaking Aseptic Surgery 2017 (http://www.lasa.co.uk/wpcontent/uploads/2017/04/Aseptic-surgery-final.pdf)
The animal house has full AAALAC and ISO9001-2015 accreditation. To conform to these standards we must ensure a high level of quality control on all fronts including husbandry, phenotyping and administrative processes. Standard operation procedures for most tests have been generated using data and expertise from multiple animal houses and can be found at https://www.mousephenotype.org/impress ARRIVE and PREPARE guidelines will be followed at all times.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

I will attend the NC3R annual conference, I will also attend international meetings focusing on animal models of dementia causing disease and monthly webinars run by the MODEL-AD consortium. In addition I will attend local 3Rs seminars and events.

Home Office

NON-TECHNICAL SUMMARY

224. Using zebrafish models to understand impaired wound healing

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Inflammation, Angiogenesis, Wound healing, Diabetes

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

To understand the mechanisms underlying how inflammation and blood vessel growth interact to drive normal wound healing, and how these go awry to result in compromised tissue repair, particularly in the context of diabetes.
Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Over 1 million compromised wounds are treated annually in the UK, resulting in increased morbidity and mortality rates, incurring significant reduction in quality of life, and are a huge burden on health services. Diabetic wounds account for a major subset of compromised wounds, with 15-25% of nearly 500 million diabetes sufferers worldwide developing non-healing wounds such as foot ulcers, the most extreme cases requiring amputation. Crucially, compromised wounds often prove unresponsive to current clinical approaches, with wound recurrence rates of up to 70%. Compromised wounds broadly share the same causative mechanisms of dysregulated wound inflammation and angiogenesis, however how these processes interface and how they go awry remains poorly understood. Improved mechanistic understanding of these processes is the most likely path to ameliorating the impaired healing of compromised wounds.

What outputs do you think you will see at the end of this project?

This project will deliver novel insight into how processes underlying normal wound healing go awry to result in compromised wounds. Specifically, we will use the zebrafish to identify and rapidly screen genes whose expression is modulated in compromised and diabetic wounds, but whose function in tissue repair remains unclear after decades of clinical and rodent research.
Beyond providing vital improvements to our understanding of this basic biology in the short term, these zebrafish models will have longer term benefits as a platform for drug and biomaterial discovery and screening, identifying how these defective processes might be rescued to improve impaired tissue healing. Ultimately, this will result in the generation of new products (e.g. dressings, topical preparations) that can be propelled towards the clinic. Both the basic and translational aspects of this project will result in numerous high impact publications, which in turn will allow this important information to be disseminated to others through conferences, press releases and public engagement events.

Who or what will benefit from these outputs, and how?

This project addresses the important question of how processes underlying normal wound healing go awry to result in compromised wounds, particularly in the context of diabetes, and how these can be corrected to re-establish tissue repair. The mechanistic insight and therapeutic leads generated by this research will have a critical impact in understanding and treatment of compromised wounds – 70% of which present as ‘hard to heal’ and respond poorly to existing therapies – and may have more broad ranging impacts in treatment of other non-healing tissues. In the short term, the main beneficiaries of this work will be academics interested in tissue repair, immune cells and inflammation, blood vessel development and disorders as well as bioengineering, who will discover the findings of this work via conferences, publications etc. and with whom collaborations will be established to expand upon this work. Furthermore, this project will generate highly trained researchers offering unique interdisciplinary skills, providing transferable skills to both the researchers involved and potentially other non-academic beneficiaries. There are numerous longer term beneficiaries from this work, including:
1) Clinicians/patients demanding more effective therapeutics for compromised wounds, which are a major cause of morbidity and mortality that currently lack effective treatments. Improving and accelerating the development of technologies that treat compromised wounds towards the clinic will greatly benefit patients suffering from these disorders. This project will therefore impact on quality of life, health and well-being, as efficient wound healing is a prerequisite for healthy ageing. Collaboration with clinicians will feed back into the design process, to establish the best possible technologies and techniques for clinical use.

2) Pharmaceutical companies wishing to discover treatments for tissue repair disorders. The models established in this proposal will be attractive resources for the pharmaceutical industry, allowing rapid drug development and testing of existing small molecules or re-purposing of existing chemical compounds for wound

healing functions. Protection of IP for these targets as they are discovered will bring significant economic gains to the UK economy.

3) Industrial biotechnology partners wishing to improve existing wound healing technology and techniques. Collaboration with these partners will permit mechanistic testing of their technologies, allowing them to improve the functioning and marketability of their products. This leads to longer-term commercial opportunities to develop technology at a higher throughput level. Industry investment in this programme and IP sharing arrangements will ensure mutual benefit from emerging knowledge for all parties.

4) NHS and health care policy makers facing tight budgets and difficult decisions as to where resources such as staff and equipment should be allocated to deal with a large range of clinical needs. Care for sufferers of compromised wounds annually consumes more than £5 billion and over 40 million doctor and nurse visits, as this condition requires careful daily management and care for weeks to years to resolve.

How will you look to maximise the outputs of this work?

To ensure other researchers benefit from our work, academic audiences will be reached by journal publications, as well as presentations at conferences and seminar series. Collaborations with other interested researchers will be actively pursued. Where practicable, we will also aim to make the results and microscopy data available via a custom built website (developed with support from a specialist academic web design team), from both successful and unsuccessful experiments.
We will use ZFIN and EuFishBioMed to engage and inform industrial parties interested in zebrafish studies of the models being established and research direction undertaken. We will also visit patient support groups, charities and clinics with high numbers of patients that suffer from compromised wounds, e.g. diabetes clinics, to engage these patients and the health care professionals that treat them, communicating the cutting edge research into wound healing biology that is being performed. **Species and numbers of animals expected to be used**

- Zebra fish: 19500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

We are using zebrafish as they are the best vertebrate model organism for rapid identification and mechanistic screening of disease associated genes, as well as visualisation of how various tissues interact with each other in vivo and in real time. We have specifically focused most of our study around the larvae, as this is the maximally translucent stage of the fish while having most of the important tissue types that are relevant in human wound healing. We will also expand some of our work to adult fish, which are not as easy to image but present robust models of Diabetes that have an increased tissue complexity approaching that seen in human tissues.

Typically, what will be done to an animal used in your project?

The focus of this project is to generate animals that have mutations in genes and pathways that are impaired in Diabetes, to identify how these genes effect inflammation, blood vessel growth and wound repair, and how this might be rescued. As such, wild type and mutant fish will undergo one or a combination of wounding, biomaterial implantation and exposure to bioactive molecules that modulate inflammation/blood vessel growth. As an example, a common larval investigation would entail making a small wound with a 30G needle at 4 days post fertilisation

(dpf), with subsequent treatment with anti-inflammatory drugs e.g. Hydrocortisone to modulate inflammation over the course of wound healing (up to 14dpf). This drug treatment may be delivered either systemically by IV injection/addition to the fish water, or locally by injection of beads functionalised with the drug. These fish could then be imaged at various timepoints post injury to establish the progression of the entire healing response within the same group, e.g. imaging at 2 days post injury (6 dpf) to observe blood vessel sprouting, 5 days post injury (9 dpf) to observe blood vessel maturation and 8 days post injury (12 dpf) to observe blood vessel remodelling and wound resolution. Alternatively, these fish may undergo long term timelapse to capture detailed cell interactions at particular points of the wound healing response. In any case, any fish that undergoes experimentation on this protocol will be humanely killed once experimentation is completed.

What are the expected impacts and/or adverse effects for the animals during your project?

We expect that some short term pain will result from our wounding/implantation experiments, categorising these protocols as moderate severity. Our Diabetes models may also be expected to result in weight gain and other adverse effects related to this disease (e.g. high cholesterol, eye and kidney damage). For larval experiments, we will end both wounding and Diabetes induction experiments no later than 14 dpf (10 days post injury). For adult fish, we will treat them with our procedures to induce Diabetes for no longer than 8 weeks, and wounding/implantation procedures on adult fish will be followed for no longer than 4 weeks.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most of the animals included in this project will not suffer more than mild severity, and this is largely categorised as such because they will be genetically altered (for example, many of these will express fluorescent molecules that label specific cells or tissues but are otherwise not expected to cause any harm to the fish). Approximately 30% of fish will be classified as 'moderate', due to the use of wounding/implantation surgical procedures that potentially cause short term moderate pain, or due to these fish being Diabetic and therefore potentially suffering moderate impairment to their well-being.

What will happen to animals at the end of this project?

- Killed
- Used in other projects

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Wound healing is a complex process requiring many cell types, mediators and interaction between these. As such, an in vivo model is required. Using the zebrafish, we are able to efficiently perform genetic manipulation and rapid mechanistic screening of the roles of these genes in wound healing. In vitro models can be a useful reductionist approach to unpick certain aspects of the interactions between immune and endothelial cells, but they lack the context of the wound environment that is crucial to improve our knowledge of how inflammation and angiogenesis interact.

Which non-animal alternatives did you consider for use in this project?

To complement our fish studies, we have previously used human macrophage-endothelial cell coculture approaches to explore the function of specific interactions that had been initially identified in the in vivo fish wound assay. We will continue to use this approach to validate our fish findings, thereby refining the fish models we use for further screening and development of clinically interventions and reducing fish numbers used in the long term.

Why were they not suitable?

Our co-culture assay is suitable for dissecting specific mechanisms of interest, identifying how conserved these interactions are and validating targets identified in the zebrafish model. However, the lack of in vivo context means that this approach is not suitable for the initial upstream identification and screening of these genetic targets.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Estimated numbers of fish used in each protocol is based upon detailed project planning undertaken within my lab (using previous experience in experiments needed), as well as between my lab and our aquarium team (using combined experience in breeding and maintenance of fish). This experimental design takes into account factors such as number of fish required to safely maintain breeding stocks, breeding new generations of fish at an appropriate age to prevent welfare issues that can arise in ageing populations, and generation of sufficient alleles of new mutants for robust genotype/phenotype correlations.
Protocol 1 - 10000 adult fish over 5 years, from a range of backgrounds, both wild-type and transgenic.
2000 of these fish will be used for Protocol 3 tissue repair studies, 500 in Protocol 4 and 150 in Protocol 5. The rest of these adults undergo no procedure other than breeding and occasionally fin clipping or gentle gamete expression.
Protocol 2 - 8000 adult transgenic/mutant fish over 5 years. For most transgenic and mutant lines, we raise approximately 100 embryos to adulthood to identify a minimum working stock of positive carriers/founders. We will make a maximum of 16 lines per year for 5 years, giving a total of 8,000 adults. 1500 of these fish will be used in Protocol 3.
Protocol 3 – limited to 4000 adult fish over 5 years, and only where experiments cannot be performed on younger animals. As part of good laboratory practice, we will write a study plan for each experiment involving regulated procedures including: a statement of the objective(s); a description of the experiment, covering such matters as the experimental treatments, details of the experimental material, and the size of the experiment (number of groups, numbers of animals/group); and an outline of the method of analysis of the results.
Protocol 4 - 2000 adult fish over 5 years, either diabetes mutants or chemical induced diabetes fish. These adults are the key colonies to this project, providing the necessary animals to examine the specific disease context of interest. Where possible, we will use fin clipping (or ZEG) at <5dpf to identify founders and reduce the numbers of embryos raised. 500 of these fish will be used in Protocol 3 tissue repair studies, and 50 in Protocol 5.
Protocol 5 – 200 fish for manual expression of gametes. Occasionally, female zebrafish become egg bound and no longer lay eggs. In order to reduce the number of fish used, these fish can be returned to full reproductive health by gentle expression of gametes. We anticipate we will need to perform 200 such procedures during the course of this licence, reducing fish numbers in other parts of the licence by this amount.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Where applicable we will use the NC3R's Experimental Design Assistant to consult on sample sizes for individual experiments to ensure only the minimum number of animals required is used. In addition, we have sufficient pilot data from all studies to perform a priori power calculations to calculate group sizes. We will not initially exceed the predicted group sizes required to detect a 25% difference with 80% power (alpha of 0.05 as per convention), allowing us to detect relatively small effect sizes associated with a biological process likely to have a large amount of variability (wound healing). We will repeat experiments with increased group sizes only if greater power is required, if the variance is greater than in pilot studies, or where the biological effect to be detected is less than 25%. Where we obtain data over time from the same animals, we will use statistics appropriate to repeated

measures. The use of the same animals over time greatly reduces the animal number required (compared with groups of animals sacrificed at each timepoint as occurs in many mammalian studies).

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

As indicated, we have used pilot studies to assist in the experimental design phase to reduce estimated numbers of fish required – we intend to continue pilot programs to inform new directions, to be constantly re-evaluating our data and to seek statistical advice to optimise animal numbers. Where feasible, early genotyping using a zebrafish embryonic genotyper system will reduce the number of larvae raised as we will only raise those of the required genotypes. We have also been early adopters of techniques to increase transgene incorporation and of transient CRISPR approaches to reduce the need for generating mutant lines. Where these approaches are suitable, we will use them to reduce the number of embryos that require raising to identify founders.
Where necessary, gametes are expressed either to maintain fertility or to allow in vitro fertilisation, and numbers are determined by the requirements of maintaining fertility and preserving lines. This procedure allows reduction of numbers required in other procedures, by preventing the sacrifice of overburdened females and by preventing the keeping of live stocks where a frozen stock would suffice.
We will also utilise individual Study Plans for experiments using protected animals. These provide the researcher the opportunity to determine:
1) They have authority on the PPL to perform the experiment (i.e. the purpose of the experiment fits with one of the objectives detailed in the project plan and that there is clear authority on the protocol to perform the procedure). In addition, that they have the relevant skills detailed on their PIL and training and competency record.

2) An opportunity to determine how many animals are required per group (including controls) to answer the question.

3) Write a clear description of what procedures each animal will receive, e.g. i.p. injection of drug X at day 1, followed by imaging analysis under terminal anaesthesia on day 6) Write down any adverse effects that may be associated with the procedures and describe clear humane endpoints.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Zebrafish have a number of advantages for these studies, including optical transparency, genetic tractability and extensive genomic resources. The use of reporter lines in zebrafish allows in vivo visualisation of cell behaviour and morphology, which is required in my project to analyse immune cells and blood vessel interactions. Moreover, the ability to rapidly screen gene functions by newly developed CRISPR technology allows for the identification of key genes and pathways that elude higher vertebrate models. Importantly, zebrafish models of diabetes recapitulate many of the pathological aspects seen in humans, and the immune system and endothelial cells of zebrafish shares significant homology with human. This makes the zebrafish a relevant model to study the interactions between these populations, and how these go awry in diabetes. Furthermore, the zebrafish is the organism with the lowest neurophysiological sensitivity that is suitable to study the interactions between the innate immune system and blood vessels during tissue repair to address our proposed aims.
The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Fin clipping and gamete expression methods rarely involve inducing any discomfort, but for all manipulative procedures animals are suitably anaesthetised (primarily for restraint). Anaesthetic is delivered by immersion (so no invasive instrumentation is required) using an anaesthetic protocol suitable for the procedure and following best practice.

Why can’t you use animals that are less sentient?

This project focuses on primarily using zebrafish as a platform for studying wound healing, as this is the lowest vertebrate model in common use that has most of the conserved structures compared to human tissue (skin, muscle, nerve cells, immune cells and blood vessels etc). Less sentient animals e.g. nematodes lack many of the structures and much of the genetic complexity that would make such studies clinically relevant. Where possible, we also focus on using fish at the earliest developmental stage when all necessary cells and structures are present, with most assays being performed at 4 days post fertilisation (prior to the age of protection).

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

Where feasible, various recently developed refinements are used: (i) the use of a zebrafish embryonic genotyper system, (ii) swabbing instead of fin clipping and (iii) the use of a DanioScope (or similar) for observing early phenotypes.
Genotyping adults requires fin clipping under anaesthesia but we have also included skin swabbing which does not require anaesthesia. This technique will be tested and upon robust and consistent genotyping results will be adopted to genotype all adult fish.
Where possible, potential therapeutic interventions (e.g. biomaterial implantation, exposure to bioactive molecules) will be assayed before 5.2dpf and only animals with signs of recovery will be raised past protected age. All animals involved in wounding, intervention or diabetes protocols will be closely monitored for healthy swimming, feeding and socialising behaviour. Pilot data suggests that wounding and treatment groups only require relatively small numbers (5 to 10 animals). To increase animal health and wellbeing if stressed or kept in lower density, environmental enrichment (e.g. laminated gravels) may be placed in or under the tanks.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

ARRIVE guidelines, and specific research guidance covering responsible use of animals in bioscience as made available by organisations such as UKRI.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

The zebrafish community in general, and the community at the REDACTED in particular, is constantly looking for ways to advance and promote the 3Rs. There are numerous bodies that disseminate these advances, from journals (e.g. Zebrafish) to local and international conferences, which we will endeavour to attend and engage with. Moreover, we will routinely monitor resource websites such as those run by NC3R and research council bodies such as UKRI for new tools and guidance, as well as engaging with the NC3R's Regional Programme Manager. New advances will be implemented where possible and with the assistance of the experience technical staff at the REDACTED aquarium, as we have already demonstrated in this project application.

NON-TECHNICAL SUMMARY

225. Viral tumourigenesis and inflammation

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

cancer, virus, therapy

Animal types	Life stages
Mice	adult, juvenile, pregnant, neonate, embryo, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Epstein-Barr virus (EBV) is a common human virus associated with several forms of cancer. The long term aim of the project is to understand viral disease mechanisms and enable the design and testing of therapeutic strategies and regimens against virus-associated cancer. The aims over the next 5 years include: to determine factors that influence the chronic inflammation that arises in several of these cancers; to discover the mechanisms by which specific viral proteins contribute to cancer development; to test candidate therapeutic treatments for efficacy.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

EBV is linked to approximately 200,000 cancer cases per year (worldwide) and is classified by the International Agency for Research on Cancer as a group 1 carcinogen. Burkitt's lymphoma (BL, which is a blood cancer) and nasopharyngeal carcinoma (NPC, which is a cancer that forms at the back of the throat, in the nasopharynx region) are two types of cancer most closely linked to EBV and together these present a significant world health disease burden. In order to gain an in depth understanding of the role played by the virus in these diseases and from there, to develop and test specific therapeutic regimens that have minimal side effects, it is necessary to have scientific, pre-clinical models of disease that faithfully recapitulate the viral component. From the safety of the laboratory, such models permit in depth molecular analyses of disease processes, providing knowledge that forms a platform for therapeutic design and disease intervention. The pre-clinical models then provide the early stage testing ground for novel treatments, that necessarily precede clinical trials.

What outputs do you think you will see at the end of this project?

By the end of this project I anticipate several new scientific publications reporting on the scientific information learnt as a consequence of these studies. I expect this to include new information regarding the role of certain cellular proteins in carcinogeneisis and inflammation, a deeper understanding of EBV associated tumourigenesis, and assessment of new treatment modalities for EBV-associated cancer. This new scientific information will contribute to the ongoing global efforts to treat and cure EBV associated disease. The study of inflammation will also shed light on chronic inflammatory diseases in general. This new information will be disseminated in the form of peer-reviewed scientific publications, but also through national and international conferences and other scientific forums for information exchange (such as seminars and lectures).

Who or what will benefit from these outputs, and how?

The scientific community will benefit in the short term from the new information gained. The knowledge will contribute to a greater understanding of EBV-associated disease processes and potential treatment routes. The cumulative scientific knowledge on this topic will benefit world health in the longer run, in directing the development of new treatments for these diseases. Scientific knowledge is arrived at in small bite-sized chunks, with multiple labs contributing to the information. It is the cumulative knowledge that can then be put to greater clinical use.

How will you look to maximise the outputs of this work?

In the past 5 years I have collaborated with labs across Europe and the USA and together we have published our work in peer reviewed scientific journals. These collaborations were initiated by collegiate discussion at scientific conferences. Likewise, over the next 5 years I will disseminate data from my lab through seminars and presentations at scientific conferences and embark upon new collaborations. In addition I will publish our data, both work that supports the hypothesis under test and data that might refute a hypothesis, as both are valuable in the research setting. I will contribute to public outreach events to disseminate new knowledge in the area of this work.

Species and numbers of animals expected to be used

- Mice: 4,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Mice are the only animal to be used in this project for several reasons. First, domestic mice can be kept easily in cages, they eat well and are happy to breed and appear to be unstressed in captivity. Second, their whole genome has been sequenced and they are highly genetically similar to humans, with the same genes and molecular processes involved in disease pathways as humans. Also, mice have been commensal with humans for thousands of years and as a consequence, their immune system has evolved along very similar lines to humans. Thus functions at the molecular, genetic, cellular and whole tissue levels (such as immune responses) are likely to be very similar between mouse and man, if not identical. Therefore, mice provide excellent models of human disease, to both understand disease processes and test potential treatments. This is especially true for cancer and immune system disorders, such as chronic inflammation. Finally, due to these advantages, there are hundreds of genetically altered mouse disease models available in the scientific community, providing a wealth of data that allows mass integration of this vast knowledge and thus deeper understanding.

Typically, what will be done to an animal used in your project?

Many of the mice in the project carry one or more of the viral genes under study within their genome. This leads the mice to display part of the disease characteristics that is seen in humans and allows the study of that characteristic. For the most part, the progression of the disease characteristic is monitored visually and finally tissues will be collected to permit an analysis of samples. Some mice will be treated and this will involve the application of a substance (for example a drug under trial), which may be injected, applied topically, or in the drinking water. How this affects the disease characteristic is then examined. At times, a blood sample might be taken from the mice. Some mice will undergo painless imaging under anaesthesia (so that they remain still), to quantify disease features and progression and this is also used when testing treatments, to determine how effective the treatments are.

What are the expected impacts and/or adverse effects for the animals during your project?

This project aims to understand processes in cancer and inflammation. As such, some mice on the project will experience chronic inflammation of the skin, not unlike psoriasis, from mild to more severe. This will be a persistent characteristic in some mice. Some mice will be expected to develop tumours, either carcinomas (typically on the skin) or lymphoma. If the tumour causes the mouse any suffering, the mouse will be humanely killed directly.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Approximately half of the mice on the project will show some disease characteristic from mild inflammation of the skin, to tumour formation.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The complex interplay between the immune system and cancer cannot be faithfully recapitulated in the test tube or in cell culture systems. Similarly, the diverse action and consequences of drug or other treatments in the body, cannot be determined in culture experiments alone. Moreover, all new therapeutic regimes and medicines benefit from being tested in an animal model system before translation to human trials. As such, non-animal alternatives for the described objectives either do not currently exist or don’t fulfil the objective.

Which non-animal alternatives did you consider for use in this project?

Tissue culture and laboratory alternatives (such as molecular and biochemical analyses) are considered and used, wherever possible, to contribute to the study. These approaches are used before animal studies begin to provide as much information as possible as a platform for the study in animals.
Equally, such methods are used after the animal studies to follow up on specific aspects of the findings.
Why were they not suitable?

At present, tissue culture methods do not faithfully recapitulated complex physiological systems, such as the immune system, or the complexity of organ function. In part, this is because these systems are highly complex and interactive and are not fully understood, but also in part because technology has not yet advanced to a stage where the complexity in the body can be replicated in a plastic dish. Similarly, biochemical and molecular experiments can allow determination of the fine detail, but fall short of predicting the greater connectivity within the mammalian body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

Animal numbers have been estimated based on considerable previous experience. Furthermore, the average annual animal use on the preceding project, over the last 5 years has been between 200 and 400. A similar plan is proposed over the next 5 years, but there is possibility for the expansion of these studies (by no more than double). As such, 800 per year represents a maximum.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

It is important that studies are conducted to produce reliable data subject to statistical scrutiny. In all protocols the numbers of mice required to generate a statistically significant and/or otherwise meaningful result are considered carefully in advance of the experiment (using both considerable experience and design tools such as that available on the NC3R site) and numbers of mice used do not exceed this.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

At the end of study, tissue samples are collected from all mice and used for experimental assays in the lab and/or shared with other labs that use tissues in their studies, thus optimising the use. The use of in vivo imaging for certain studies (particularly time courses) reduces the numbers of mice required on study compared to conventional assays. The use of pilot studies to enable reliable calculations for subsequent larger studies is used as standard.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

Mice provide an excellent model for human disease, particularly diseases of the immune system and cancer, for

several reasons. They are highly genetically similar to humans, suffer from the same range of diseases and have an almost identical immune system to humans. As such, determining gene function and immune responses in mice has proved to be hugely informative with regard to human disease. In this project we will use mice with genetically altered genomes alongside normal mice to address the aims described. We will use well established reagents and protocols to study the mice. In all protocols, the procedures which cause least pain and distress in achieving the objective are followed. In all cases the mice will be closely monitored and any mouse showing signs of distress during the procedure will be humanely killed.

Why can't you use animals that are less sentient?

The aims of this project concern disease modelling and treatment of cancer. There is an intricate interplay between cancer cells and immune system cells and this factor is especially important to this study. The immune system of mammals is substantially different to other animals, especially those less sentient and the study is simply not possible in non-mammalian species. The immune system of the mouse is highly similar to humans, which makes it an ideal animal model for such studies, indeed, in evolutionary terms (and therefore also genetical terms) rodents are the closest animal group to primates.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In all protocols, the procedures which cause least pain and distress in achieving the objective are followed. As refinements to these procedures become available (either published or advised), these will be implemented where possible. We are working to refine the sampling methods for genetic screening. We have developed and are optimising a system using fluorescent factors to track tumour development by imaging. This provides a more robust method to assess the efficacy of therapeutic treatments.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

The institution has established best practice forums and provides such guidance and this is based upon veterinary advice and up to date published information. In addition, information provided in "Guidelines for the welfare and use of animals in cancer research" Workman et al. (2010, Br. J. Cancer 102:1555-1577), ASPA "code of good practice" website and NC3Rs website, will be followed.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

Advances in the 3Rs are reported in the scientific literature, on the NC3Rs website and through institutional bulletins and practices. Such advances will be implemented alongside institutional and veterinary guidelines, practice and advice.

Home Office

NON-TECHNICAL SUMMARY

226. WILD MAMMAL POPULATION STRUCTURE

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (d) Protection of the natural environment in the interests of the health or welfare of man or animals. (e)
- Research aimed at preserving the species of animal subjected to regulated procedures as part of the programme of work. **Key words**

bats, dormice, wildlife conservation

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The work conducted under this licence is intended to inform directly the conservation of dormice and bats. It fills key knowledge gaps identified by decision-makers including Natural England and Local Authorities that are currently barriers to effective population management. The two main aims of the work are to

1. Develop robust assessments of population size and trends;

2. Assess of the impact of habitat loss and fragmentation on the conservation status of the target species.

These areas are repeatedly highlighted as research priorities for the mammals studied in this project (e.g. Detra 2011; State of Nature Report 2013; JNCC 2013; Sutherland et al. 2006). Bats and dormice are of high conservation concern across Europe due to dramatic historical declines in their distribution and abundance (Habitats &c Species Regulations 1992). The information generated by this project will not only addresses ecological questions of scientific interest, but will also contribute to the ability of the UK's competent authorities to discharge their statutory duties to monitor the population size and conservation status of the study species.
The objectives are:

1. improve estimates of the population size and structure of the target species.

2. validate survey methods routinely used by professional ecologists, contributing to the development of better methods for monitoring changes in conservation status over time.

3. provide quantitative evidence on the effects of different forms of habitat fragmentation on population structure, social networks, animal dispersal and genetic interchange.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

The work will provide a better evidence base for the conservation management of the species. It will also help stakeholders discharge their statutory requirement to monitor and report on the size of British populations, their change over time, and the primary threats facing the target species.
Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

This project will focus on dormice and bats. It will involve approximately 100 dormice which will be radiocollared and also microchipped (using the same technology used for identifying pet animals). Samples will be taken from approximately 500 bats for analysis of their genetic relatedness and place of origin.

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The severity of the procedures is low.

The marking procedures (PIT tagging and ringing) and fur clipping on their own would fall outside the remit of the Scientific Procedures Act.

The main risk is that fixed radiocollars are carried by the animal for life (<5%) and present a small risk of entanglement (<2%). Therefore a range of different approaches are being deployed to try to ensure that the collars are removed at the end of the monitoring period. There are small risks of abrasion (<2%) from the collar which are being addressed through the use of appropriate materials and careful monitoring of recaptured animals. There is a small risk of bleeding or infection from the wing puncture site and site of insertion of the PIT tag (<1%). These risks will be minimised by the use of new sterile equipment and careful technique.

All the animals will be released back into the wild at the point of capture.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

This project specifically investigates wild animals in their natural environment so non-animal alternatives are not possible. The data will help to improve non-invasive approaches such as the use of faecal samples for genetic monitoring

Reduction

Explain how you will assure the use of minimum numbers of animals.

The principal investigator has in-depth knowledge of statistical design, and will keep the proposed sample sizes under constant review during the project. The sample sizes will also be agreed by Natural England which has statutory responsibility for safeguarding the conservation status of the species concerned.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

The study aims to gather species-specific information in order to inform dormouse and bat conservation. However they are also good models with which to assess the effect of habitat fragmentation.
Radiocollars have previously been used with a range of small mammals to provide detailed information which cannot be gathered in any other way. Steps are being taken to minimise the likelihood of any adverse effect including ensuring that collars never exceed 10% of body weight, making exhaustive attempts to retrieve all animals in order to remove collars; and use of appropriate materials and fitting techniques to minimise the chance of abrasion. Wing punch samples are generally considered the best means of obtaining high quality DNA samples and are rarely associated with adverse effects. The welfare costs will be minimised through the use of sterile equipment and appropriate technique.

Home Office

NON-TECHNICAL SUMMARY

227. Wound healing and Ano rectal Fistula

Project duration

0 years 6 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants.
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants.

Key words

Fistula, ano-rectum, therapy, stem cells, collagen

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the project's objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

Current treatment options for ano-rectal fistulae (an abnormal connection between the anus/rectum and outer skin) are inadequate resulting in poor and variable healing rates. Patients experience considerable pain and poor quality of life. Having previously investigated why these fistulas don't heal we have developed a collagen paste. Our goal is to use this paste to heal the fistula by replacing the lost collagen framework within the fistula tract with one supplied by the paste. The paste can also be combined (optional) with antibiotics or the patient's own stem cells to speed up the healing process.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration

of the project or long-term benefits that accrue after the project has finished.

What are the potential benefits that will derive from this project?

Current treatments are either surgical or non-surgical, the former can result in incontinence (lack of voluntary control over urination and defecation) and the latter in variable healing (it may or may not work in each patient). The benefit from our approach is that it will not damage the surrounding tissue and therefore, even in the unlikely event it doesn't work, it will cause no harm, unlike surgical treatments. It has been specifically developed to repair the damaged tissue and can be used as vehicle for the delivery of either drugs or cells to promote healing. The scientific knowledge gained would support the concept that in order to promote long term healing, the underlying structure of the tissue is crucial and where possible we should be aiming to replace like for like.

Species and numbers of animals expected to be used

What types and approximate numbers of animals will you use over the course of this project?

Our chosen animal is the pig due to it close resemblance in anatomy and physiology to humans. Over the course of the licence approx. 10 pigs will be used

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

In the context of what you propose to do to the animals, what are the expected adverse effects and the likely/expected level of severity? What will happen to the animals at the end?

The severity of the study is moderate because the experiments require all animals to undergo a surgical procedure, possible adverse effects may include pain (moderate).
No adverse effects are expected from the surgical procedure itself. In our experience, animals tolerate these procedures very well with no adverse effects to their health and welfare.
There is a very remote risk of bleeding and infection post surgery, or loss of the indwelling setons (this is a thin silicon thread which is placed into the fistula tract to allow it drain and prevent the accumulation of pus). All of these incidences will be closely monitored for and treated if necessary under veterinary instructions and any changes that significantly impact on the health and welfare of the animal would define a humane endpoint and result in the animal being humanely killed.
No adverse effects are expected from the use of immuno-suppression (drugs that prevent rejection) since we have successfully used this in previous studies. Since a full depth analysis of the fistula tract and surrounding tissue will be essential, all animals will be humanely killed at the end of the experimental period.

Replacement

State why you need to use animals and why you cannot use non-animal alternatives.

An ano rectal fistula is a painful and debilitating disease in humans; treatment options include either surgical intervention with the possibility of permanent loss of voluntary control over urination and defecation or non-surgical treatment with unreliable healing rates. Ano-rectal fistulae created in pigs are unlikely to be as debilitating because unlike humans who sit on their "bottom" thereby placing pressure on the ano rectal fistula, pigs predominantly lie on their belly or on their side resulting in less pressure and soreness on the outer surface of the ano-rectal fistula. We have developed a novel collagen paste to fill the fistula track and replace the damaged tissue. The paste has been tested in the lab and in lower sentient animals (i.e. rats) to ensure it is safe (i.e. non-toxic) and cell friendly. We are now at the stage where we need to test the paste for its intended clinical application in a model which closely mimics the human with respect to ano rectal anatomy and function.

Reduction

Explain how you will assure the use of minimum numbers of animals.

To date all the necessary experimentation surrounding the development of the paste has been completed and tested in rodents, removing the need to test the paste in large animals. Additionally, a separate study investigating the paste for skin wounds is underway allowing for considerable knowledge to be gained on how the paste performs. This will further reduce the number of animals required in this study. Typically, for comparison of three modes of treatment requiring replicates of 6 of each treatment a maximum of 6 animals would be used as this is calculated to provide robust statistical data during subsequent analysis.
From previous experience, we know we can increase the number of fistulae per animal (up to 3) with no additional cumulative adverse effect, thereby reducing the number animals in each experimental arm.

Refinement

Explain the choice of species and why the animal model(s) you will use are the most refined, having regard to the objectives. Explain the general measures you will take to minimise welfare costs (harms) to the animals.

Our chosen animal is the pig; this animal has a diet similar to humans and hence it anatomy around the rectum and anus closely matches making it an ideal model, including similarities such as e.g. little hair, dermal and epidemal structure, musculature, vasculature and healing properties. Additionally, this model allows for the creation of fistulas of comparable size and potentially similar complexity. Whilst this is the best model, we have been able to develop it is recognised that the pig is quadrupedal (stands on 4 legs) while man is bipedal (stands on 2 legs) and we have accounted for this in the way we analyse our results.
Furthermore, although animals may need to be singly housed for a shorter period as possible after surgery to prevent damage to the wound area by pen mates, our accommodation provides enrichment in the way of toys (e.g. balls and other objects to encourage rooting behaviour) and allows visual, auditory and scent contact with other animals of the same species.
Also by pre-acclimatising the animal, to single housing prior to the initial surgery, any adverse effects can be minimised; we have not observed any obvious adverse effects when using this technique.
Animals welfare will be closely monitored by the NACWO who can be supported by the NVS if required; animals will be placed on a loose diet to ensure a soft stool and reduce the risk of constipation prior to and after the creation of the fistula to help with bowel movement.

Home Office

NON-TECHNICAL SUMMARY

228. ZEBRAFISH MODELS OF CARDIOVASCULAR DEVELOPMENT & DISEASE

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

No answer provided

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult, aged

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

We seek to understand the biological mechanisms responsible for development of the cardiovascular system and which go wrong to cause cardiovascular disease. We do this by studying how the heart and blood vessels develop in zebrafish, and by measuring the effect of drug treatment, genetic manipulation or injury on the cardiovascular system.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Cardiovascular disease is the leading cause of death worldwide. Despite much progress, we still do not understand in detail how the cardiovascular system develops and how genetic or other disturbance leads to disease. Our work will discover new mechanisms of cardiovascular development and examine the effect of drug and other treatments on zebrafish models of human disease.

What outputs do you think you will see at the end of this project?

This work will provide significant and novel insights into the mechanisms that form the cardiovascular system in vertebrates, and in many cases will provide information about the functions of genes known to, or suspected to, cause human cardiovascular diseases. This will provide the following benefits;

A greater scientific understanding of the basic mechanisms of cardiovascular development
, disseminated through conferences, publications, and other materials including in public engagement events.

A better understanding of the causes of some human cardiovascular diseases
.

Possible discovery of new drugs for scientific study and consideration of clinical assessment
.

A greater awareness of zebrafish models of cardiovascular development and disease
.

These are worthwhile because they will add to the sum of scientific knowledge in a fundamental and clinically important area, they will contribute to reducing, refining, or replacing animal studies in other species, and they may provide scientific insights that could lead to clinical improvements or new therapies.

Who or what will benefit from these outputs, and how?

The immediate beneficiaries will be the scientific community via dissemination of the results of our research. This will also benefit the scientists and doctors trained in my lab, by increasing their understanding of research (including the considerations of animal research) which in their careers they will also disseminate.

In the longer term, the results of our research may identify novel therapeutic strategies that benefit patients and their families. This would also benefit healthcare systems such as the NHS.

How will you look to maximise the outputs of this work?

We have moved to routinely placing all data where possible on publicly available websites such as BioRxiv prior to submission for publication. We frequently take part in public engagement events, speak at conferences, and disseminate our new knowledge in journals and via our websites.

Species and numbers of animals expected to be used

- Zebra fish: 50,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Using zebrafish to study vascular health and disease taking advantage of their transparency in early stages of life. We will also use older fish to study gene function and in particular models of cardiovascular disease where this is necessary because it requires a more developed cardiovascular system than in young embryos.

Typically, what will be done to an animal used in your project?

OMost animals will be bred to generate fish embryos, larvae to study gene function. This may involve manipulation of their genome and/or pharmacolgical intervention to treat or develop phenotypes to understand gene function. We may also use advanced imaging techniques to study the effects of these alterations such as injury to the heart to mimic human myocardial injury, or exposure to glucose as a model of human diabetes.

What are the expected impacts and/or adverse effects for the animals during your project?

Normal husbandry and breeding (protocol 1) is not expected to have any adverse effects. Altering genes that may be required for the heart and circulatory system to develop (protocol 3 and 4) may result in fish that present with heart problems leading to fluid retention (oedema) and/or abnormal swimming behaviours due to reduced heart function. These effects if significant would be likely to be permanent and so would lead to human killing if there is evidence of harm, suffering or adverse effects. Animals that have undergone cardiac injury (protocol 5) will be recovering from surgery and so will experience some post-operative pain which we will address with anaethesia during the procedure and postoperative analgesia. It is expected that the animal will swim normally within hours of the procedure but may swim less for 1-2 days as the wound recovers. Feeding should not be affected for longer than this and if so we would monitor the animal and in discussion with the NVC and NACWO we would humanely kill any animals exhibiting these signs to an abnormal extent or for an abnormal duration. For cardiovascular imaging (Protocol 4) we do not expect animals to suffer harm or exhibit suffering after these procedures, but if this is observed we will discuss with the NVS and NACWO, humanely kill the animal and review our methods and procedures to establish whether further refinements are required.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most (>90% of all animals used) of the animals will present with no more than mild severity or even subthreshold as these will be animals that are used to breed. However, a subset of animals that carry gene alterations that effect heart function may present with moderate severity at later stages of development or with age (1-5% of all animals used). All animals that undergo cardiac cryoinjury will experience a moderate severity procedure (<1% of all animals used). However, we will minimise any suffering by identifying early intervention timepoints to end the experiment, but still obtain the answers to the scientific questions posed.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Because we study the living organism and the interactions between many different cell types and the physical and

physiological conditions of blood flow, neuronal activation, etc, we are currently obliged to use animals and the zebrafish is the most appropriate and lowest neurophysiological organism which can be used.
Although there is currently no alternative to the studies proposed, we will continuously seek non-animal alternative options. We will do this by monitoring the scientific literature, and particularly materials generated by NC3Rs. Within the zebrafish community there is a strong culture of communication of advances that can be rapidly adopted, both via conventional methods (publications and conferences) and more novel methods (social media, particularly twitter).

Complementary to the animal studies described, we are developing collaborations with cell biologists to begin to develop cell-based studies to test some of our hypotheses (for example co-culturing astrocytes and endothelial cells to examine whether these develop kugeln). In time these data may reduce the need for some mechanistic in vivo studies.

However, the observations we make in the model can then be used to develop non-animal alternatives to test individual mechanisms. For example, it would not have been possible to identify the novel endothelial behaviour "kugeln" in any other organism, but we are now using cell-based assays coculturing endothelial cells with neurons and glial cells to attempt to develop in vitro assays to understand the mechanisms and reduce the number of animals used.

We are developing mathematical (in silico) models of neurovascular modelling (paper in preparation) which use the data we have collected to understand the mathematical relationships between neuronal activation, blood flow and vascular diameter. This would allow us to perform in silico experiments to reduce animal numbers used.
Which non-animal alternatives did you consider for use in this project?

We considered in vitro studies using human cultured cells, in silico models, but none of these are sufficiently yet advanced enough to model the complexity of the in vivo cardiovascular system.
Why were they not suitable?

We could not devise an in vitro system that reproduces the complex anatomic and physiological environment of the cardiovascular system. Specifically; there is no current non-animal model that contains endothelial, vascular mural cells, cardiac cells, inflammatory cells, neuronal cells and other cell types which also reproduces the physiology of the cardiovascular system (a beating heart with flowing blood and blood pressure, with the associated physical forces exerted on multiple tissues).

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

From previous licence animal usage based on the size of my research group and considering plans for future studies, and in discussion with NACWOs and acquarium staff. We have used the NC3Rs experimental design assistant (EDA) to perform group size calculations to establish the numbers of animals used for representative experiments, and based the likely number of experiments performed based on a forecast of 2-4 PhD students and postdoctoral scientists per year each performing a project involving 90% zebrafish experimentation.
What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

I am using cutting edge microscopy that will gather more information from each animal than any previous studies, and time course studies where the same animal is studied over time, rather than using separate animals.
What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

Our centre is a pioneer in the ability to rapidly genotype embryos to identify which to raise to adulthood, which has the ability to greatly reduce the numbers of adults maintained on this licence (as adult breeding stocks represent the majority of the regulated procedures). The protocols in this application include the ability to genotype animals earlier than 5dpf and so to discard animals before this stage if they are not required, which would greatly reduce the number of animals used according to the requirements of ASPA. We are refining our breeding including extending the age to which we maintain our animals which reduces the total number of animals maintained for breeding stocks. We are developing computer models of neurovascular coupling that may reduce the number of animal experiments required and we routinely share surplus embryos generated during matings with other groups to reduce both number of matings and numbers of embryos raised to adulthood.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The zebrafish is the animal model of lowest neurophysiological sensitivity that can be used for any studies of cardiovascular development, as lower animals than the zebrafish do not possess a cardiovascular system. This is why we use the zebrafish in preference to rodents or other mammalian species.

We use non-invasive imaging of transgenic animals to visualise the cardiovascular system (protocol 4). This reduces the harms associated with instrumentation for other methods of vascular imaging such as angiography. There is no current method to visualise the cardiovascular system in a way that is less harmful (the animals that undergo this do not display any sign of harm and are not subjected to a procedure that would be expected to induce suffering).

To study the response to cardiac injury (protocol 5), it is unfortunately necessary to induce cardiac damage by some method in some animal model. As above, the zebrafish is the lowest species in which this is possible, and the method (cryoinjury) has been established to reduce as much as possible the discomfort and suffering induced by the surgery, including the use of anaethesia and analgesia in recovery. This does not induce lasting harm; indeed unlike other animals, the cardiac injury repairs completely over weeks, leaving cardiac function normal after injury.

We will continue to seek to minimise harms by; expert husbandry and handling of our animals and by close monitoring of animals that have undergone any intervention.

Why can't you use animals that are less sentient?

There are no lower organisms that possess a functional cardiovascular system. Wherever possible we use embryos in place of older animals as these are likely to be less sentient.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

We will seek to refine our studies by discussing any new experiments with the NACWO and NVS to identify the optimal monitoring and post-op care and analgesia requirements, and to further improve these based on our experience and any relevant publications or other source of information.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will monitor the NC3Rs websites and publications and zebrafish husbandry publications and scientific conferences to identify new ways to refine our studies.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

We will stay informed with the literature and developments in the field by monitoring NC3Rs literature and outputs and attending conferences in this area and in liaison with the NC3Rs Regional Programme Manager

Home Office

NON-TECHNICAL SUMMARY

229. Zebrafish models of retina development and disease

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man, animals or plants
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants

Key words

Zebrafish, Vision, Glial cells, Retina, Gliosis

Animal types	Life stages
Zebra fish	embryo, adult, neonate, juvenile

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

In this project I aim to determine the role of specific cell adhesion molecules in the development and healthy function of the retina.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

The central nervous system (CNS) consists of the brain, spinal cord and retina (eye). It controls most functions of the body and mind. Despite the importance of these tissues are made up of only two major cell types: neurons and glia. Most researchers focus on neurons because they are the electrical wires passing signals to perform daily functions. However, glial cells outnumber neurons in the CNS and they support neurons to make sure they are healthy and function properly. To make up the CNS, neurons and glia need to meet during development and make specific partnerships that last a lifetime. Glial cells have special shapes so that they can connect to the neurons. Changes in glial shape can make neurons sick and potentially lead to disease. I want to explore this really important question: how glial cells get their shape in the first place so we can make sure they keep it and support the neurons throughout life.

What outputs do you think you will see at the end of this project?

The work in this proposal will be of great relevance and interest to academics studying two of the fundamental questions in neurobiology: How is the nervous system built and what causes it to break down in disease? The data will provide for the first time a characterisation of glial morphology and their contact with specific synapses throughout development in real time in vivo. This work will provide significant and novel insights into the mechanisms that form the brain in vertebrates, and in many cases will provide information about the functions of genes known to, or suspected to, cause human neurological diseases and blindness.
REDACTED

Who or what will benefit from these outputs, and how?

This work will provide the following benefits;

A greater scientific understanding of the basic mechanisms of retina development
A better understanding of the causes of some human retina diseases
A greater awareness of zebrafish models of retina development and disease
These benefits are worthwhile because they will add to the sum of scientific knowledge in a fundamental and clinically important area, they will contribute to reducing, refining, or replacing animal studies in other species, and they may provide scientific insights that could lead to clinical improvements or new therapies in the future. These may be broken down as follows:
Short term benefits (1-2 years): Generation of novel zebrafish models which will provide tools with which to investigate retina development in zebrafish. Furthermore, these tools will be of wider interest to the developmental biology community (genes important in eye development often play roles in other developmental processes, and therefore these models can be shared within the scientific community)
Medium term benefits (3-5years): Analysis of retina development in the embryonic models generated will further our understanding of how the nervous system development is regulated. This will also provide the basis for future studies in zebrafish and/or other organisms refining our understanding of this regulation. Analysis of the potential roles for specific mutations in juvenile/adult zebrafish may also help us link mild developmental defects with abnormalities in visual function later in life.
Long term benefits (5+ years): Better defining the genetic regulation of retina development has several long-term implications. Together with the use of next-generation sequencing technologies identifying candidate causative mutations in blind patients, we can better understand why specific mutations may cause blindness, and how this can impact upon long-term vision health – with implications for genetic counselling and treatment plans. In addition, understanding how to build a retina in an embryo has important implications for regenerative studies, and

I expect that some candidate genes we identify as part of this project may represent good candidates to investigate as mediators of retina regeneration in zebrafish, with direct relevance to treatment of human degenerative diseases.

How will you look to maximise the outputs of this work?

-- All data generated from zebrafish will be published at the earliest reasonable opportunity. We have a strong track record for publishing their data in the highest impact journals REDACTED and will continue to strive for these standards of publication for all data arising from the use of zebrafish. The applicants are regularly asked to speak about their research at international scientific conferences, policy meetings, special interest groups and public events. We also regularly participate in outreach events to help promote the work we do and engage with key groups including patients, eye charities and research councils, politicians, and schools. These interactions have a significant bearing on our research objectives.
-- We are part of the establishment zebrafish community that is highly visible through their website. Any new data will be announced and displayed on the appropriate sections of the website describing zebrafish work. This includes unsuccessful approaches and "negative" data that may impact on the future experiments, and animal use, by others in the field.

Species and numbers of animals expected to be used

- Zebra fish: 24,000

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Zebrafish represent arguably the best model for carrying out the research described in the project plan. It has an excellent capacity for in vivo imaging of externally-fertilized embryos – since most of the phenotypic work in the proposal analyses retina development in embryos below the age of protection, this reduces the numbers of zebrafish used for much of the project to breeding stocks subject to potentially moderate visual testing procedures, but are not expected to generate significant discomfort. Furthermore, zebrafish also represents the organism with the lowest neurophysiological sensitivity possible for work that focuses on the nervous system.
All genetically manipulated animals which are to be taken over 120hpf, either for generation of transgenic line or analysis of phenotypes in larval and adult stages will be subject to regular intensive surveillance, and culled if they display behaviours or symptoms outlined in Protocols 2 and 3 (e.g. weight loss, arched back, cataracts) to prevent undue suffering. All other adults maintained for breeding stocks will be subject to the regular health checks as part of our normal animal maintenance procedures.

Typically, what will be done to an animal used in your project?

Most animals will be used for breeding and generating transgenic and/or mutant lines. Fish will be grown to selected time-points, where they may be culled for post-mortem analysis of fixed tissues or isolated cells from selected tissues.
Fish may also undergo non-invasive behavioural vision testing, where we film animals responding to visual stimuli, which will allow us to measure visual system function.

What are the expected impacts and/or adverse effects for the animals during your project?

Some of the mutant zebrafish lines may have dominantly or recessively inherited neurological phenotypes manifesting as a
progressive swimming deficit. In dominant models 50% will be affected, in recessive models 25% will be affected. In order to characterise neurological phenotypes in new zebrafish models it is important to fully document any abnormal behaviours. In order to characterise the progressive, transient or stable nature of the phenotype, a daily visual inspection of their behaviour will be performed and a record kept when appropriate, working closely with NACWO and veterinary staff. We anticipate there may be a moderate impairment of the wellbeing of the zebrafish disease models, however once their condition begins to deteriorate rapidly we will sacrifice them humanely via schedule one. If a severe abnormal behaviour
(e.g. inability to swim, severe listlessness) persists for longer than 10 minutes or severe emaciation is evident in an individual fish, this fish will be sacrificed immediately by a schedule one method. Any fish displaying a moderate phenotype or intermittent phenotype (including altered swimming activity or buoyancy, general listlessness), will be monitored closely and sacrificed by a schedule one method if the conditions deteriorates. The provoked response to feeding is a reliable way of determining the overall condition of a fish. Any phenotypic fish which do not respond to the introduction of food into the tank will be sacrificed by a schedule one method.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

Most animals will be used for breeding and generating transgenic and/or mutant lines (Mild). To understand how the specific cell interaction we are studying is impaired with ageing requires animals to age, whether naturally, or in the presence of mutations that mimic premature ageing syndromes in humans. During the course of their life-span premature ageing will result in weight loss, arched back, cataracts (ageing phenotypes in later time points are considered moderate; non-recovery 0 %; mild 25 %; moderate 25%)
A small portion of animals will be imaged under anaesthesia post fin clipping or post skin incision (nonrecovery 0 %; mild 20 %; moderate 0%). Larvae may require embedding in agarose up to a maximum of 2 hours or up to 8hrs when the procedure is terminal (AC).

What will happen to animals at the end of this project?

- Used in other projects
- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Zebrafish represent an excellent model in which to study the eye, both in development and disease. The eye is structurally well-conserved between zebrafish and mammals, including the retina. In the zebrafish over 80% of genes with disease-causing mutations are conserved. The potential of the zebrafish model in clinical practice is extremely high, as evidenced by the successful identification of treatments for human disease using drug screening. The zebrafish is an eminent model for visualising cells in vivo as there are transgenic lines that label every neuron and glial cell, thereby facilitating the unambiguous identification of each cell type based on reporter expression. These transgenic lines facilitate the imaging of cell interactions in real time in vivo.
The proposed experiments need to be performed in vivo. The patterning of glial cells is a dynamic process requiring interactions in a heterogeneous environment, between neurons and glial cells, meaning it cannot be modelled in any meaningful sense in vitro.

Which non-animal alternatives did you consider for use in this project?

I have considered performing cell
culture studies to inform the interaction studies that will be performed in zebrafish. Where it is possible to identify candidate genes from literature searches of publications, I will do this to replace in vivo screens. In the instance studies have been done in other systems, and the data is available, these studies will not be repeated in my model.

Why were they not suitable?

It is
very difficult, if not impossible, to recreate the complexity of the in vivo state in this manner, and not possible to test genetic manipulations of glial patterning in this manner. In the instance studies have been done in other systems, and the data is available, these studies will not be repeated in my model. It should be noted I choose to use zebrafish embryos for this study, as a non-mammalian model organism, with the lowest neurophysiological sensitivity possible for work focusing on the nervous system.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The number of animals that we require for transgenesis and embryonic analysis are based on practical stock keeping considerations i.e. ensuring sufficient animals of the right sex and genotype for embryo collection and stock maintenance.
I have used data generated from previous PPLs (postdoc supervisor) to gain insight into the number of animals required per line and protocol. I established this using power calculations, based on http://www.3rs-reduction.co.uk/html/6__power_and_sample_size.html .

When the given protocol has not yet been tested by me, I will perform a small pilot study with maximum 3 animals per genotype as a refinement strategy. I have used data from the literature to estimate number of animals required for such new protocols. Overall, data suggest I need a maximum of 16 animals per genotype, per time point to allow statistical interpretation.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Only in selected cases will we perform phenotypic analysis on larvae or adult fish. We have sufficient pilot data from all studies to perform a priori power calculations to calculate group sizes. We will not initially exceed the predicted group sizes required to detect a 40% difference with 80% power (alpha of 0.05 as per convention). We will increase group sizes only if greater power is required, if the variance is greater than in pilot studies, or where the biological effect to be detected is less than 40%. Where we obtain data over time from the same animals, we will use statistics appropriate to repeated measures.
We will increase group sizes only if greater power is required, if the variance is greater than in pilot studies, or where the biological effect to be detected is less than 25%. Whenever possible we will use the same adult fish for in vivo assays, including non-invasive, non-harmful behaviour assays, followed by schedule 1 and in vitro cell culture assays, to try and reduce the number of fish that have to be grown in parallel for the different experiments. Furthermore, an advantage of working with zebrafish, both as larvae and adults is that we only need one animal to look at all tissues at the same time, on the same slide, which increases the quantity and relevance of the

information retrieved per animal. Where possible temporal studies will be performed using the same animal to gather serial data. As part of good laboratory practice, we will write an individual study plan (ISP) for each experiment involving regulated procedures.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The number of animals that we require for transgenesis and embryonic analysis are based on practical stock keeping considerations i.e. ensuring sufficient animals of the right sex and genotype for embryo collection and stock maintenance.

Many of the functional assays will be performed in vitro using isolated cells from different tissues of the same animal, allowing large amount of data to be collected from reduced number of animals To minimise the number of animals grown to an age protected by the Act, we will try and genotype the lines before the age of 5 days post-fertilization, after which they are protected by the Act, to identify unwanted genotypes to reduce the number of adults to grow. For example, embryos may be genotyped through micro-abrasion using the ZEG system.

Opportunities to reduce the number of animals required to develop a new line may be possible as new transgenic technologies are developed (e.g. genome editing). Breeding programmes to develop the new lines and intercrosses will be developed and we will use in-house databases (e.g. labtraks) to aid our efforts to maintain the minimal number of animals per line. Where necessary, gametes are expressed either to maintain fertility or to allow in vitro fertilisation, and numbers are determined by the requirements of maintaining fertility and preserving lines.

Furthermore, whenever possible we will use the same adult fish for in vivo assays, including non-invasive, non-harmful behaviour assays, followed by schedule 1 and in vitro cell culture assays, to try and reduce the number of fish that have to be grown in parallel for the different experiments.

Additionally, using such a small sized animal like the zebrafish allows us to look at all tissues at the same time, on the same slide, which increases the quantity and relevance of the information retrieved per animal. Where possible, temporal studies will be performed using the same animal to gather serial data.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Fin clipping and gamete expression methods rarely involve inducing any tissue damage or discomfort, but for all manipulative procedures animals are suitably anaesthetised (primarily for restraint) by addition of immersion anaesthetic to the medium (no instrumentation is required even for the anaesthetic) using an anaesthetic protocol suitable for the procedure and following best practise (Tricaine immersion). Where necessary euthanasia is by anaesthetic overdose.

Fin clipping for genotyping purposes will be performed whenever possible in larvae before independent feeding (before 5.2dpf (non-protected).

Any new procedures will be tested first in few animals in pilot experiment (up to 3 of each experimental and control group), under NACWO and NVS guidance.

Why can’t you use animals that are less sentient?

We will use the zebrafish in our research project because the proposed experiments are best performed in vivo. The patterning of glial cells is a dynamic process requiring interactions in a heterogeneous environment, between neurons and glial cells, meaning it cannot be modelled in any meaningful sense in vitro. I have considered performing cell culture studies to inform the interaction studies that will be performed in zebrafish. However, it is very difficult, if not impossible, to recreate the complexity of the in vivo state in this manner, and not possible to test genetic manipulations of glial patterning in this manner. It should be noted I choose to use zebrafish embryos for this study, as a non-mammalian model organism, with the lowest neurophysiological sensitivity possible for work focusing on the nervous system.
Studying vertebrate retinal development in this project can only be carried out using zebrafish as they have a retina similar in composition and organisation to humans, unlike invertebrate species. Further, this project relies on visualising dynamic interactions between different retinal cell types in real time in vivo. These experiments require fluorescent transgenes to specifically label these cell types which do not exist in other vertebrate species, like reptiles or amphibians. Furthermore, visualising these dynamic intercations rely on the optical clarity of the zebrafish embryo (before 120hpf), which is when retinal organisation takes place and is completed. As such, zebrafish are necessary to investigate retinal cell dynamics in development and achieve my specific scientific objectives.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

I will follow the ARRIVE guidelines and use the checklist when reporting animal use in papers, therefore maximising information published and minimising unnecessary studies.
The methods for generating mutants and transgenics are optimised to minimise numbers and adverse effects are minimal. Zebrafish have a number of additional advantages for these studies, including their near transparency, genetic tractability, extensive genomic resources and small size. My previous work has provided experimental data to develop defined end-points for my protocols that will be employed in this PPL. In particular, my previous work has allowed me to optimise histology, so I know that the culling methods chosen are ideal for tissue preservation, required to address the scientific questions in this project. Scoring sheets and imaging (photographs) will be used to further refine the end-points. Finclipping for genotyping purposes will be performed whenever possible in larvae before independent feeding. Procedures will be tested first in few animals in pilot experiment (up to 3 of each experimental and control group).

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

I will follow the latest relevant literature and in house expertise as well as 3Rs resources and guidelines for zebrafish (https://norecopa.no/media/7384/zebrafish.pdf)

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

At my establishment, the excellent team of NACWOs, the director of the animal facility maintain regular contact with all PPL and PIL holders regarding latest advances and help us implement these. I will have regular discussions with them about my experiments and the 3Rs. I will visit the N3CRs website (https://www.nc3rs.org.uk/the-3rs) and continue to receive their newsletter to make myself aware of relevant advances.

Home Office

NON-TECHNICAL SUMMARY

230. Zebrafish: an alternative model for drug safety & efficacy

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants
- (c) Development, manufacture or testing of the quality, effectiveness and safety of drugs, foodstuffs and feedstuffs or any other substances or products, with one of the following aims mentioned in paragraph (b)

Key words

Drug toxicity, Central nervous system disorders, Organ regeneration, Heart and kidney failure, Anaesthesia

Animal types	Life stages
Zebra fish	embryo, neonate, juvenile, adult

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is required, and should be submitted within 6 months of the licence's revocation date.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The overall aim is to use the zebrafish as an alternative, non-mammalian, model for assessing the safety and efficacy of new human drugs and human drug targets with a view to understanding how they might act in humans. This is achieved by studying the effects of drugs and drug target modification on the development, structure and function of major organs systems of the body, including nerves, heart, skeleton, kidneys, liver and digestive systems.

A retrospective assessment of these aims will be due by 13 April 2026

The PPL holder will be required to disclose:

- Is there a plan for this work to continue under another licence? Did the
- project achieve its aims and if not, why not?

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

A very high proportion of new human drugs fail to reach patients as they show some toxicity or are relatively ineffective. Moreover, many of these failures occur after a considerable amount of time, money and animals (usually mammals) have already been used to test their safety and effectiveness. Consequently better approaches for measuring drug toxicity and effectiveness are needed, which can be deployed early in drug development so that more effective and safer medicines reach the market, without wasting these valuable resources on drugs that subsequently fail. This is where the zebrafish, in particular the embryonic and larval forms (<14 days old) is proving invaluable for several important reasons. These reasons include: good genetic and physiological similarity to humans; transparent development allowing visualisation of organ function (e.g. heart rate and blood flow); ease of genetic manipulation allowing us to test the effects of altering gene function; and a small size (a few mm's) meaning we only need to use very small amounts of drugs for testing. This project aims to utilise these attributes to develop and apply approaches in which we can measure the toxicity and effectiveness of new drugs, and test the effects of potential drug target modification on major organs system of the body.

What outputs do you think you will see at the end of this project?

Overall, the outputs from this project will include: new information regarding drug safety, efficacy and target validation; new fundamental knowledge regarding the endpoints under investigation; new methodology to complement or in some cases replace the use of higher vertebrates for testing drug safety and efficacy; new data on the translational power of the zebrafish as an alternative model to mammals for these research areas; and publications, presentations and information for educational purposes.
Objective 1) Outputs will primarily be data on the safety profile of new candidate drugs with respect to seizure liability, developmental toxicology, cardiovascular, kidney toxicity and hearing and visual impairment. These data will be used for internal decision making processes in order to drop compounds with unacceptable liabilities, allow alterations in compound chemistry to be undertaken to avoid such liabilities, and to prioritise the further development of compounds showing a good side-effect profile. In the absence of such data, the first stage of *in vivo* testing (in which the integrated whole organismal biological activity of new drugs can be adequately assessed) would be in traditional mammalian toxicological and safety pharmacological assessments, and the selection of compounds for testing in such systems would be made in the absence of any other *in vivo* data. Consequently, the data provided in this project will enable better decision making regarding the progression of compounds into higher vertebrate testing programmes and reduce unnecessary testing in higher vertebrates on compounds destined to fail later in development
Objective 2) Outputs will primarily be the provision of new *in vivo* methods for the assessment of gastrointestinal toxicity, liver toxicity and neurobehavioral toxicity that may be deployed in the early stages of drug development provided sufficient levels of translation to higher vertebrates including man are achieved. Subsequently these methods may be used in the same way as the established assays in Objective 1 leading to gains in the efficiency and effectiveness of the drug discovery and development process. In all cases, assays are developed and validated for only high impact and/or high incidence adverse drug reactions and only in the absence of an appropriate existing approach to address a specific safety liability in a whole animal context early in the drug

development process. This means in all cases that at present the first stage of *in vivo* testing is undertaken in mammals at a relatively late stage of development after a considerable amount of resources have already been invested (animals, money and time). Using kidney toxicity as an example, the ultimate impact on organ function constitutes the extremely complex culmination of the influences of many different organs systems and initiating pathways. Firstly, delivery of the drug to the kidney (or relevant indirect target), is clearly dependent on the Absorption Distribution Metabolism and Elimination of the drug in question (e.g. protein binding, partitioning, metabolism etc). Once at the target the drug may exert its toxic influence via many different mechanisms, for example: physical occlusion via altered local haemodynamics through vasoconstriction or microthrombosis; crystal nephropathy caused by tubular uric acid accumulation; cellular injury for example due to rhabdomyolysis, acid/alkylosis or localised oxidative stress; or altered tubular membrane conductances or impaired solute transporter activities at multiple sites along the kidney nephron(s). This complexity simply cannot be recreated *in vitro* and as the most important consequence is an adverse impact on renal function, the development of *in vivo* measures of functionality are crucial.

Objective 3) Outputs will primarily be data on the efficacy profile of new candidate drugs with respect to the treatment of epilepsy, diabetes, kidney and hearing regeneration, alongside other general research and educational outputs. In common with Objective 1, data will be primarily used for internal decision making processes in order to drop compounds showing insufficient efficacy against the disease phenotype in question, compared with other compounds within that specific discovery project. Again, in common with assessment based upon safety liability, in the absence of zebrafish data the first stage of *in vivo* testing would be in a mammalian non–clinical efficacy model, for example a mammalian genetically-modified mouse model that recapitulates the disease phenotype of interest. Consequently, the selection of compounds for this *in vivo* efficacy assessment would be made in the absence of any prior *in vivo* data and as such the inclusion of zebrafish efficacy data allows better decision making regarding the progression of compounds and reduces unnecessary testing in higher vertebrates on compounds destined to fail later in development. For the specific disease models being used here, there are no appropriate *in vivo* approaches suitable for early stage efficacy assessment available. Using epilepsy as an example, as epilepsy is a complex multifactorial neurological disorder, *in vivo* models have been crucial in gaining a better understanding of ictal and inter-ictal processes, as well as for testing the effectiveness of antiepileptic drugs (AEDs). Traditionally the assessment of AED efficacy has focused on the use of pharmacologically or electrically-induced rodent seizure models, or rodent genetic models of specific epileptic syndromes such as Dravet syndrome (caused by a mutation in a voltage-gated Na^{2+} channel). The zebrafish has emerged over recent years as a viable lower vertebrate model for assessing AEC efficacy and unlike rodent models can be deployed early in the drug development process when compound numbers are high, and compound availability is low. In addition to its value as an efficacy assessment model, our use of video tracking and our development of the functional imaging approach promise the potential for identifying novel mechanisms of antiepileptic action by providing mechanistic data following specific pharmacological intervention. For example, using functional imaging we have already started to identify specific neural circuits that are more frequently activated during pro-convulsive compound exposure (e.g. the cerebellum and associated circuitry) and other circuits that appear particularly activated during exposure to specific pharmacological classes of compound (such as monoaminergic and cholinergic agents).

Consequently, the data outputs from such work are helping us to understand which circuits could be novel targets for AEDs, what drug-induced seizures look like (thus improving their detection during drug development), and what the neural-network processes (such as altered functional connectivity between certain brain regions or the recruitment of specific circuits associated with specific neurotransmission systems) leading from the resting state to the ictogenic state might be. Importantly regarding these 3 points: most AEDs target a limited number of ictogenic mechanisms, and as such there is still a massive unmet need for AEDs to treat refractory epilepsy; seizure liability still presents a major cause of CNSrelated attrition during drug development; and finally the exact mechanisms that lead to ictogenesis, or the transition from local excitation to widespread hyper-synchronicity typical of a seizure are still poorly understood. Collectively, therefore, our work will further the fundamental understanding of the development, progression and treatment of seizures and the chronic seizurogenic syndrome epilepsy in humans.

Objective 4) The main output from this objective will be the provision of *in vivo* data on the link between genotype and phenotype in zebrafish in relation to high impact and/or incidence human diseases. Generation of these data will serve three main purposes: firstly they will allow drug discovery scientists to make data-driven decisions about which genetic targets to prioritise for further evaluation in genetically modified mouse models (currently decisions are made using only *in silico* and i*n vitro* data meaning only a limited number of targets can be pursued *in vivo*, and some targets subsequently fail due to poor *in vitro* to *in vivo* translation); secondly, in some cases they could

provide zebrafish-based disease models that can be used as alternatives to mouse-based disease models and allow assessment of multiple novel drugs at a much earlier stage of discovery; and thirdly, these data will help to improve our understanding of the genetic basis of the targeted human disease for example by allowing exploration of the link between a gene mutation identified from clinical assessments of patients, and an *in vivo* phenotype that has not yet been described in a non-clinical model. Demonstration of a similarity between the clinical and non-clinical phenotypes supports the involvement of mutation of this gene in the disease in question. Specifically, no CRISPR-based knockout and subsequent systematic organ development and functional data in zebrafish exists for any of the genes being proposed here. For those genes identified in patients suffering from heart or renal failure, for example, there are no published studies in which gene knockout followed by detailed phenotypic analysis and measurement of cardiovascular (e.g. heart rate, blood flow, vasodilation/constriction) or renal function/pathology (e.g. glomerular filtration rate, podocyte number) are available. Consequently to date there are no data to support a functional link other than that from *in silico* or *in vitro* assessments, and therefore limited data to support their further development in mammalian models as potential targets for therapeutic intervention, or to support further research into the molecular mechanisms involved in the transition from gene mutation to altered protein function. This project will provide these data. For those genes identified as associated with ADHD and ASD, there is still a lack of fundamental data on which brain structures and circuits, or which neurotransmitter systems underpin these multifactorial diseases, and how alterations in these results in the human disease phenotype. Using our functional imaging approach we will generate data on altered brain circuitry associated with mutation of several risk genes compared with non-mutated animals, and assess the resultant effect on dopaminergic signalling in the vertebrate brain. This will provide an insight into the factors linking genotype with phenotype in these conditions, providing further knowledge of the aetiology of these diseases as well as potential targets for further therapeutic intervention.
Objective 5) The work undertaken under this objective will provide researchers with the first definitive data on appropriate anaesthetic and analgesic agents and treatment regimes in embryo-larval zebrafish (the most widely used species/life stage of laboratory fish), improving understanding of appropriate anaesthetic doses and induction/recovery times, as well as providing information on post-surgical analgesia. The data generated will also help to refine the accuracy of visual indicators of anaesthetic status for in-procedure monitoring, which are routinely used during such procedures. These data will be generated in zebrafish, but will provide a foundation for refining anaesthetic protocols in other species of fish. We will provide the first detailed data on the effect of agents on specific zebrafish neural circuits allowing CNS researchers to select the most appropriate agents for their research. These data will also provide fundamental information on fish (un)consciousness and pain perception, and in addition, the functional imaging component will provide fish CNS researchers with a potential non-invasive replacement for implanted electrode techniques in CNS functional studies.

Who or what will benefit from these outputs, and how?

Industry will benefit from the provision of techniques, data and improved knowledge of their drugs to enable faster and more effective decisions to be made about the potential of certain projects. This is turn will lead to economic and animal savings destined to be used for studies on drugs that subsequently fail. The wider public will benefit through the generation of safer more efficacious medicines, more efficiently and rapidly than would otherwise be possible using traditional *in vivo* testing approaches.
The scientific community will be benefit from improved knowledge, development of techniques and access to publications and presentations of our research findings.
Objective 1) These data will allow safety assessment scientists within our collaborator laboratories to make decisions regarding the further development of certain compounds based on their safety profile. The data generated will allow them to drop compounds, redesign chemistry or prioritise additional safety assessment tests this leading to increased efficiency (including saving animals, time and money used on compounds with safety liabilities) and success in the development of new medicines for patient use. These gains are expected to be immediate. These gains are expected to be within the life span of the current project, as has been the case with previous licences.
Objective 2) It is anticipated that these outputs will be used by collaborator and other laboratories both for drug screening purposes, but also for other purposes as has been the case in the past for example with the use of cardiovascular screening approaches in the assessment of the effects of environmental chemical exposure in fish.
Objective 3) These data will be used by discovery biologists within our collaborator laboratories to make decisions

regarding the further development of certain compounds based on their efficacy profile. This data will allow them to assess many more compounds than is currently possible using traditional i*n vivo* model systems with the aim of selecting the most efficacious for further testing and development, for example in mouse disease models. These gains are expected to be immediate in the case of current models, and within the time scale of the current project in the case of models that require additional development time.
Objective 4) Discovery scientists within our collaborating laboratories will use these data to contribute towards the discovery of new drug targets for high impact human diseases. This information is likely to be used alongside *in silico* and *in vitro* data on new drug targets to justify the generation of mouse models of the most promising gene targets thus allowing more effective evidence-based triaging. In addition, in some cases new screening models may be produced in which new candidate drugs can be tested at a higher throughout than is currently possible with mouse models used in target validation and early drug testing. Data generated from this objective are likely to be the most commercially sensitive, however wherever possible general research and educational outputs will be provided to increase learning about the function of these genes and their roles in human disease aetiology. These gains are expected to be within the life span of the current project, as has been the case with previous licences.
Objective 5) Researchers using fish models will gain the first definitive data on appropriate anaesthetic and analgesic agents and treatment regimes in embryo-larval zebrafish (the most widely used species/lifestage) and zebrafish neuroscientists with data to assess compatibility with their work as well as fundamental information on fish (un)consciousness and pain perception. Although focused on zebrafish, it is anticipated that this project will also provide valuable translational data for aiding decision making in other fish species for example by helping to refine the accuracy of visual indicators of anaesthetic status for in-procedure monitoring by veterinary surgeons, or by providing a starting point for large-scale fish anaesthesia for transportation, vaccination, tagging etc. in the ornamental fish industry.

How will you look to maximise the outputs of this work?

We are a highly collaborative group and always seek to exploit opportunities for collaborative working.
This is illustrated by a number of publications in which some of our in house developed techniques have been used for studies outside of our core aims of assessing drug safety and efficacy (e.g. for assessing the physiological impact of environmental contaminants).
In addition, we are active presenters at scientific meetings and other universities, for example delivering presentations at international conferences, specialist meetings, local seminars and outreach events.
Despite a close working relationship with pharmaceutical companies, as a group it is our policy to publish (as evidenced by our collectively strong publication records, given our industry focus), wherever possible in peer-reviewed journals. This approach maximises the benefit of developments made under this project licence to the scientific community, and contributes towards the body of evidence supporting the usefulness (and ultimately regulatory acceptance) of the zebrafish as a mammalian alternative for drug safety and efficacy testing.

Species and numbers of animals expected to be used

- Zebra fish: 104500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

The zebrafish has emerged as a credible vertebrate model for the assessment of human drug safety and efficacy. In particular, the embryo-larval possesses a number of important attributes that infer advantages over more traditional, higher vertebrate (e.g. mammalian) models. These include: rapid and transparent development meaning biological processes can be easily be seen under a microscope; good genetic similarity with humans (a reported 83% of human disease-related genes are found in the zebrafish); and a small size meaning they do not require a large amount of space or large amounts of drug for use in tests.

Typically, what will be done to an animal used in your project?

Procedures used are: modifying a gene and assessing the effect this has on an animal or its organs; exposing zebrafish to drugs by immersion or injection and assessing the effect this has on an animal or its organs; assessing whether drugs are effective in treating fish in which the development or function of an organ has been compromised.
Apart from the provision of adult broodstock, in the vast majority of cases, these procedures will be undertaken in young zebrafish embryos and larvae (typically <10 days old and a few mm's in length). In many cases, the duration of the experiments is short (e.g. 1 hour-2 days) with the longest part of all procedures associated with exposure to the drugs to ensure sufficient absorption into the animal.

What are the expected impacts and/or adverse effects for the animals during your project?

In many cases, the effects of genetic modification, drug exposure or specific procedures will be mild with little more than transient effects on the welfare of the animals used. For example, over the past 4 years 46% of the animals used have been classified as of mild severity. The following adverse effects are based upon the worst case scenario where a new drug is being tested in larval zebrafish (<14dpf) without prior knowledge of its toxicity or a new disease model has been created:
Death
Morphological defects (estimated duration in protected animals 8 hours)
Seizures (<2 hours)
Moderate water retention (lifespan of the animal)
Abnormal posture or loss of balance (estimated duration 2 days)
Any of these observed in adult animals would lead to those animals begin humanely killed immediately.

Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The expected severities range from mild through to severe across all protocols. The numbers expected within each category can be estimated from previous figures (2016-2019) as an average across all protocols:
Mild ~45%
Moderate 42%
Severe ~11%
Non-recovery ~2%
All animals used are zebrafish and in the vast majority of cases will be embryos and larvae of <14 days old. Specifically, >99% of exposures will be undertaken in animals of <14dpf, with adult animals only used under specific circumstances (e.g. for the assessment of later-stage endpoints for developmental toxicity), or for the production of brood stock to supply embryos and larvae for subsequent drug testing.

What will happen to animals at the end of this project?

- Used in other projects
- Killed

A retrospective assessment of these predicted harms will be due by 13 April 2026

The PPL holder will be required to disclose:
- What harms were caused to the animals, how severe were those harms and how many animals were affected?

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

Drug safety assessment and a true representation of human disease characteristics require intact animal models to accurately recreate a full organism response. For example, seizures and epilepsy are complex neurological processes and, as such, *in vivo* models with intact nervous system structure and function are crucial for furthering our understanding and for confidently detecting seizures as a side effect of new drugs.

Similarly the overall aim of the target validation work is to use the zebrafish as the first *in vivo* model for assessing the likelihood of new drug target working. Cell-based approaches are suitable for understanding basic function, but the complexity of a whole animal is vital to fully understand the structural and functional effects of gene alteration and interactions with new drugs. Normally mice are used for this but this project aims to use the zebrafish as a precursor in order to ensure only the most scientifically-appropriate and relevant mouse models are then generated for further study.

Which non-animal alternatives did you consider for use in this project?

The ultimate purpose of this project is to understand the effects of drugs and the biology of drug targets in humans. With increasing knowledge through the project, there is the potential for replacement of protected with non-protected animals. A good example is with our recent advances in brain imaging in which we may be able to detect and measure seizures at 4dpf instead of 7dpf. Similarly, in the target validation work our strategy is to use non-protected life-stages of zebrafish initially, and only use protected life stages when and where is absolutely necessary in order to answer the specific biological question being posed. This approach makes sense as the specific properties of the embryo-larval zebrafish allow target validation to be undertaken more simply and rapidly than in older animals, or in mice.

Why were they not suitable?

The endpoints selected represent those for which no appropriate alternatives exist to bridge the gap between cell based and traditional (e.g. mammalian) animal testing models. For example, the emphasis in the drug safety assays is on functional assessment of side effects, and thus these types of assessments in their entirety cannot be recreated using cell based assays. Using seizures and epilepsy as an example, although some invertebrate models have been proposed (e.g. fruit flies) these lack the level of nervous system complexity and human translatability that the zebrafish offers and the larval
zebrafish is currently the most refined animal in which the detection of, and mechanistic studies into, seizures can be undertaken. In this respect, the overall aim of this project is reduce or replace the use of rats and mice for this purpose. Our approaches, therefore, offer the best level of refinement for this process and this is supported by existing published and recently derived data.

Similarly with the target validation work, although some invertebrate models have been proposed, these broadly lack the level of physiological complexity and human translatability that the zebrafish offers, and again the zebrafish offers the most refined vertebrate species for use in this context. In common with the drug safety and effectiveness tests, the aim of the target validation work is to use the zebrafish as a lower vertebrate bridge from cell based to whole animal translation to ensure evidence for the link between gene and target is strong prior to investing in mouse models.

A retrospective assessment of replacement will be due by 13 April 2026

The PPL holder will be required to disclose:

- What, if any, non-animal alternatives were used or explored after the project started, and is there anything others can learn from your experience?

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

The numbers estimated reflect our average annual returns over the last 4 years with a 30% increase added in anticipation of an expected increase in demand, especially with respect to the target validation work which is in its relative infancy in our group.
In mitigation, our data reflect the fact that embryo-larval zebrafish have higher throughput amenability, that we use individual animals as the experimental unit in our work rather than using the tank as the experimental replicate measure, and that we use the most appropriate age of animal to meet the requirements of the endpoint under investigation. For example, method development work and model validation exercises suggest that 7 days is the earliest age for assessing particular behaviours, although our proposed work to validate the use of brain imaging for seizure detection may mean this is reduced to 4dpf.
Adult fish are only used in drug exposures under rare circumstances (e.g. <1% of animals used), for example where the investigation of a specific endpoint requires analysis of an older animal (e.g. for developmental toxicity assessment).

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

Despite the relatively high numbers proposed, for every endpoint investigated the numbers used will be minimised by employing the following control measures:
Careful experimental design (e.g. utilising shared control groups and/or intra-individual controls where possible, power calculations, and previously generated datasets) has allowed the development of methods to obtain usable data with the minimum number of animals.
To reduce embryo-larval numbers used in established assays (seizure liability and developmental toxicology), the assessment of general toxicity (via the Maximum Tolerated Concentration or MTC assessment) is integrated into the main assessments rather than being conducted as a separate study. For any adult fish exposures, and during larval fish assay development, however, a pilot study is undertaken using a reduced number of animals to establish an appropriate exposure regimen, prior to commencing the main study. For non-proprietary drugs, this is supplemented with information on toxicity from the published literature. The overall aim is to minimise inappropriate drug-exposure related adverse effects in the definitive assessments.
Where appropriate, power calculations will be used, although when assessing drugs with unknown toxicological and pharmacological properties, the magnitude of response is less predictable. In such cases, experimental experience will be used to judge an appropriate number of animals to use in the first instance, after which standard operating procedures will be used.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

A key strategy is to maximise the amount of information extracted from each animal used. Examples include using the same animals for morphological assessment and histopathology in the target validation work, use of toxicity data for multiple assays employing the same test compound, and the measurement of multiple endpoints in the same animals. The latter approach is important; as well as providing more scientifically-relevant and robust data, this also serves to increase the throughput of any assay developed which is central to the success of any work that is undertaken using the zebrafish as an alternative model.
Ultimately, the overall purpose is to reduce the number of tests undertaken unnecessarily on mammals with drugs that will eventually fail due to a poor side effect profile or low efficacy, or for which the evidence for target translation to humans is poor.
A retrospective assessment of reduction will be due by 13 April 2026

The PPL holder will be required to disclose:

- How did you minimise the numbers of animals used on your project and is there anything others can learn from your experience?

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

All of the work contained within this project uses the zebrafish, and in the vast majority of cases, embryo-larval fish will be used in exposures (>99% expected to be <14dpf). Only under very specific circumstances will older animals be used, for example for the investigation of a specific endpoint requiring analysis of an older animal (e.g. for developmental toxicity), or when genetically-modified fish are maintained and bred to provide embryos and larvae for subsequent drug testing. With regards to the specific models and techniques to be used:
Basic brain structure and function of relevance to seizures and epilepsy are highly conserved between mammals and zebrafish. The actual measurement of seizures in zebrafish are non-invasive (behaviour and imaging) in contrast with the use of implanted electrode recording in the brains of rodents.
The Zebrafish developmental toxicity assay has shown high predictive value against rats and rabbits traditionally used for developmental toxicity testing. Assessing development defects in zebrafish is noninvasive (imaging) and can be undertaken without the need to sacrifice pregnant rats or rabbits.
Zebrafish embryo-larvae possess an anatomically simple kidney that is easily accessed and functionally comparable to mammals. The actual measurement of renal function in zebrafish is noninvasive (imaging), and due to *ex vivo* development can be observed without the need for invasive surgery.
Due to external and transparent development, cardiovascular endpoints (e.g. heart beats, blood flow and vessel diameter) can be observed without the need for invasive procedures as is the case in mammalian models.
The lateral line hair cells of the zebrafish are structurally and functionally comparable with those of the inner ear of mammals, and have been shown to be sensitive to the action of ototoxic drugs. These can also be observed without termination of the animal and sectioning of the head, as is required in mammals.
The zebrafish visual system shows good comparability with humans having similar retinal structure and an abundance of cones providing rich colour vision. The measurement of visual acuity in zebrafish is non-invasive (imaging), and can be measured using passive assessment of behavioural responsiveness without the need for restrictive experimental chamber containment, for example in the case of rat based assays.
The zebrafish gastrointestinal system shows anatomical and cellular architecture that is similar to that of the human tract. Crucially the transparent nature of the body wall in larvae allows non-invasive visualisation of contractions following drug treatment.
The zebrafish liver is functionally comparable with that of the mammalian liver, even in larval life stages. In common with other endpoints, observation of liver structure and function can be undertaken noninvasively in embryo-larvae due to their optical transparency.
The zebrafish pancreas is structurally and functionally comparable with mammals and can be observed non-invasively through the use of imaging in transgenic zebrafish models in which specific cell types are fluorescently-labelled.
In addition to the study of seizures and epilepsy, the zebrafish is emerging as a valuable model for other neurological and behavioural disorders, for example into the genetic basis of autism spectrum disorder (ASD) and attention defect hyperactivity disorder (ADHD). The use of non-invasive brain imaging can provide better insights into potential therapeutic targets.

Why can’t you use animals that are less sentient?

Fish are arguably the least complex vertebrates that are generally regarded as an appropriate surrogate species for the assessment of mammalian (including human) drug safety and efficacy. More specifically, the zebrafish, particularly in the embryonic and larval stages, possess a number of features that make them particularly valuable

for use in assays that address drug safety and efficacy. In particular they possess functionally comparable major organ systems; they exhibit good genetic comparability with mammals in key regions; they are easily genetically manipulated; and they are transparent and small meaning organ function can be easily visualised, and small amounts of compound can be used to undertake small-scale studies which are amenable for use early in the development process of any given drug.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

In addition to the use of generic indicators of adverse effects as humane endpoints, information is gathered to provide more specific humane endpoints for use on both existing and future models.
Protocol 5 is rated as severe as many of the new candidate drugs begin tested have very few if any available information on their toxicology. Consequently, there is the possibility of severe adverse effects including death the first time these drugs are tested. For this protocol only immature life stages (no adults) will be used. As the larval zebrafish is the first 'whole animal' in which any testing will be undertaken it is difficult to predict the likelihood of adverse effects in advance of testing. Where prior data are available (rare), the concentration range used initially will be refined accordingly. Where not available, standard concentration ranges are used for each assay which are further refined based on compound solubility. In addition, exposure periods are either very short and the animals are under almost constant observation with the animal begin humanely killed as soon as the aims of the experiment are achieved (e.g. to assess seizure liability), exposure is commenced on day 0 (before) protection and the animals are terminated on day 5 when aims of the experiment are achieved (developmental toxicity), or for longer exposure in protected animals, frequent checks for adverse effects and limits of severity (e.g. hourly for the first 6 hours of exposure), extending to a standard regime of at least 2 times in any 24 hour period with no more than 14 hours between any two checks are undertaken. In all cases the Maximum Tolerated Concentration (MTC) of the drug will be ascertained allowing adjustment of the dose regimen in subsequent experiments.
For genetic modification, animals will be sacrificed as soon as the experimental aims are reached. in many cases, these are fluorescent reporter lines showing no adverse effects of genetic modification. For target validation, phenotypes that are considered sufficiently mild to grow on for further assessment will only be grown on when the specific requirements of the experiment necessitate it. For example: to assess for a phenotype that emerges later in development; to allow phenotypic analysis in adults without the influence of active development or to provide sufficient tissue for detailed histological analysis; to provide brood stock for drug efficacy screening; or to assess trans-generational effects. It is estimated that this will apply to less than 10% of the genes investigated.
The use of fin clipping is widespread for the purposes of genotyping fish, but a growing number of publications are proposing skin swabbing as a more refined method, especially in older animals. Despite this, there is still some debate around which method is less stressful for the fish and if skin swabbing is appropriate in earlier life stages. As part of this project we will further investigate the appropriateness of skin swabbing for the purpose of genotyping individual zebrafish, particularity at younger life stages (as well as a very new method involving skin sampling from larvae via non-contact collection of sloughed cells). Provided adequate comparability in terms of DNA quality, contamination and sample size between skin swabbing and fin clipping are achieved, we will move to skin swabbing for all genotyping work under this licence. These data will also inform existing projects within our facility that still routinely use fin clipping for the purposes of genotyping zebrafish.
The use of individual animals as our experimental replicate often necessitates the housing of animals in individual wells of micro-plates during drug exposure. Prior to commencing the experiment, embryolarval stocks are held in groups of around 50 animals in Petri-dishes (circa. 35 ml volume) until experimental use where they may be transferred to micro-plates. Typically 24 (maximum volume ~ 3 ml) or 48 well (maximum volume ~ 1.6 ml) plates are used for animals up to 8dpf, and larger volume wells used for older animals such as 12 well plates (maximum volume ~6 ml) or Petridishes up to 14 dpf.
With full validation, and assuming good concordance with clinical outcome, much of this work could lead to the a reduction or even the replacement of mammalian *in vivo* techniques, thus replacing animals of higher neurophysiological development with those of lower sentience, or replacement of protected with non-protected (pre free feeding) embryo-larval forms. Indeed progress made under previous licence(s) has meant that the use of established assays in drug safety screening programmes within industry allows, in some cases, deselection of drugs with poor safety profiles prior to testing in mammals, and in other cases prioritisation of endpoint-specific studies earlier in development than would otherwise be the case. This is expected to be expanded further with the addition of genetic target validation work into our experiential portfolio.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We adhere to the Home Office, UKRC and NC3Rs guidance on the application of the 3Rs to our research. We also adhere to the PREPARE guidelines for animal experimentation and ARRIVE guidelines for the publication of our *in vivo* experimental findings.

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during the project?

As a laboratory we are highly active in the promotion and application of the 3Rs to our work as evidenced by some of our recent publications and presentations including at fora promoting the use of alternative models in toxicology and pharmacology.
Moreover, some of work we undertake is directly funded by the NC3Rs and we have been active in the development of refined techniques throughout the tenure of previous licences, such as the development of the non-invasive neural imaging approach in non-protected larvae.
We will continue this approach throughout the tenure of this licence by keeping up to date through publications, conference attendance, collaboration and funding body interactions.
A retrospective assessment of refinement will be due by 13 April 2026

The PPL holder will be required to disclose:

- With the knowledge you have now, could the choice of animals or model(s) used be improved for future work of this kind? During the project, how did you minimise harm to the animals?

NON-TECHNICAL SUMMARY

231. Microvesicles and the prevention of tissue wasting

Project duration

5 years 0 months

Project purpose

- (a) Basic research
- (b) Translational or applied research with one of the following aims:
  - (i) Avoidance, prevention, diagnosis or treatment of disease, ill-health or abnormality, or their effects, in man, animals or plants
  - (ii) Assessment, detection, regulation or modification of physiological conditions in man,animals or plants

Key words

Stem Cells, Cancer, Microvesicles, Ageing, Progeria

Animal types	Life stages
Mice	adult, embryo, juvenile, aged, neonate
Rats	juvenile, adult, aged, neonate

Retrospective assessment

The Secretary of State has determined that a retrospective assessment of this licence is not required.

Objectives and benefits

Description of the projects objectives, for example the scientific unknowns or clinical or scientific needs it's addressing.

What's the aim of this project?

The objective of the project is to explore the clinical benefit of stem cell secretory factors on age related degenerative diseases and those associated with cancer treatment. To facilitate the safe translation of pre-clinical testing to human clinical testing, animal testing is necessary in this project.

Potential benefits likely to derive from the project, for example how science might be advanced or how humans, animals or the environment might benefit - these could be short-term benefits within the duration of the project or long-term benefits that accrue after the project has finished.

Why is it important to undertake this work?

Previously studies have shown that molecules produced by stem cell when given to the person from whom the cells were first taken (autologous treatment) had therapeutic uses. However, most work has concentrated on degenerative illnesses including multiple sclerosis and injury conditions like joint damage.

This project will serve to explore properties of the molecules produced by stem cells and expand the range of conditions that it could help. Specifically, we will now focus on age related tissue loss and cancer treatment. This will provide pre-clinical data on safety and efficacy to facilitate early clinical application of therapy in diseases which currently have few treatment options.

The clinical use of molecules produced by stem cell provides an attractive, less invasive, safer alternative (minimising cancer, reducing immunological risks) to stem cell transplantation.

Our approach is novel since it is aimed at ultimately being used in a large number of people. To this end, we have been mindful that any approach that we investigate has to be amenable to almost industrial level scaling. Our approach outlined in this license is unique since both the source of regenerative molecules, i.e. the stem cells, and their particular properties support this primary requirement. We have been mindful that any stem cell that we use has to be capable of large scale culture in order for it to be used in a clinical setting. To that end, we will use stem cells which can be maintained for long periods of time before they are unable to divide. Additionally, a novel feature of our work, in the development of potential therapeutics, has been the understanding of stem cell activity, which depend on their environment. We have shown in a number of studies, that stressing stem cells, changes their secretory properties, which prime them to make molecules that show superior regenerative capacity than cells maintained in unstressed conditions.

What outputs do you think you will see at the end of this project?

This project will serve to explore stem cell conditioned media and expand the range of conditions that it could help. Specifically, we will now focus on age related tissue loss and cancer chemotherapy induced tissue loss. This will provide pre-clinical data on safety and efficacy to facilitate early clinical application of therapy in diseases which currently have few treatment options.

The key outputs will be the generation of new information, which will be communicated via publications in peer reviewed international journals.

Who or what will benefit from these outputs, and how?

The clinical use of differentiated or undifferentiated stem cell conditioned media provides an attractive, less invasive, safer alternative (minimising cancer, reducing immunological risks) to stem cell transplantation. The benefits could be in future be reaped by those who suffer muscle loss as a consequence chemotherapy use or during the ageing process.

However, this is only the first step towards use in the community. Future studies will require safety testing a process that is likely to take many years after the successful completion of this project.

How will you look to maximise the outputs of this work?

We will communicate the results arising from this study by presenting our progress at both national and international conferences and meetings as well as communicating completed studies in the form of publications.

Species and numbers of animals expected to be used

- Mice: 6700
- Rats: 1500

Predicted harms

Typical procedures done to animals, for example injections or surgical procedures, including duration of the experiment and number of procedures.

Explain why you are using these types of animals and your choice of life stages.

Rodents are being used in this project as they can be used to develop the symptoms of the diseases that are the focus of this project: muscle wasting associated with cancer chemotherapy-induced muscle wasting and muscle wasting associated with ageing.
For the cancer chemotherapy-induced muscle wasting work, we will focus on rodents at stages of life which mimic when humans could suffer from this condition which will be juvenile and adult stages.
For the work on ageing, we will focus on older animals but will also work on rodents that have genetic backgrounds that result in them ageing in an accelerated manner.

Typically, what will be done to an animal used in your project?

Typically, rodents will be bred so that they have the correct genetic background. They will then be induced to develop a disease state, this is be achieved either through breeding or exposure to a chemical.
Thereafter they will be treated with stem cells or molecules produced by stem cells which have potential therapeutic properties.
The treatment will be allowed to have time to work, during which time the rodents will be monitored to assess the impact of the treatment.
The experiment will be terminated at a set period, typically. The animals will then undergo physiological examination which will allow us to gauge how well the muscle are working. Thereafter the animals will be killed and tissues collected for further investigation aimed at revealing how the treatment has altered the course of the disease.

What are the expected impacts and/or adverse effects for the animals during your project?

It is likely that in all models we will induce loss of body weight which will be monitored during the course of the experiments. We plan to terminate the experiment when the intervention to induce tissue wasting results in greater than 20% of body weight loss compared to control mice.
Expected severity categories and the proportion of animals in each category, per species.

What are the expected severities and the proportion of animals in each category (per animal type)?

The most severe category is moderate which will be experience by no more than 20% of the animals in this proposal.

What will happen to animals at the end of this project?

- Killed

Replacement

State what non-animal alternatives are available in this field, which alternatives you have considered and why they cannot be used for this purpose.

Why do you need to use animals to achieve the aim of your project?

The objective of the project is to explore the clinical benefit of stem cell secretory factors on age related degenerative diseases and cancer chemotherapy-induced muscle wasting induced tissue wasting. To facilitate the safe translation of pre-clinical testing to human clinical testing, animal testing is necessary in this project.

Which non-animal alternatives did you consider for use in this project?

With some aspects of the project, experimental animals can be replaced by in-vitro testing, and as outlined in the programme of work such in-vitro testing will replace intact animal experimentation wherever possible in the project. Such in-vitro testing will include appropriate dissociated cell culture, cell line testing and testing on organotypic slice culture preparations appropriate for each disease model.

Why were they not suitable?

While in-vitro studies are very informative on the impact of a disease or condition on a particular tissue, they have very little value when the nature of the disease or condition acts in the whole body.

Reduction

Explain how the numbers of animals for this project were determined. Describe steps that have been taken to reduce animal numbers, and principles used to design studies. Describe practices that are used throughout the project to minimise numbers consistent with scientific objectives, if any. These may include e.g. pilot studies, computer modelling, sharing of tissue and reuse.

How have you estimated the numbers of animals you will use?

For quantitative experiments sample size will be set statistical predictions based on the difference we want to detect to give us an indication that a treatment is working. We will draw on our work conducted using the same animal models and how the experiments were run to give similar but unique outcomes.

What steps did you take during the experimental design phase to reduce the number of animals being used in this project?

More generally, advice will be sought from our Consultant Statistician, where appropriate, to ensure a statistical design that is used is efficient and minimises the number of animals required, yet maintains sufficient precision and power. For example, advice will be sought when a specific pre-clinical model introduces large subject-to-subject variation.
Furthermore, our studies have shown that the impact of ageing and cancer chemotherapy-induced wasting effect more than just the primary tissue under investigation, that being skeletal muscle. Therefore, in order for an intervention to be examined further for possible use in humans, it is now apparent that an intervention should be examine at the organismal level as well as a range of tissues.
We have developed a pipeline that extracts the maximal amount of data from each animal by not only determining its behaviour and movement prior to its death, but then to isolate as many tissues as possible. This approach means that a single animal will generate data related to a wide variety of bodily functions.

What measures, apart from good experimental design, will you use to optimise the number of animals you plan to use in your project?

The proposal aims to minimize animal usage by drawing on our extensive experience in this area of research. These insights will be deployed not only to keep the number of mice to their lowest possible number but also to conduct the experiments in the shortest time span thus minimizing animal suffering.

Refinement

Give examples of the specific measures (e.g., increased monitoring, post-operative care, pain management, training of animals) to be taken, in relation to the procedures, to minimise welfare costs (harms) to the animals. Describe the mechanisms in place to take up emerging refinement techniques during the lifetime of the project.

Which animal models and methods will you use during this project? Explain why these models and methods cause the least pain, suffering, distress, or lasting harm to the animals.

The choice of models employed in the project also reflects the wide variety of degenerative diseases and components of damage they inflict. Thus the models selected provide the most data on whether stem cells or factors produced by stem cells can induce repair of tissue damage.

Why can't you use animals that are less sentient?

Small rodents (mouse: rat) are the simplest appropriate pre-clinical models to study these diseases and their potential amelioration. While there are species differences in physiology between humans and rodents, these are minimal and the use of species genetically closer to humans is not required by the appropriate regulatory bodies and thus is not proposed as part of this project. The mouse is the species of choice due to availability of appropriate genetically modified lines that phenotypically display progeria (accelerated ageing). Furthermore genetically modified mice, either through gene knock-out or gene over-expression studies allows us to develop mechanistic explanations at the molecular level of the processes of cachexia and ageing.
Non-mammalian models including nematode worms and fruitflies do not share the same physiological parameters as humans and are thus not informative for this type of study.

How will you refine the procedures you're using to minimise the welfare costs (harms) for the animals?

During the tenure of this license other progeria models may become available and appropriate advice will be sought as to their suitability for this work and on any welfare issues pertaining to their phenotype.

What published best practice guidance will you follow to ensure experiments are conducted in the most refined way?

We will seek to carry out the experiments using best practice advised by differing parties including:
Laboratory Animal Science Association (LASA) for best practice guidelines for administration of substances and genetically modified mouse welfare guidelines.
We will also turn to the Workman guidelines for cancer research (https://www.nature.com/articles/6605642) as these principles are particularly relevant to our study as they describe welfare issues and how to use best practice for models which experience tissue wasting, the core focus of this proposal. Please see:
Workman P, Balmain A, Hickman JA, McNally NJ, Rohas AM, Mitchison NA, Pierrepoint CG, Raymond R, Rowlatt C, Stephens TC, Wallace J (1988) UKCCCR guidelines for the welfare of animals in experimental neoplasia. Br J Cancer 58: 109–113

How will you stay informed about advances in the 3Rs, and implement these advances effectively, during

the project?

We will seek advice from the Home Office inspector as well the named veterinary surgeon for alternative approaches using either less sentiment animals or non-animal systems that allow us to achieve our goals.
